As an appendix, we will add here some illustrations (Figs. 59 to 63) to represent, in a diagrammatic fashion, the distribution of the sensory cutaneous nerves. These diagrams will be of service, both in the consideration of anæsthesia and in the diagnosis of the neuralgias to be described in the following chapters.

FIG. 63.

FIGS. 62 AND 63.—Distribution of the sensory cutaneous nerves to the lower extremities. FIG. 62. Posterior aspect. FIG. 63. Anterior aspect. (From HENLE.) *il*, Ileo-inguinal nerve. *li*, Lumbo-inguinal nerve. *se*, External spermatic. *cp*, Posterior cutaneous. *cl*, Lateral cutaneous. *cr*, Crural. *obt*, Obturator. *sa*, Saphenous. *cpe*, Peroneal communicating nerve. *cli*, Tibial communicating nerve. *per*, Superficial branch of the peroneal nerve. *per'*, Deep peroneal nerve. *cpm*, Posterior median cutaneous nerve. *cpp*, Cutaneous plantar nerve.

### CHAPTER III.

#### NEURALGIA IN GENERAL.

ALTHOUGH every pain is, of course, excited by abnormal irritation of the nerves, still we are justified in giving a certain special variety of pain the name of neuralgia. The characteristics of this particular "nervous pain" are as follows: 1, it is felt exactly in the course or in the distribution of one or more special nervous trunks or nervous branches; 2, it is usually of very considerable intensity; and, 3, as a rule, it is not present continuously, but it shows manifest remissions and intermissions. It often comes on in single pronounced paroxysms of pain, which

are due to definite causes, or which can not be referred to any evident external irritation.

**Pathogenesis and Ætiology.**—In many cases the cause of neuralgia is entirely unknown, but in other cases we can discover factors which may be regarded either as more or less direct exciting causes, or at least as predisposing causes, for the appearance of neuralgia; but in all these cases the precise form of action, and the peculiar nature of the disturbance produced in the nerves, are almost wholly unknown to us. At best we may suspect that perhaps sometimes we have to do with slight inflammatory changes in the nerve-trunks, with hyperæmia, exudation, cedema, etc.

We may mention the following as predisposing factors, which clinical observation has taught us: 1. Age. Neuralgia comes on most frequently in middle life, but it is also found in older people, and more rarely in children. 2. Sex exerts an influence so far that certain forms, such as trigeminal neuralgia, are seen more frequently in women, and other forms, such as sciatica and brachial neuralgia, are more common in men. Certain phases of sexual life, too, such as puberty, pregnancy, childbed, and the climacteric, favor the disposition to neuralgia. 3. The general neuropathic predisposition, which is hereditary in the majority of cases, is of great significance. Neuralgia often appears in people who suffer from other neuroses, or in whose families other nervous diseases, such as the psychoses, epilepsy, hysteria, or neurasthenia have repeatedly occurred. 4. The physical constitution also seems to be of influence. We often see neuralgia in anæmic people, or in those whose constitution has been impaired by physical and mental strain, by imprudent living, or by mental excitement.

We may mention, as exciting causes of neuralgia: 1. Cold, the action of draughts, wind, or wet—the so-called "rheumatic neuralgias." It is not perfectly clear how the cold acts in such cases. We usually assume that by its action slight anatomical (inflammatory ?) changes arise directly or in a reflex manner in the nerves themselves. 2. Mechanical and traumatic action. Among these are, first, wounds and contusions which directly involve the nerves. Thus, for example, extremely severe neuralgia sometimes arises from the pressure of foreign bodies, such as splinters of wood or of bones in wounds, on the branch of a nerve. We may also mention here the very severe neuralgia sometimes met with after amputations, which develops as a result of the so-called amputation neuromata. To this class, too, belong diseases in the neighborhood of nerves which act as mechanical irritants. Diseases of the bones or periosteum often lead to neuralgia in those nerves which run through bony canals or grooves. Lastly, tumors, aneurisms, herniæ, or the gravid uterus, may lead to neuralgia by pressure on the neighboring nerves; but we must call to mind that every pressure on a nerve does not lead to neuralgia in the same way, so that we must assume a special consequent change in the nerve in "neuralgia from compression."

The relation which certain infections and poisons have to the development of neuralgia is very important. In the first place, it is not impossible that many of the apparently "idiopathic" neuralgias are to be referred to infectious causes—an assumption which may be made, for instance, in intercostal neuralgia associated with an eruption of zoster (*q. v.*), or in many acute trigeminal neuralgias. Many neuralgias, however, also have a definite relation to other infectious diseases. We may mention in particular the malarial neuralgias, which are directly dependent upon the malarial infection, often come on at regular intervals, and are cured by specific treatment, namely, quinine. Neuralgia is often seen during the course, or as a result, of typhoid, small-pox, and similar acute infectious diseases, and in the secondary stage of syphilis. Among toxic substances we may mention especially lead, copper, mercury, and also alcohol and nicotine, as those which have a special relation to the development of neuralgia.

Neuralgia is also found in many constitutional diseases, in gout, and quite often in diabetes mellitus, and seems to bear a direct relation to the general disease; and hence, like many of the other neuralgias mentioned as symptomatic, it may be contrasted with the idiopathic neuralgia due to some direct affection of the nerves themselves. Finally, neuralgia is met with sometimes in distant nerves in diseases of other than nervous organs, like the sexual organs, and is termed "reflex neuralgia"; but we must be very cautious in accepting the theory of reflex neuralgias, since in most of these cases we have to do with other affections, such as hysteria, etc.

**General Symptomatology of Neuralgia.**—The neuralgic paroxysm begins either quite suddenly, or, more frequently, after certain prodromata, such as cold feelings, prickling, slight painful sensations, etc., have preceded it for some time. The pain during the attack is usually of the greatest severity, and is described as either burning and boring, or as shooting and tearing like lightning. There are frequently short temporary remissions of the pain. The location of the pain usually corresponds precisely to the distribution of the affected nerve, so that the patient can often point out quite definitely the anatomical course of the nerve. At the height of the attack there is often an "irradiation" or shooting of the pain into the territory of neighboring nerves. External irritants, such as cold air, mental excitement, and especially movements of the affected part, often produce an increase of the pain.

On physical examination, we notice, first, certain disturbances of sensibility. The skin in the neuralgic part often shows more or less anæsthesia, which is most apparent in the intervals between the separate attacks and immediately after them. Much more frequently, however, both during the attack and during the time when the patient is free from pain, there is hyperæsthesia of the skin and the parts beneath. There are certain definite points which are often very sensitive and tender even to light pressure. These are called painful points (*points douloureux*). They were first fully described by Valleix, in 1841, for the different forms of neuralgia, and they have considerable diagnostic importance, since they may often be found, not only during the attack itself, but also during the free intervals, although in a lesser degree. The painful points always correspond to certain places in the course of the trunk or the larger branches of the affected nerve, and are found especially where, in marked and deep pressure on the nerve, we can press on some firm part beneath. They are probably always due to an abnormal sensitiveness to pressure in the affected nerve itself. In many cases of neuralgia they may of course be wholly wanting.

Motor symptoms as well as sensory are not infrequent in neuralgia. Co-existing symptoms of paralysis must always be regarded as a complication caused by some coarse lesion of the motor nerves; hence in ordinary idiopathic neuralgia they are entirely absent. The co-existing symptoms of motor irritation, which are often seen, are usually directly dependent upon the neuralgia, however, and hence are to be regarded as reflex contractions, set up in the muscles by the great irritation of the sensory nerves.

Vaso-motor symptoms are often seen in neuralgia. In the face especially, in trigeminal neuralgia, we often see a marked pallor or a decided reddening of the skin and conjunctiva. Abnormal secretions, of tears or sweat, may also be seen during the attack or at the end of it. We do not know whether all these symptoms arise from direct or reflex nervous irritation. Trophic disturbances are noticed in various ways. During the attack we see eruptions of urticaria, or still more frequently of herpes vesicles, along the course of the affected nerves, as in herpes zoster. In severe and protracted neuralgias permanent changes in the tissues have been repeatedly seen in the parts supplied by the affected nerves.

Among these are a falling out or a whitening of the hair, or more rarely an abnormally great growth of hair, thickening or atrophy of the skin, staining or pigmentation of the skin, etc. Lastly we may mention that during the neuralgic attack we sometimes find a diminished frequency of the pulse.

The general nutrition of the body often does not suffer at all in neuralgia, but in many cases, especially when sleeping and eating are constantly disturbed by the attacks of pain, the disease gradually has a noticeable action on the whole constitution. The patient becomes pale and emaciated, and often the persistent and distressing pain is not without influence on his mental condition. He becomes irritable and inclined to melancholy. Patients have, in repeated instances, even committed suicide as a result of severe and incurable neuralgia.

The whole course of neuralgia shows the greatest diversity. As has been said repeatedly, the onset of the disease in separate attacks is the chief characteristic feature. The precise pathogenesis of these attacks is, of course, entirely unknown to us. These attacks usually come on every day or several times a day, or sometimes at greater regular or irregular intervals. They may last only a few minutes or several hours. During the period between the attacks many patients feel quite well, but some have still a certain sensitiveness of the skin. The disease as a whole sometimes lasts only a few days or weeks, but sometimes it persists with manifold variations for years and years, and, in a word, is not capable of improvement; although, on the other hand, there are recoveries after the disease has lasted for years. In many cases, of course, the disease depends upon the presence of some definite anatomical cause, such as a tumor, a disease of the bone, or an aneurism.

Many details as to prognosis and also as to the diagnosis of neuralgia will be spoken of in the following chapter.

**General Treatment of Neuralgia.**—Prophylaxis of neuralgia is possible in this way, that certain constitutional anomalies, such as anæmia or a general nervous predisposition, favor its appearance, as we have seen; and in attacking these conditions, we may recognize a factor which can prevent to a certain degree any subsequent development of neuralgia. It is still more important, in people who have already suffered from neuralgia, to prevent the return of the affection if we can. For this object we must first consider the strengthening of the whole body, in order to make it better resist the action of any causes of disease. The measures to be chiefly employed for this purpose are proper food, good air, baths, sea-bathing, cold bathing, gymnastics, etc. Of course, we must also particularly guard the part of the body that has once been attacked from any irritation, such as cold, mechanical irritants, or over-exertion.

In treating neuralgia itself we must always look first with great care for some causal factor, which may be accessible to treatment. This fulfillment of the causal indication is often possible in neuralgias which are due to mechanical causes. The extirpation of tumors, the excision of cicatrices, the removal of foreign bodies, the treatment of inflammatory new growths, of syphilitic affections, of aneurisms, etc., is in many cases attended by brilliant success, but, of course, in many other cases the underlying disease is unfortunately not amenable to successful treatment. We should also carry out a causal treatment in the neuralgias which are to be referred to general anæmia, to a general neuropathic constitution, to hysteria, etc. In such cases we must always ascribe great value to the general treatment, such as diet, manner of life, baths, iron, and nervines, as well as to the special treatment directed against the neuralgia; and the same holds true, of course, in the neuralgias occurring in diabetes, gout, and syphilis. Lastly, we may fulfill the causal indication in the malarial neuralgias. If neuralgia comes on at approximately regular intervals in persons who come from a malarial district, and

who perhaps have already suffered from other malarial affections, the exhibition of quinine in large doses, twenty to forty-five grains (grm. 1.5-3.0) at once, will usually speedily cut short the attack. In obstinate cases in which quinine does no good, we should try arsenic, as Fowler's solution. In many toxic neuralgias, too, from lead, mercury, or alcohol, our first endeavor in treatment should be to remove the cause of the disease.

In all cases where the causal treatment can not be carried out, or where it alone is not sufficient, we must consider those numerous remedies and methods of treatment which correspond to the *indicatio morbi* and to the symptomatic indications. Starting with the hypothesis of an inflammatory condition of the nerve, we have often tried to exert a favorable influence on the disease by local derivatives, mustard plasters, irritating embrocations, such as spirits of mustard, veratrine ointment (two and a half per cent.), or tincture of iodine, or by blisters, or even by the cautery. The remedies first mentioned are used only in mild cases. Vesicatories, placed along the course of the affected nerve, or behind the ear in facial neuralgia, sometimes act very well in fresh cases, especially those of a "rheumatic" character. We resort to the hot iron chiefly in old and very severe cases, in which, indeed, especially in sciatica, some very favorable results have been thus obtained.

The local electrical treatment of neuralgia is more important and more efficient than the remedies mentioned. Although we do not know certainly how electricity acts, still it is unquestionably often attended with great success in the treatment of neuralgia. We many times secure an improvement in the symptoms, which is of course temporary, even in those cases where the special cause of the disease is not influenced by the electricity, although in idiopathic neuralgias in fresh, and sometimes even in old cases, we can often obtain a complete cure. There are no general rules with regard to the methods to be employed, since different specialists have their own favorite methods. The following forms of application are most in use and are most to be recommended: 1. Stable action of the anode of a constant current on the affected nerve-trunk over as great an extent as possible, especially on any painful points. We must entirely avoid any great variations in the current or interruptions of it. We gradually increase the intensity of the current up to medium strength. The sittings should last three to six minutes, and sometimes even longer, and must be repeated daily. 2. In neuralgia of the larger nerves we should use a stable descending (sometimes ascending) constant current, in which the anode is placed on the most central point of the nerve-trunk available, or on the vertebral column, and the cathode on different peripheral points. 3. The faradic current also frequently acts very well. We faradize the nerve either with a moderately strong "increasing" current, or we apply the wire brush to the skin over the affected nerves. The latter method is very painful, but it is often attended with excellent results. 4. Some electro-therapeutists, like Moritz Meyer, lay stress upon the stable application of the anode of the constant current to any painful points on the vertebral column, such as have been described in many neuralgias by Trousseau.

As a general rule, it is always well to begin with a mild and very cautious use of electricity, and not to go on to the stronger currents until later. Electricity often acts brilliantly at once, during the attack of pain, but sometimes no improvement is seen until after several sittings. If, after two or three weeks, we obtain no result at all, after employing different methods of applying electricity, it is the best plan to give up electrical treatment entirely as not suited to the case.

In the treatment of neuralgia we must consider a number of internal remedies, as well as electricity; some of these act symptomatically, like the narcotics, while others have obtained the reputation of having a specific action. Among the

latter, quinine has decidedly the greatest value. In severe cases quinine may do excellent service, not only in malarial neuralgias, although most surely in these, but also in "idiopathic" neuralgias. It is in these cases that the remedy is given in large doses. We begin with fifteen to thirty grains (grm. 1-2) a day, best given in one dose, and in severe cases we may increase to sixty or seventy-five grains (grm. 4-5) or more. We see the best results from quinine in trigeminal neuralgia, while in other forms, like sciatica, it is much less efficient. Some cures have been obtained by salicylate of sodium. Antipyrine, in fifteen to thirty grain (grm. 1-2) doses, antilebrine, in three to seven grain (grm. 0.25-0.5) doses, and phenacetine, in seven to fifteen grain (grm. 0.5-1) doses, have lately been very often used. Next in rank come arsenic and bromide of potassium. The former is given in pill form or as Fowler's solution, five drops three times a day, increasing gradually. Bromide of potassium acts only in large doses, forty-five to seventy-five to a hundred and fifty grains a day (grm. 3-5-10). Among the many other remedies which have been recommended, we may mention here ergotine, internally and subcutaneously, oil of turpentine, oxide of zinc, valerianate of zinc, tincture of gelsemium, aconitine, phosphorus, iodide of potassium, subcutaneous injections of osmic acid, ten to fifteen minims (grm. 0.5-1) of a one-per-cent. solution, etc.

In all severe neuralgias the use of narcotics, especially of morphine, is unavoidable. Morphine is used almost exclusively during the attack, and is best given as a subcutaneous injection of one-twelfth to one-sixth of a grain (grm. 0.005-0.01) in the vicinity of the painful part. The anodyne effect almost invariably follows, but in obstinate and protracted cases the patient gradually becomes accustomed to the remedy. We must then resort to still larger doses, and these, too, finally fail in their effect. Among the victims of the morphine habit we find many patients who have suffered or who still suffer from severe neuralgia, so that we must always be very cautious and conservative in the protracted use of morphine. We should be especially cautious before deciding to put the hypodermic syringe into the patient's own hand. Many physicians ascribe not only a palliative but a permanent benefit to injections of morphine in neuralgia. We sometimes see, in fact, that mild neuralgias recover under the exclusive use of morphine injections; but these are probably cases of spontaneous recovery. The internal use of morphine and opium preparations is decidedly inferior to the subcutaneous administration in certainty and rapidity of action. The external application of narcotic ointments, or embrocations, is much employed in practice, but it appears to be of advantage only in milder cases. We prescribe ointments with extract of opium (one to ten), extract of belladonna (two to ten), extract of opium and veratrine (one part of each to twenty of simple ointment), etc. We may also use chloroform (equal parts of chloroform and oil of hyoscyamus) and ether. Chloral and also paraldehyde are often prescribed in chronic neuralgias for their hypnotic effect. Croton chloral has been especially recommended in neuralgia. Finally, we must add that some physicians have praised the anodyne effect of subcutaneous injections of atropine, gr.  $\frac{1}{120}$  to  $\frac{1}{60}$  to  $\frac{1}{20}$ ! (grm. 0.0005-0.001-0.003!) at a dose, sometimes even in cases where morphine does not act.

In severe cases the surgical treatment of neuralgia is often of great importance—the section of nerves, neurotomy, or the excision of a portion of the nerve, neurotomy—in order to prevent the union of the divided nerve. Without doubt this operation is often attended with success; but in some cases, of course, it has no effect at all on the disease, or else the neuralgia returns with its old severity after a temporary improvement. We can understand the success of neurotomy in cases where we can assume that the cause of the abnormal sensory irritation is peripheral to the point of section; but observations are reported in literature where the operation has had a favorable influence even on central neuralgias. The operation is

to be proposed only in severe cases, where all other remedies have been tried in vain, and the patient can always be promised the possibility, or even the probability, of success, but never the certainty of it. Besides section of the nerves, nerve stretching has lately been frequently tried in neuralgia—sometimes, but not always, with distinctly good results.

The chief question as to the use of baths arises only in the treatment of neuralgias in the domain of the nerves of the extremities, especially in sciatica, and therefore these and massage will be spoken of more in detail in connection with the separate forms of neuralgia.

We see, then, that a large number of remedies are at our command in the treatment of neuralgia, and that the choice among them is not always easy. In any given case we look for the causal indication, and try to fulfill it if possible. In the many cases, however, where we fail to find this, we must first of all try to alleviate the pain, for which purpose, if external derivatives do not suffice, our most effective remedy is morphine. We must then lay out a special plan of treatment. We try electricity, or, if this be not practicable, one of the other remedies mentioned above. We put most trust in quinine, especially in fresh cases; among other remedies, in anæmic persons, arsenic, and, in more robust persons, bromide of potassium are of service. If all these and similar remedies give no aid, in proper cases we may still hope for success from operative interference, or else we must confine ourselves simply to a purely symptomatic treatment with narcotics.

#### CHAPTER IV.

#### THE INDIVIDUAL FORMS OF NEURALGIA.

##### 1. NEURALGIA OF THE TRIGEMINUS.

(*Protopalgia. Tic douloureux. Fothergill's Face-ache.*)

**Etiology.**—Trigeminal neuralgia is one of the commonest and most important neuralgias. In its origin many causes and predisposing factors of all sorts play a part, as we have learned in the preceding chapter. Many cases, especially the milder ones, come from taking cold. Sometimes we can not find any definite cause. Malarial neuralgias are very often localized in the region of the trigeminus. The other especial causes which may give rise to trigeminal neuralgia are diseases of the cranial bones and periosteum, very often diseases of the teeth, caries, exostoses, and anomalies in development and position; and also diseases of the nasal and frontal cavities as well as of the middle ear. Romberg found an aneurism of the internal carotid, pressing on the Gasserian ganglion, as a cause of a severe and incurable case. We have since seen a precisely analogous case. Lastly, excessive use of the eyes is not infrequently related to the development of trigeminal neuralgia.

**Symptoms and Course.**—The attacks of pain in neuralgia of the fifth pair are usually quite intense, and in severe cases they may attain a most distressing and terrible severity. They arise either entirely without cause, or from some slight influence, like washing, taking physical exercise, or mental irritation. The pain is usually limited to the distribution of the different branches of the trigeminus, but it sometimes shoots into the occiput, the back of the neck, the shoulders, etc. We can often perceive reflex twitchings in the face, especially blepharospasm, and twitching of the corners of the mouth. The vaso-motor disturbances are noticed at first as abnormal pallor, but later usually as quite an abnormal redness of the

face and conjunctiva. In neuralgia of the upper two branches we often see, during the attack, an unusually great secretion of tears. An excessive flow of saliva and an increased secretion from the nasal mucous membrane are more rare. Sometimes, but still quite rarely, we see herpetic eruptions in the course of the affected nerve, zoster frontalis, herpes of the conjunctiva, etc. In some cases, too, more severe diseases of the eyes, belonging to the category of neuroparalytic ophthalmia, have been observed. In neuralgias that have lasted longer, we often see still further trophic disturbances: changes in the skin and subcutaneous cellular tissue, the hair turning gray or falling out in the frontal region, etc.

Most trigeminal neuralgias are situated, not in the whole distribution of the nerve, but only in one or more of its branches (see Fig. 57, page 513). We accordingly distinguish: 1. *Neuralgia of the first branch (ophthalmic neuralgia)* which is especially frequent as supra-orbital or frontal neuralgia. In this we find as a rule, that pressure on the point of exit of the nerve at the supra-orbital foramen is more or less painful. More rarely we find painful points also on the nose, at the inner angle of the eye, or the parietal eminence, etc. 2. *Neuralgia of the second branch (supra-maxillary neuralgia)* is most frequent in the distribution of the infra-orbital nerve, infra-orbital neuralgia, with the chief painful point at the infra-orbital foramen, and others on the zygoma, on the upper lip, etc. 3. *Neuralgia of the third branch (infra-maxillary neuralgia)*, whose most frequent seat is in the territory of the inferior alveolar nerve; but neuralgia also occurs in the temporal region, in the auriculo-temporal nerve, and in the tongue, in the lingual nerve. The chief painful point is at the mental foramen.

The general course of neuralgia of the fifth pair differs very much in different cases. We see all forms, from the mildest, which rapidly passes off, to the severest and incurable types, which may drive the patient to despair and even to suicide. In general, neuralgia of the first branch usually belongs to the relatively milder forms; neuralgia of the second, and especially of the third branch to the severer forms. Trousseau has termed a particularly severe form "epileptiform neuralgia," although we can find no definite relation between this disease and genuine epilepsy. We can find no cause for epileptiform neuralgia; the attacks of it come on with the greatest intensity either after brief pauses or after intervals of weeks and months, and they defy all attempts at cure with the greatest obstinacy. It is worthy of note that this form appears in individuals with the neuropathic taint.

**Diagnosis.**—In all pronounced cases the diagnosis of trigeminal neuralgia is easy. We must regard accurately the distribution of the pain, its paroxysmal onset, and the points of pressure. Otherwise in a superficial examination we may of course confuse it with inflammatory affections of the bones and periosteum, with genuine tooth-ache, with migraine, and with other forms of headache and face-ache.

**Prognosis.**—The prognosis is never to be made with complete certainty. It is most favorable in fresh cases which have a manifest cause, which may be removed, as a basis; but if the affection is due to a coarse anatomical cause which can not be removed, or if we are dealing with old cases "which have become habitual," the prognosis, unfortunately, is often utterly unfavorable.

**Treatment.**—The treatment of trigeminal neuralgia rests entirely upon the principles given in the preceding chapter. In searching for the causal indications we must look chiefly, in neuralgia of the second and third branches, for diseased teeth, and also in all cases for any affections of the nose, of the frontal sinuses, or of the middle ear. Carious teeth, which are painful and which seem to have any relation to the neuralgia, should always be removed, and any of the other affections mentioned are to be treated on special principles.

Of other remedies we use first of all electricity, the anode to the painful points, with the cathode on the back of the neck, or the wire brush, etc.; we also use quinine, Fowler's solution, and in severe cases narcotics. In cases where the neuralgic attacks come on with approximate regularity, quinine especially often does excellent service; we give fifteen to twenty grains (grm. 1-1.5) at first, two or three hours before the expected attack. If quinine does no good, we try arsenic in not too small doses, and if these remedies are unsuccessful we may try one of the other drugs recommended: butyl chloral (croton chloral) in two- to five-grain capsules (grm. 0.1-0.3), or, according to Liebreich's formula:

R Croton chloral..... gr. lxxv-3 ijs. (grm. 5-10);  
Glycerine..... 3 vj. (grm. 20);  
Aque destill..... 3 iv. (grm. 120). M.

S. One or more tablespoonfuls every five or ten minutes.

We may also give tincture of gelsemium sempervirens, five to twenty drops several times a day; aconitine in pills of  $\frac{1}{200}$  to  $\frac{1}{120}$  of a grain (grm. 0.0003-0.0005), three to five times a day; nitrite of amyl, ammoniated copper, in powders of one or two thirds of a grain (grm. 0.02-0.04), oil of turpentine, [cannabis indica], etc. Special indications for all these remedies can not be given, so that we are recommended simply to try different ones. In desperate cases Trousseau has tried very large doses of opium, which he gradually increased until he gave two to three drachms (!) (grm. 8-12) a day. Sometimes an attack may be diminished or shortened by compression of the carotid.

If a severe neuralgia persists in spite of rational treatment by electricity or drugs, we should not delay too long in proposing to the patient operative treatment if possible. In frontal and infra-orbital neuralgia especially the section of the nerve is a comparatively slight operation, which—of course with many failures—has many excellent results to show. The full description of the technicalities of the operation, as well as the description of nerve-stretching, and of the ligature of one carotid, which has been done in some desperate cases, must be left to the textbooks on surgery. [Unfortunately the only operations that promise permanent benefit are the more serious ones of resection of the nerve at the foramina, at the base of the skull, or excision of the Gasserian ganglion.—K.]

## 2. OCCIPITAL NEURALGIA.

Of the neuralgias involving the sensory region of the upper four cervical nerves, neuralgia of the occipitalis major is the most frequent and practically the most important. Besides the factors to be considered in all neuralgias, we must pay particular attention, in regard to etiology, to diseases of the upper cervical vertebræ—caries and new growths. The painful paroxysms may attain the greatest severity. They are usually located in the two occipital nerves at once, being accordingly bilateral, although often more severe on one side than on the other. Painful points are most frequently found midway between the mastoid process and the upper cervical vertebræ. Vaso-motor disturbances, falling out of the hair, etc., have been often observed.

The prognosis is comparatively favorable in cases which have no severe anatomical disease, such as spondylitis, as a basis. The most efficient remedies are strong cutaneous irritants to the back of the neck, vesicatories in fresh cases, the constant current, and injections of morphine.

Other neuralgias in the distribution of the cervical plexus are rare. They occur in the distribution of the occipitalis minor, which, according to Seeligmüller, is quite frequently due to syphilis, and then is easily cured by iodide of potas-

sium, and in the distribution of the great auricular and the supra-clavicular nerves. A phrenic neuralgia even has been described, in which the pain extends along the course of the phrenic nerve to the insertion of the diaphragm; but this is at all events very rare.

### 3. NEURALGIA IN THE REGION OF THE BRACHIAL PLEXUS.

(*Cervico-brachial Neuralgia.*)

Brachial neuralgia is, on the whole, rare, and it is hardly ever strictly limited to the distribution of a single nerve. In general, the radial and ulnar nerves are rather more frequently affected than the median. We also see at times neuralgia of the internal cutaneous nerve. In regard to ætiology, we have to mention first wounds and contusions of the nerves, and also cicatrices and foreign bodies. The amputation neuralgias also belong to this class. Severe neuralgia in which the pain may extend over a greater part of the whole arm is sometimes seen after injury of the fingers (crushing, cuts, etc.). In some of these cases we may have to do with an ascending neuritis, starting from injury of a small nerve branch; in other cases there are probably cicatricial contractions, thickenings of the neurilemma, or small neuromata developing after the injury, which excite the pains. The "amputation neuralgias," which are often very severe in amputation stumps, are due to neuromata which form on the cut ends of nerves. Severe neuralgia often arises from pressure on the brachial nerves, as in cases of tumors in the axilla (cancer, etc.), aneurisms of the aorta, etc. Rheumatic neuralgia may also occur. Double brachial neuralgia should always excite suspicion of disease in the neighborhood of the upper posterior nerve roots, especially of cervical pachymeningitis, spondylitis of the lower cervical vertebrae, etc.

We have little to add concerning the special symptomatology of brachial neuralgia. The pain is usually ascribed to the whole course of the nerves without being very exactly localized, as we have stated. Painful points are sometimes found over the brachial plexus, over the radial on the external surface of the upper arm, over the ulnar in the sulcus at the internal condyle, over the median at the inner border of the biceps, and where the cutaneous nerves emerge from the fasciæ. Vaso-motor and trophic disturbances have sometimes been seen, as "glossy fingers," a peculiar, shiny, atrophic condition of the skin of the fingers. In severe neuralgia a pronounced atrophy of the whole arm has also been observed. The diagnosis is usually easy; we must bear in mind only the risk of confusion with articular affections.

The treatment of brachial neuralgia is often no easy task, since we frequently have to do with protracted and obstinate diseases. The causal indications should be met if possible; besides these we should make use chiefly of electricity (the descending galvanic current along the affected nerves). We may also use narcotics, morphine, cocaine, sodic salicylate to alleviate pain, antipyrine, phenacetine, etc.; and lastly local warm peat baths. In severe cases we must consider the possibility of surgical interference, such as nerve-stretching, the extirpation of cicatrices, etc.

### 4. INTERCOSTAL NEURALGIA.

(*Dorso-intercostal Neuralgia.*)

The neuralgias of this class are almost always pure intercostal neuralgias, since the posterior dorsal branches of the thoracic nerves are only exceptionally involved. The middle intercostal nerves, from the fifth to the ninth, are usually affected, one or more of them being attacked at the same time. The affection is much more frequent on the left side than on the right.

In regard to aetiology, it is important to remember that obstinate intercostal neuralgias are often a symptom, and for a long time the only symptom, of severe organic disease, especially affections of the ribs; diseases of the vertebræ, such as caries and carcinoma; diseases of the cord, such as tabes dorsalis, spinal meningitis, and tumors; and aneurism of the aorta. Genuine idiopathic intercostal neuralgia, however, is often met with, as well as these symptomatic forms, especially in anæmic and nervous women and girls in youth and middle life. Traumatic lesions of the intercostal nerves and taking cold also play a part in the aetiology.

The pain in intercostal neuralgia may attain a remarkable severity, and is usually increased by any considerable movement of the thorax. Hence the patient avoids deep inspirations, coughing, loud talking, etc., as much as possible. We usually find three painful points—one near the vertebral column, one somewhere in the middle of the nerve, and a third near the sternum or over the rectus abdominis. We may mention, among the trophic disturbances, the comparatively frequent occurrence of herpes zoster. In such cases we probably always have an actual neuritis of one or more nerves. The pain precedes the eruption of zoster, or comes on at the same time with it. It often lasts for a long time after the cutaneous affection has healed. The formation of zoster has usually been considered until the present time a "trophic disturbance," but recent careful anatomical investigations (A. Dubler) favor the hypothesis that the formation of vesicles arises simply from a direct extension of the inflammatory process from the terminal branches of the nerves to the skin. It is worthy of note that the attacks of zoster often exhibit a certain epidemic and sometimes even an endemic distribution, so as to suggest an infectious agency. The almost constant swelling of the neighboring lymph-glands, in the axillæ, at the lower border of the pectoral muscle, etc., perhaps supports this view.

The course of intercostal neuralgia depends chiefly upon the aetiology of the affection. Primary neuralgias are often quite obstinate, but on the whole they usually give a favorable prognosis. The differential diagnosis between genuine intercostal neuralgia and rheumatic affections of the muscles, incipient pleurisy, etc., is not always easy. In these cases a careful physical examination, a consideration of the localization of the pain, of the presence of painful points, and of the whole course of the disease, are needed to protect us from errors.

The treatment is governed by the general rules given in the previous chapter. Blisters often act very well in fresh cases. Electricity is given by the faradic brush or the constant current; with the latter, the cathode is placed on the vertebral column, and the anode on the lateral and anterior painful points, using quite a strong stable current. In severe cases we can not avoid injections of morphine. Herpes zoster heals by simple treatment with salves or by dusting on powders, like one part of zinc oxide to two of starch.

**Mastodynia** (*Neuralgia of the Mammary Gland*).—Mastodynia ("irritable breast" of Astley Cooper) is to be considered as a special neuralgia in the distribution of the intercostal nerves. It occurs almost solely in women, after the age of puberty, and is a very painful, distressing, and obstinate affection. The pain is either continuous, or it comes on in separate paroxysms, sometimes accompanied by vomiting. The whole breast is extremely sensitive to the touch. We know little that is definite as to its aetiology. Anæmia, hysteria, and traumatic action seem to have some influence on it. We sometimes feel little nodules in the breast, which are very painful (*tubercula dolorosa*, *neuromata*?), and which may sometimes give rise to the suspicion of the development of carcinoma.

The disease may last for years. Treatment is difficult. Warm packs to the breast, bandaging the breast, and especially narcotics, may afford relief. Elec-

tricity may be of distinct service. In the worst cases operative interference has been attempted—amputation of the breast, or extirpation of the painful nodules—but its results are uncertain.

#### 5. NEURALGIA IN THE REGION OF THE LUMBAR PLEXUS.

As the neuralgias of this class are rare, and show few peculiarities, we will content ourselves with a brief account of the most important forms.

Lumbo-abdominal neuralgia causes pain in the lumbar region, which shoots into the buttocks, the hypogastrium, and the genitals. Crural neuralgia is seated, in part, in the region of the external anterior cutaneous nerve of the thigh, and in part in the region of the cutaneous branches of the crural nerve, the internal and middle cutaneous. Its distribution over the cutaneous distribution of the great saphenous nerve, the inner portion of the calves, and the inner border of the foot, is especially characteristic. In obturator neuralgia the pain extends along the inside of the thigh, down to the vicinity of the knee-joint (see Figs. 62 and 63, page 515).

In their individual characteristics, all these neuralgias agree with what has been said in the previous chapter. The diagnosis is not always easy, and we must pay special attention to avoid confusing them with affections of the bones and joints, with lumbago, renal colic, etc.

#### 6. SCIATICA.

(*Ischiatic Neuralgia. Malum Cotunnii.*)

**Ætiology.**—Next to trigeminal neuralgia, neuralgia of the sciatic nerve is by far the most frequent, and practically the most important form of neuralgia. In contrast to most of the other neuralgias, it is more frequent in men than in women. Cold, wet, and over-exertion of the leg are found to be the most frequent ætiological factors. More rarely venous stasis in the pelvic veins (hæmorrhoids) and habitual constipation give rise to the development of sciatica. We see symptomatic neuralgia in the region of the sciatic nerve in pelvic tumors, caries of the sacrum, and analogous affections. Other traumatic influences, and compression of the nerve, as in constant, uncomfortable sitting, are sometimes evident causes of the disease. Pressure of the gravid uterus on the sciatic plexus may sometimes excite sciatica, and in women it has been seen as a result of delivery by forceps.

**Symptoms and Course.**—The pain, coming on usually with mild prodromata and gradually increasing to severe paroxysms, generally begins at the posterior surface of the thigh, in the vicinity of the sciatic notch. From this point the lightning-like pains shoot down, usually into the peroneal region, the outer part of the leg, and the outer border and top of the foot, or more rarely into the tibial region, the sole of the foot. They either come on in characteristic neuralgic paroxysms, or they are more continuous, and are then described by the patient as "burning," "boring," and the like. They are often worse at night. In severe cases the leg can scarcely be moved, owing to the pain, so that walking becomes very difficult or almost impossible, and the affected leg is kept quiet in a slightly flexed position. Very often the pain comes on after long standing or sitting. Painful points are often found along the course of the sciatic, over the gluteus maximus, or at its lower border, in the popliteal space (tibial nerve), at the head of the fibula (peroneal nerve), at the malleoli, on the top of the foot, etc.

Besides the pain, we often find other disturbances of sensibility in the affected leg, such as paræsthesia, hyperæsthesia, or slight anæsthesia. Reflex muscular tension, tremors, and even complete clonic spasms have been repeatedly observed in severe cases. A slight stiffness and weakness of the leg are very often found. A

slight atrophy of the muscles often develops, but the higher degrees of atrophy indicate that there are serious anatomical changes in the nerve. Eruptions of zoster have been repeatedly observed, but, on the whole, it is rare.

The disease lasts several weeks, although sometimes, in many obstinate cases, it continues for months and even years; but, except in cases which have an incurable anatomical lesion as an underlying cause, the termination is at last usually favorable. Relapses are, of course, quite frequent.

**Diagnosis.**—The diagnosis of sciatica is easy in the majority of typical cases, but it may sometimes be quite difficult. It is chiefly confused with lumbago, an acute coxitis, nervous coxalgia (*vide infra*), and psoas abscess. We must also bear in mind the occurrence of sciatic pain in the beginning of tabes dorsalis. In doubtful cases we can decide only after the most careful physical examination, embracing every part and function, and by considering the localization of the pain and of the painful points.

**Treatment.**—Sometimes we can obtain favorable results by fulfilling the causal indication. In regard to this we may mention especially the improvement of many cases of obstinate sciatica, associated with habitual constipation, by methodical treatment with laxatives, especially by the springs at Marienbad, or Kissingen, and also improvement after the removal of tumors, foreign bodies, etc., when they exist.

In regard to the treatment of ordinary sciatica, we must first take care, in all severe cases, to keep the leg perfectly quiet and in a good position during the painful paroxysm. Usually the local application of warmth, warm poultices, or bandages, is grateful to the patient. Sometimes a vapor bath gives real relief. More energetic local derivatives, blisters, or even local blood-letting, are of especial use in cases of "rheumatic origin." If the pain be very severe, a subcutaneous injection of morphine is the only certain remedy, and is sometimes indispensable. Embrocations of narcotics are also frequently prescribed in practice.

Of the other remedies to be considered we may mention, in the first place, electricity and massage. In electrical treatment we usually employ quite strong descending currents with large electrodes, which we let act on the nerve for five or ten minutes a day, while we include one portion of the nerve after another in the current. Where there is much stiffness in the leg, we open and close the current a few times, in order to excite muscular contraction. Many cases are suitable for the use of the faradic current, especially for the wire brush. Besides electricity, massage has often given excellent results in sciatica. Details of the technique to be employed may be found in the special treatises on this important method of treatment.\*

Besides electricity and massage, baths deserve special consideration in tedious cases. Good results are often obtained from the indifferent thermal baths, such as Teplitz, Wildbad, and Wiesbaden. We would also recommend warm local douches and hot sand baths, like Köstritz, as particularly efficient.

In general, we can promise but slight results from the very many internal remedies recommended against sciatica, but, if there be a suspicion of syphilis, we must try iodide of potassium. Quinine has usually no effect in sciatica. We sometimes see somewhat better results from the exhibition of sodic salicylate, antipyrine, phenacetine, etc. We have also very rarely seen any definite action from oil of turpentine, which is much used, especially in England. Some good results have lately been obtained by injections of osmic acid (see page 520).

\* Busch, "Allgemeine Orthopädie, Gymnastik u. Massage," Leipzig, Vogel, 1882; Schreiber, "Praktische Anleitung zur Behandlung durch Massage," Vienna, 1883 [translated by Mendelson, Philadelphia, 1887]; Reibmayr, "Die Massage und ihre Verwerthung in der prakt. Medizin," Vienna, 1888, etc. [Graham, "A Treatise on Massage," New York, 1890].

In very severe and obstinate cases, in which all other remedies have been tried in vain, we are justified in proposing to the patient to try nerve-stretching. This operation has been attended with very good results in some cases—but unfortunately, of course, not in all. Some favorable action in old cases has been ascribed to the use of the hot iron, and finally it may be mentioned as a curiosity that different observers claim to have obtained a recovery from sciatica by cauterization of the lobe of the ear!

[Mention should be made here of a method of treatment advocated by Weir Mitchell, which is occasionally useful in other forms of neuralgia as well as in sciatica. It consists in absolute rest of the leg by application of a splint. With this he combines the application of cold, by an ice-bag over the length of the nerve, which may be continued for a number of hours.—K.]

#### 7. NEURALGIA OF THE GENITALS AND THE RECTAL REGION.

Neuralgic affections of the parts named are not frequent, but still a number of cases have been described by different observers. The pain has its seat either in the external genitals, or in the urethra, or in the anal and perineal region. The most frequent form is spermatic neuralgia ("irritable testis" of Astley Cooper), in which there is the most intense pain in the spermatic cord and the testicles, which is almost always associated with an extreme hyperæsthesia of the affected parts. The treatment of this form of neuralgia by narcotics and electricity is often unsuccessful, so that in severe cases resort has sometimes been had even to castration. In women, genuine uterine and ovarian neuralgia seem to occur especially as one symptom of hysteria.

Coccyodynia is the name of a form of severe pain in the coccygeal region, seen usually in women, which is much increased by walking, defecation, etc. The affection is so distressing that operations have been repeatedly performed on account of it to remove or to cut around the coccyx. We have twice seen this same symptom as a complication of tabes.

### CHAPTER V.

#### NEURALGIA OF THE JOINTS.

(*Articular Neuroses.*)

NEURALGIA of the joints, first described by the English physician Brodie, was first generally known in Germany after Esmarch proved, by publishing many observations, that apparently severe and very painful diseases of the joints are often found, at the basis of which there is no discoverable anatomical disease of the joint, and which we are therefore justified in regarding as nervous affections. Since the localized pain in the joint is the chief symptom in most of the cases of this class, the term "neuralgia of the joints" has been quite fitly chosen, although we do not find here such typical and paroxysmal attacks of pain as in genuine neuralgia, and although, too, a number of other symptoms are usually present, which are not seen in genuine neuralgia.

We see neuralgia of the joints chiefly in nervous hysterical persons, and therefore more frequently in women and girls than in men.

We can very often make out a psychological cause for the origin of the disease. The affection is often caused by injuries which affect the joint, and which would be in themselves without significance, if they were not associated with a decided

fright, and did not direct the patient's thoughts to the affected limb. Articular neuralgias do not, therefore, belong to the pure neuralgias, but are symptoms of hysteria (traumatic hysteria). At any rate, the name of articular neurosis is more suitable than that of articular neuralgia.

Either immediately after such an occurrence, or often only some weeks later, the patient begins to complain of pain. The knee- or hip-joint is almost always affected, only rarely the joints of the upper extremity. The pain is continuous, but it is more severe at times, especially on motion, or mental excitement. At other times, especially if the patient's attention be diverted from the trouble, it seems to diminish to a considerable extent. It is mainly localized in the joint, but the whole leg is often painful. Patients are usually very sensitive to pressure, or jarring, and sometimes we may even discover some painful points on pressure over the joints. The patients can not walk at all, or at least walking is very painful, and they limp badly. In severe cases, especially if the excessive sympathy of those about them reduces the patients' power to resist their suffering, they become completely bedridden for weeks or months. There is usually a decided weakness in the affected leg, which is almost always associated with great muscular rigidity and tension. The leg is extended, or flexed and rotated inward, in just the same way as in genuine coxitis.

The diagnosis of articular neurosis is often quite difficult, but it is almost always possible, with long observation of the case. At first, of course, the disease often seems to be a severe affection of the joint, on account of the great pain, the rigid position, and the complete inability to use the leg. The experienced physician, however, is usually struck by the absence of any definite physical changes in the joint, especially of swelling, and also by the changes in the intensity of the complaint, by the influence of mental emotion on the suffering, and finally by the general impression he gets from the patients, the way they behave, and the contrast between their great complaint and their usual (though, of course, not invariably) good appearance, appetite, and undisturbed sleep. In doubtful cases an examination under chloroform is very advisable. With this, contractures apparently the most severe vanish, and the normal character and mobility of the joint become plainly manifest.

As soon as the diagnosis of an articular neurosis is made the treatment has quite definite indications. All embrocations, poultices, bandages, etc., are to be laid aside. The patient is to be brought to the conviction that she can walk, if she will only first learn to will to walk again. We make the patient practice walking methodically; these attempts at first prove very poor and apparently distressing to the patient, but they often lead to better results very speedily. These exercises are very much aided by electrical treatment of the joint, passing a strong current through it or using the faradic brush, and also by local cold douches and massage. Under some circumstances the use of internal remedies may be indicated, in many cases with regard only to the mental condition. We give iron to anæmic patients, and also the nervines. (See the chapters on hysteria and traumatic neuroses.)

## CHAPTER VI.

**HABITUAL HEADACHE.***(Cephalæa. Cephalalgia.)*

In addition to the neuralgias, we must speak here of habitual or "nervous" headache, an affection which is very often met with in practice, but in regard to whose precise causes or whose special nature our knowledge is still in many respects very unsatisfactory.

We do not term the symptomatic headaches, so often observed, "nervous headaches." The former come on in acute febrile infectious diseases, in pronounced general anæmia, in the different anatomical diseases of the brain and its membranes, of the skull, the frontal sinuses, etc. Just as little ought we to confuse habitual headache with other painful and well-characterized affections, especially typical neuralgia in the frontal branch of the trigeminus, or in the occipital nerves, or with genuine migraine or hemicrania (*vide infra*). Those cases, rather, belong to this class in which the headache forms to a certain degree a disease in itself, and is the sole, or at least the chief, symptom of which the patient complains, and for which he seeks aid. We know no definite anatomical basis for these cases. We usually assume disturbances of circulation and of the fine nutrition as the special causes of headache; but it is only in a very few cases that anything definite as to the form of these changes can be stated. We can also state little that is definite as to the special place where these pains arise. We do not know whether painful irritations may arise in the brain-substance itself. The cerebral meninges, however, especially the dura mater, are decidedly sensitive, and hence they may usually be regarded as the special seat of headache.

The manifold character of the circumstances under which headaches arise renders it probable that the causes of headache are very different in different cases. We have to do either with persons who seem perfectly healthy in other respects, or with weak and anæmic people, or again with robust, very well nourished, "full-blooded" persons with red faces. Hence we look for the cause of the pain, according to the general constitution of the patient, either in an abnormal hyperæmia or anæmia of the brain and its membranes—a hyperæmic or anæmic cephalalgia. We very often find headache, too, as the chief symptom in nervous, neurasthenic people—neurasthenic cephalalgia. To this class belong especially people who are overworked physically and mentally—scholars, officials, students before an examination, etc. If we believe that we can make out "rheumatic" influences, such as taking cold, or toxic influences, such as alcohol, nicotine, or chronic lead poisoning, we speak of a rheumatic or a toxic cephalalgia. Patients with habitual headache often suffer at the same time from chronic gastric disturbances or habitual constipation, so that the latter disorders, in many cases, stand perhaps in a causal relation to the headaches. Finally, it is a very important point that headache is sometimes associated with chronic diseases of neighboring organs, especially of the nose, the naso-pharynx, and the ear. In very many cases, however, we can find no definite cause at all for the affection, so that we have to do with a genuine idiopathic disease. It is worthy of mention, merely, that in not very rare cases a pronounced hereditary predisposition to habitual headache seems to exist. [One of the frequent causes of persistent headache is eye-strain due to the persistent unconscious effort of the muscles of accommodation to overcome some error of refraction, such as astigmatism or hypermetropia. In some cases this eye-strain may be associated with insufficiency of some of the external muscles of the eye. This condition may be associated with normal visual

power, so that the patient often maintains that there can be no trouble with the eyes; this is especially true where the refractive error is slight, less than one dioptric. It is therefore essential in every case of persistent headache, to have a thorough examination of the eyes, in order to determine whether there is astigmatism or hypermetropia. The adjustment of proper glasses, or, in rare cases, tenotomy of some of the external muscles, will often give marked relief, although even in these cases attention must also be paid to the general condition.—K.]

Habitual headache is a chronic disease. It may last for months or years, or even through the whole life, either being present continually, or, what is more frequent, coming on in separate attacks and lasting several hours or days. These attacks sometimes come without any evident cause, but they may often be referred to definite influences, to mental excitement, physical exertion, errors of diet, etc. The pain is felt either in the forehead or in the occiput, or sometimes over the whole head. It is sometimes limited to a definite and quite sharply defined part of the head. The precise form of the pain is described in different ways, either as boring, or tearing, or as if the head were pressed together from without, or as if it would split open. In many cases the intensity of the pain is not great; there is merely a dizziness and a feeling of "pressure" in the head, but in other cases the pain is very severe. In such cases there is also at times a pronounced hyperæsthesia of the skin of the head, so that it may cause pain even to touch the hair.

The general health is almost always disturbed in headache. The patient can not work, he is often ill-tempered and irritable, and he loses his appetite. We sometimes see more marked gastric symptoms, especially nausea and vomiting, and sometimes copious perspiration. Severe cases of the disease are of great importance, since by an attack the patient is rendered almost wholly unable to attend to his business.

The treatment of headache is always a difficult task. In the first place, of course, we should try to adapt our treatment to the ætiology of the disease if it is evident. We should therefore never neglect to make a thorough examination of all the organs which are to be considered (nose, ear, stomach, heart, kidneys [eyes], etc.). In such a case the existing primary disease requires special treatment. If there is any suspicion of syphilis, which must especially be considered if the pain is worse at night, we must first of all try iodide of potassium. For anæmic patients we prescribe iron, arsenic, a country residence, strengthening diet, etc. We order full-blooded persons, especially if they also suffer from indigestion, to drink bitter waters, or we send them to health resorts like Marienbad or Carlsbad. Nervous headaches in hysterical and neurasthenic patients require a rational general treatment: electricity, general faradization, galvanism to the head, or to the sympathetic, cold-water cures, etc. For persons who have overworked, we most urgently advise complete physical and mental rest. We send them to the country or to try sea-bathing.

The number of symptomatic remedies recommended to relieve headache is very considerable. In most of the tedious cases the patient himself has learned to know his disease perfectly well. Many know that there is no remedy for "their old headaches," and they merely desire to rest, waiting until the pain ceases of itself. Others have become accustomed to employ certain domestic remedies: they put poultices on the head, take a cold or a hot foot-bath, put a mustard plaster to the back of the neck, bathe the forehead with cologne-water, bind a towel tightly about the head, drink strong tea, smell ammonia or "smelling-salts," etc. We sometimes see good results, although frequently we do not, from the internal remedies. These may be used, either during the attack or for a longer period, to prevent the return of the pain. There are no special indications for the different

remedies, so that we must try to see which one is the most efficacious. Antipyrine is most used of late in doses of seven to twenty grains (grm. 0.5-1.5). Its efficacy in migraine is undoubted, but it sometimes gives distinct relief in other forms of headache. We may also use antifebrine, in doses of three to seven grains (grm. 0.25-0.5), phenacetine, seven to fifteen grains (grm. 0.5-1), and quinine, six to ten grains (grm. 0.3-0.75). In headaches which come on after exposure to cold, draughts, etc., we may try sodic salicylate, half a drachm to a drachm (grm. 2-4). Of other remedies we may mention paullinia serbilis (guarana, which contains caffeine), in seven to thirty grain powders (grm. 0.5-2), three to six one-grain ergotine pills (grm. 0.05) a day in hyperæmic headache, potassic bromide half a drachm to a drachm (grm. 2-4), arsenic, [cannabis indica], etc.

Electrical treatment (*vide supra*) has given decidedly good results in many cases, but we must always begin it with great caution, and try first what method is best borne. Cold-water cures, too, are sometimes beneficial, or residence in the country, at the seashore, or in the mountains.

We can sometimes do the patient good service with the remedies mentioned, but in other cases the evil obstinately defies all attempts at cure. Then, however, the patient has still the encouragement left that the disease often ceases at last spontaneously in advanced age, after lasting years and years.

## CHAPTER VII.

### ANOMALIES OF THE SENSE OF SMELL.

ANOMALIES of smell, which depend upon a disease of the olfactory nerve itself, or of its terminal apparatus, or of its central termination, are not infrequently observed, but they have no great practical interest. It is well known that only the upper two turbinated bones and the upper part of the septum of the nares, the olfactory region, are supplied by fibers of the olfactory nerve. The branches of the olfactory nerve pass into the cranial cavity through the openings of the lamina cribrosa and form the trunk of the nerve. Nothing certain is known as to their further central course. The hemianosmia, in affections of the posterior portion of the internal capsule, is worthy of notice, and also the anosmia of the left nasal cavity which has sometimes been claimed to be observed in cases where there was also right hemiplegia and aphasia.

In testing the sense of smell, we use substances which do not at the same time irritate the sensory fibers of the trigeminus in the nasal cavity. The best substances to use are cologne-water, ethereal oils, such as oil of cloves or oil of bergamot, oil of turpentine, camphor, musk, valerian, asafoetida, etc.

Hyperæsthesia of the sense of smell (hyperosmia) makes itself manifest either by a remarkably fine perception of odors, or by an abnormal sensitiveness to them. The latter symptom is often noticed, especially in the hysterical. Patients have headaches, or attacks of fainting, from slight odors, which healthy persons notice but little. Subjective sensations of smell (hallucinations of smell) are quite frequent among the insane, and sometimes during the aura of an epileptic attack.

A diminution of the power of smell (olfactory anæsthesia, anosmia) is also not infrequent. We see it in the different diseases of the nose—coryza, etc.; also in affections of the base of the skull, such as tumors, and acute and chronic meningitis, which involve the trunk of the olfactory sympathetically, and also in cerebral disease, tumors, etc., and most frequently in severe hysteria. In far-advanced tabes dorsalis we have sometimes found pronounced anosmia, dependent, perhaps,

upon an atrophy of the olfactory nerve. It is important to state that in every marked enfeeblement of the smell the "taste" for many forms of food suffers, since it is well known that their "aroma," as in roast meats, wines, and the different sorts of cheese, is due chiefly to the co-existing sensations of smell.

The treatment of anomalies of smell almost always coincides with the treatment of the primary disease. In case the disturbance of smell makes special interference desirable, we can try electrization of the nasal mucous membrane, or painting it with a one-per-cent. solution of nitrate of strychnine in olive-oil.

## CHAPTER VIII.

### ANOMALIES OF THE SENSE OF TASTE.

SENSATIONS of taste are obtained from two nerves—the glosso-pharyngeal, and the lingual nerve from the third branch of the trigeminus. The glosso-pharyngeal is the nerve of taste for the posterior third of the tongue and the palate, the lingual for the anterior two thirds of the tongue. The gustatory fibers of the lingual, all, or at least a great part of them, pass over to the chorda tympani, and reach with this the trunk of the facial; they do not remain in the facial, however, as many pathological experiences have most plainly shown, but they finally come back to the trigeminus, and, probably chiefly by the great superficial petrosal nerve and the Vidian nerve to the spheno-palatine ganglia, in this way they pass to the second branch of the trigeminus. There may be some other channels, however, by which the gustatory fibers finally unite again with the trigeminus, and enter the brain with its trunk. We know nothing definite as to their further course and their central termination.

Hyperæsthesia of taste is rare, and it has been seen almost exclusively in the hysterical. Paræsthesia of taste is sometimes found in patients with facial paralysis, who complain of an abnormal taste in their mouths. In the insane, too, subjective sensations of taste (hallucinations of taste) may occur. Anæsthesia of the gustatory nerves (gustatory anæsthesia, ageusia) is, however, quite frequent. As follows from what has gone before, this may be seen: (1) In affections of the peripheral terminal organs of the gustatory nerves, as in disease of the mucous membrane of the tongue; (2) in affections of the glosso-pharyngeal, such as compression; (3) in affections of the lingual nerve, and of the trigeminus within the cranial cavity; (4) in affections of the chorda tympani, from diseases of the middle ear; (5) in affections of the facial nerve between the entrance of the chorda tympani and the geniculate ganglion; but we know from experience that any obstacle to conduction in this nerve, above or below the points named, causes no disturbance of the sense of taste. Central disturbances of taste have been observed in affections of the posterior portion of the internal capsule. Disturbances of taste are very common in hysteria and allied conditions (traumatic neuroses, etc.).

The test of the sense of taste must be performed separately for all the different varieties of the sensation of taste, since partial paralyses of taste are not infrequent. The test is performed by putting small amounts of the substance to be tasted in solution on the tongue with a glass rod or a brush. The anterior and posterior parts are to be tested separately. A solution of quinine or tincture of nuxvomica serves as a test for bitter, a solution of sugar for sweet, vinegar or dilute muriatic acid for sour, and a solution of common salt for salt. We may also use as a test for taste the well-known galvanic taste, which is strongest at the anode,

but is also detected at the cathode in even very weak currents, and hence is so often noticed from by-currents in galvanizing the head, neck, etc.

An accurate diagnosis as to the seat and cause of disturbances of taste can be made only by considering the other symptoms which are also present. Direct treatment may best be employed by the aid of electricity

## SECTION II.

### DISEASES OF THE MOTOR NERVES.

#### CHAPTER I.

#### GENERAL REMARKS UPON THE DISTURBANCES OF MOTILITY.

##### 1. PARALYSIS.

**General Classification of Paralyzes.**—By "paralysis" we mean the loss of voluntary motion in the muscles of the body controlled by the will. We usually distinguish between the complete loss of the power of active motion (paralysis) and the mere weakening of it (paresis). In complete paralysis of any part of the body, or of a single muscle, the slightest voluntary motion can not be produced in it; while in paresis in a diseased part certain movements are still possible, but they are more or less below the normal in strength, extent, and duration.

In every portion of the tract that leads from the motor portions of the cortical gray matter of the brain to the muscles—that is, in every part of the so-called great "cortico-muscular conduction-path" or "pyramidal tract"—disease may lead to paralysis if it takes away from the part affected its power to conduct voluntary motor irritations. Every destruction or inhibition of function of the motor centers in the cerebral cortex, with whose integrity the initiation of voluntary innervation is associated, must also lead to a paralysis in the corresponding muscular region. Finally, it is conceivable, at least *a priori*, that diseases of the muscles may also lead to a paralysis, since the muscles may either have their contractile substance injured, or lose their power to respond by a contraction to any nervous irritation that reaches them; but an absolute confirmation of such "myopathic paralyzes" is associated with great difficulties, because diseases of the special muscular substance can scarcely be separated from diseases of the terminal branches and terminal apparatus of the motor nerves.

If we represent to ourselves briefly the precise course of the chief tract for exciting voluntary movements, as far as it is now known, we must put the begin-

FIG. 64.—Horizontal section through the right cerebral hemisphere. NC, Caudate nucleus. Th, Optic thalamus. LK, Lenticular nucleus (first, second, and third divisions). CS, Anterior limb of the internal capsule. AS, Posterior limb of the internal capsule. Pa, Fibers belonging to the facial nerve. Py, Pyramidal tract (motor). S, Sensory tract (probably cutaneous nerves and those of special sense). O, Occipital lobes.

ning of this tract, according to all recent experiments, in the region of the central convolutions of the cerebrum and of the paracentral lobule. Here we find the so-called psycho-motor centers (see the details in the chapter on cerebral localization), from which the motor fibers in the corona radiata converge and pass downward. The latter, after they have united into quite a compact bundle, enter the internal capsule, which they traverse obliquely. As we see in a horizontal section through the cerebral hemispheres (see Fig. 64), the internal capsule consists of two limbs—an anterior, between the lenticular and the caudate nuclei, and a posterior, between the lenticular nucleus and the optic thalamus. The two limbs form an obtuse angle, opening outward, whose top—that is, the junction of the anterior and posterior limbs of the internal capsule—is termed the "knee of the capsule." The motor tract (*Py*) lies in the posterior limb of the internal capsule about the posterior end of its middle third. In this it runs downward rather obliquely, so that in the upper part of the internal capsule it lies somewhat farther forward than in the lower. From the internal capsule the pyramidal tract enters the crura. It lies first in the third quarter, counting from the inside, then farther down in the middle third of the crura (see Fig. 65), and from this point it passes into the anterior half of the pons. In the pons the fibers of the pyramidal tract are somewhat separated, but they come together below it into the compact bundle of the pyramids on the anterior surface of the medulla. At the lower end of the pyramids the decussation of the (lower) motor pyramids takes place—that is, the motor fibers of each pyramid pass over, for the most part, into the lateral column of the opposite half of the spinal cord, and here form the distinct bundle of the lateral pyramidal tract (*PyS*, see Figs. 66 and 67). A small part of the pyramids, which sometimes seems to be entirely wanting, remains uncrossed, and passes downward in the anterior column

FIG. 65.—Transverse section through the crura cerebri in secondary degeneration of the right pyramidal tract. (From CHABCOFF.) *as*, Substantia nigra. *p*, The degenerated and therefore translucent pyramidal tract. *III*, Oculo-motor nerves. *AS*, Aqueduct of Sylvius.

of the cord on the same side as the so-called anterior pyramidal tract (*PyV*, Fig. 66). From the lateral column, or the anterior column of the cord, the motor fibers pass into the anterior gray columns of the cord, and are here directly connected with the large motor ganglion-cells of the anterior cornua. The anterior root-

fibers pass out from these ganglion-cells, as is well known, and become the anterior spinal roots of the peripheral nerves. Through the latter the motor impulses, coming from the cerebrum, finally reach the special motor apparatus, the voluntary muscles.

The long motor tract, just described, the cortico-muscular path or the pyramidal tract, has been quite accurately determined in its details by the results of pathological observations (Türk, Charcot), and investigations into the history of its development (Flechsig). It forms, at all events, the chief path for the conduction of voluntary innervation. It is possible that there are other motor paths of conduction besides this tract, but we know nothing definite concerning them.

If we pay attention to the course of the motor tracts described, we shall easily understand certain peculiarities in the distribution of motor paralyses, which are of great importance in diagnosis. Since the motor centers for separate parts of the body, such as the face, the arm, or the leg, are separated from one another in the cerebral cortex, and are distributed over a comparatively large surface, as we shall see more fully later on, it is easily explained why affections of the cortex, if they are not very extensive, may lead to paralysis of only a single part of the body. We call such an isolated paralysis of one part of the body *monoplegia*, and thus we speak of a cortical facial or brachial *monoplegia*. Farther downward in the brain, in the internal capsule and the crus cerebri, however, as we have seen, all the motor fibers are collected into one bundle, whose diameter takes up comparatively little space. Hence we comprehend that any disease of the brain, which is situated in this part of the motor tract, may easily make this tract incapable of conduction throughout its whole extent, or at least throughout the greatest part of it. The result must be, then, a more or less complete paralysis of the facial muscles, the arm, and the leg at the same time—that is, of the entire half of the body—a form of paralysis which is termed *hemiplegia* or *unilateral paralysis*. We may note here that, as a result of the passage of the motor fibers to the other half of the cord in the decussation of the pyramids, the paralysis must develop on the side of the body opposite to the focus of disease in the brain. Farther down in the medulla and the cord the fibers coming from both hemispheres, and belonging to the two sides of the body, lie quite near each other. Since many diseases of the cord have a tendency to affect the two halves of the cord at once, or gradually to extend over the whole transverse section of the cord, a simultaneous paralysis of the corresponding portion of the two sides of the body will readily arise as a result of this. This form of paralysis we call *paraplegia*. Diseases in the cervical cord may have as a result a paralysis of all four extremities or of the two arms—*cervical, brachial, or superior paraplegia*; diseases in the dorsal and lumbar cord a *paraplegia of the two legs—inferior paraplegia*, often called simply “*paraplegia*,” without further prefix. In affections of the peripheral nerves we have, of course, again a limitation of the paralysis to the region of the affected nerve. The paralysis may be quite extensive in diseases of a nervous plexus—paralysis of a peripheral plexus; or it may confine itself wholly to the region of a single nerve, or even of a single branch of the nerve—paralysis of a peripheral nerve.

We will have to add many more details to what has just been said, but as a fundamental principle we may now note that *hemiplegia* is the chief form of cerebral paralysis, while *paraplegia* is the chief form of spinal paralysis. *Monoplegias* are usually either cortical cerebral paralyses, or peripheral paralyses.

**General Ætiology of Paralysis.**—The kind of lesion which leads to paralysis may, in the different cases, be very diverse. From easily understood reasons we can very rarely decide as to the kind of lesion from the intensity and extent of the paralysis, but only from the manifest ætiological factors, from the development and course of the paralysis, from other morbid symptoms that are also

present, etc. In general, we may divide the paralyses into two groups, according to the nature of their cause: into paralyses from causes that can be discovered anatomically, and into the so-called functional paralyses, in which no anatomical cause for the paralysis can be found; but since our anatomical, and especially our histological, methods of investigation have become better developed and are more employed, the domain of functional paralyses has become gradually more and more restricted, and a definite anatomical cause has now been found for many paralyses which were once regarded as functional.

All the diseases of the nervous system may be anatomical causes of paralysis, if they lie in a spot where they damage or destroy the paths of motor conduction. Inflammation, degeneration, new growths, hæmorrhages, and severe disturbances of circulation, with their results, especially embolic and thrombotic softening, are found in the brain, the cord, and the peripheral nerves, and under some circumstances give rise to the appearance of paralysis. Mechanical lesions of the nervous system also play a great part in the pathogenesis of paralysis, especially traumatic injuries, and compression of the brain, the cord, and the peripheral nerves by swellings, new growths, and other diseases in their vicinity.

We also know certain toxic substances which produce paralysis from their persistent action on the organism. Of these toxic paralyses, lead paralysis is the most important in its clinical relations; but other poisonous substances, such as copper, arsenic, and certain vegetable alkaloids, may cause paralysis. In regard to lead paralysis (*vide infra*), which was once considered a purely functional paralysis, we now know that anatomical changes form its basis. These can be plainly made out, especially in the peripheral nerves.

We may group a large number of paralyses together under the term of "paralysis after acute diseases." Since in these cases we always have to do with acute infectious diseases, we may assume, as their most probable cause, certain changes in the nervous system, sometimes in the brain, but more frequently in the cord or the peripheral nerves, which stand in direct relation to the specific infectious material. There seem to be chemical poisons ("ptomaines") which form in the body in infectious diseases, and cause degeneration of certain nerve fibers, in the same way, for example, as lead. We most frequently see paralysis appear after diphtheria, diphtheritic paralysis (*vide infra*), or more rarely after typhoid, small-pox, dysentery, the acute exanthemata, etc. The paralyses which may arise in certain chronic infectious diseases, especially in syphilis and tuberculosis, usually have another origin. Here we usually have to do with the specific morbid product itself (gumma, tubercle), which may invade various parts of the nervous system.

Those paralyses which come on most manifestly because of exposure to cold are termed paralyses from exposure to cold, or "refrigeratory," or frequently "rheumatic" paralyses. Although many spinal diseases, like myelitis, may perhaps be referred to exposure to wet or cold, we usually reckon among rheumatic paralyses only certain peripheral paralyses, like that in the region of the facial nerve. The functional disturbance of the nerves in these cases probably depends upon mild inflammatory changes in them produced by cold, and is accordingly of an anatomical and not merely of a functional nature.

There are, however, quite a comprehensive group of paralyses which we must to-day still term functional paralyses. To this class belong the hysterical paralyses, the paralyses from psychical causes, like paralysis from fright, the "paralyses from imagination," etc. We shall learn to recognize these more fully in the chapter on hysteria.

In conclusion, we must bear in mind the "reflex paralyses," whose ætiology is not yet fully explained—that is, paralyses which come on in the course of diseases of certain internal organs, especially of the intestine, and of the urinary and

sexual organs. An attempt has been made to explain their origin, from analogy with well-known physiological experiments, by the idea that a "reflex inhibition" is excited in certain motor regions by a sensory irritation arising in the diseased organs, a theory which has not yet been fully confirmed. Leyden's hypothesis is somewhat more probable, but it is by no means proved beyond a doubt. According to it the paralyses of this class are explained by an ascending neuritis, arising from the organs originally affected (see the chapter on neuritis). Generally speaking, the whole conception of "reflex paralyses" is still far from clear, and we will do well to be extremely guarded in their diagnosis. Lépine has also regarded the paralysis of the arm of the affected side, seen in some cases of empyema, especially after operative interference, as a "reflex paralysis," an explanation which may be proper in some cases, but in regard to which we should be the more cautious, as metastatic abscesses of the brain are not very infrequently found in empyema (see the chapters on purulent meningitis and cerebral abscess).

**General Symptomatology of Paralyses.**—We can recognize the existence of a paralysis, except from the patient's statements as to the impossibility of performing certain motions and functions, only by a careful and thorough physical examination of the power of voluntary motion. This examination in patients with nervous disease must extend to all parts of the body, and demands an accurate knowledge of all the movements that can normally be executed by the different joints, and of the muscles and nerves requisite to produce them. In the description of the different single forms of paralysis we will go more into detail in regard to the anomalies of motion to be observed.

In each individual case of paralysis some other symptoms must be considered besides immobility—first the condition of the paralyzed muscles, and then certain accompanying symptoms that are often present with the paralysis.

In regard to the first point, the trophic condition of the paralyzed muscle is of the greatest diagnostic and practical importance. In comparing a large number of paralyses, a very evident difference in this respect strikes us at once. We see on the one hand paralyses where the paralyzed muscles retain their normal volume and their normal state of nutrition entirely, or almost entirely, for years, and on the other hand we see cases in which there is a considerable atrophy in the paralyzed muscles in a few weeks or months. This difference is so effectual that all the last-named paralyses have been classed together under the name of "atrophic paralyses." Since muscular atrophy does not occur in every case of paralysis, it can not be simply the result of the rest and inactivity of the muscles, but it must have its special cause.

If we once more represent to ourselves the whole course of the motor tracts, from the cerebral cortex to the voluntary muscles, we shall remember that the nerve-fibers through this long route undergo a single interruption—namely, by the interposition of the large ganglion-cells of the anterior cornua of the gray matter of the spinal cord. Clinical and anatomical experience teaches us that, in all those paralyses where the cause, that is, the break in conduction of the motor fibers, lies in the first portion, that is, between the cortex and the cells in the anterior cornua, there is, as a rule, no atrophy, or only a slight amount of atrophy, in the paralyzed muscles, while in those paralyses where the cause is situated in these ganglion-cells themselves, or in the portion of the motor tract peripheral to them, a pronounced muscular atrophy rapidly develops. The only possible interpretation of this fact is, that the large motor ganglion-cells of the anterior cornua have, as we express it, a trophic influence on the muscles. If these cells are intact, and the conduction from them to the muscles is not interrupted, the muscles keep approximately their normal condition of nutrition, even if they are paralyzed, while an affection of the ganglion-cells themselves, or an interruption of conduction in the

peripheral nerves, rendering the transmission of the trophic influences from the cells to the muscle impossible, necessarily results in an atrophy of the muscles. This atrophy is not confined merely to the muscles separated from their "trophic center," that is, from the ganglion-cells in the anterior cornua of the cord, as we must note here, but the nerves proceeding downward from the point of the lesion also take part in the atrophy. Since this atrophy, both of nerve and muscle, is associated with a destruction of tissue to be more fully described later—a genuine "degeneration" of the fibers—we speak of a "degenerative atrophy" of the nerves and muscles, in contrast to the simple muscular atrophy which occurs in almost all severe diseases, in starvation, etc. The degeneration of the nerves is, of course, not evident to our sight and touch during life, but it is proved, as we shall soon see, by certain changes in their electrical excitability.

From the above statements the following extremely important points in the anatomical diagnosis of paralysis are at once evident: that in cerebral paralyses there is never a degenerative atrophy in the paralyzed muscles; that atrophy is present in spinal paralyses only when the large ganglion-cells in the anterior cornua of the cord, belonging to the muscles, are destroyed or injured in their functions by the cause of the paralysis; but that in all long-continued peripheral paralyses a degenerative atrophy of the paralyzed muscles and nerves must inevitably develop. These fundamental principles may suffice for the present; further deductions from them must be postponed until the special chapters on the various forms of paralysis.

We observe a further distinction in the condition of the paralyzed muscles if we perform passive motion in the paralyzed parts. There are paralyses where we can perform passive motion in the paralyzed parts at any joint with perfect ease and freedom, and without perceiving the slightest resistance. We term such paralyses "flaccid paralyses," but there are also paralyses where passive motion meets with considerable muscular resistance, so that it can be performed only with a certain greater or less amount of exertion, or only within certain limits, or not at all. This difficulty in performing passive motion may have different causes. It is most frequently caused by the development of persistent shortening in the paralyzed muscles themselves, or in their antagonists (the so-called contractures), which prevent the free performance of passive motion. In other cases there is no special contracture, but the paralyzed muscles exhibit a peculiar rigidity. There are all sorts of muscular contractions, which either are to be regarded as symptoms of direct motor irritation (*vide infra*), or have a reflex origin. Paralyses in which the performance of passive motion is hindered by such muscular contractions are termed "spastic paralyses." The details of all these symptoms will be spoken of in the special chapters.

Finally, in every case of paralysis, we must consider the other nervous symptoms which accompany it, since these may also be of great importance in judging of the cause of the paralysis. We must first of all investigate the condition of the reflexes (*vide infra*) in the paralyzed parts, from which many conclusions can be drawn as to the seat of the lesion which causes the paralysis. We must also test the state of the sensibility, both in the skin and in the muscles themselves. Certain attendant trophic and vaso-motor symptoms are also to be regarded. The skin over the paralyzed parts sometimes appears cyanotic, or marble-like; it feels cool, is cedematous, and sometimes is peculiarly dry, hard, and scaly.

## 2. SYMPTOMS OF MOTOR IRRITATION.

As we have termed the symptoms of motor deficiency "paralysis," we group the symptoms of motor irritation in general together under the name of "spasm." We mean by this all the morbid movements occurring in the muscles involunta-

rily and even against the will. Although we may find spasm in the smooth muscles, which generally are not controlled by the will, as in spasm of the bronchial muscles, spasm of the vessels, etc., we will concern ourselves here only with the spasmodic movements in the voluntary muscles. We must look for the cause of these in abnormal irritation exerted in some way on the motor tracts, but we know very little of the precise nature and character of this irritation in most cases. The abnormal irritation often acts directly on the motor nervous region, as in the frequent spasms in affections in the neighborhood of the cortical motor centers; but the motor irritations often seem to be excited secondarily through some reflex channel—reflex spasms.

For a long time two kinds of spasm have been distinguished symptomatically. We term those spasms clonic where the abnormal muscular contraction lasts only a short time, and then is interrupted by a short period of relaxation, to come on again afresh. The affected parts of the body are thus put in a constant convulsive motion. In distinction from this we term those abnormal muscular contractions tonic spasms where the muscle remains spasmodically contracted for a longer time—minutes, hours, or days. The affected part of the body is thus kept motionless in some abnormal position. Both forms of spasm, however, show many transitions and combinations, so that we must often speak of "tonic-clonic" spasms.

A more careful examination of the symptoms of motor irritation, however, gives a still greater number of different forms. We will here group together the most important varieties of morbid involuntary movements without giving a completely exhaustive review of the manifold forms of spasm.

1. *Epileptiform convulsions* are severe, and usually clonic spasms, at times tonic-clonic, spread over the whole body or limited to one half or one portion of the body. By them the whole body or the part affected is put into violent motion, usually thrashing and shaking movements. The pure epileptic spasm in epilepsy is the type of this form of spasm, but precisely analogous spasms, "epileptiform" spasms, are seen in organic diseases of the brain, in hysteria, etc.

2. *Rhythmical contractions* in single groups of muscles are sometimes seen in certain cerebral diseases, such as apoplexy and sclerosis, and also, as we have lately observed, after acute myelitis. In these the part of the body affected is put in motion by continuous, separate, weaker or stronger thrusts, which follow one another in a regular rhythm. Rhythmical contractions are also seen as precursors or at the end of epileptiform spasms.

3. *Trembling motions, or tremor*, as we say in ordinary parlance, are moderate motions, rapidly following one another, with a not very marked excursion. If the tremor is more pronounced, we term it "shaking." Tremor is an important symptom, almost pathognomonic in many nervous diseases, such as paralysis agitans, but we know almost nothing in regard to the more intimate manner of its origin. We often see pronounced tremor, especially in the hands in exophthalmic goitre. We know that tremor is often present in old people—senile tremor; and in alcoholic subjects—alcoholic tremor. Tremor sometimes appears in muscles at rest, that is, not innervated by the will, and sometimes only in those which are moved voluntarily. This latter form of tremor, which is seen most frequently in multiple sclerosis (*vide infra*), is termed "intention tremor." Very marked intention tremor, which is increased by any mental excitement, is seen as a symptom in chronic mercurial poisoning (mercurial tremor), particularly in mirror-makers, etc.

We may mention here the so-called essential tremor, that is, a condition where the tremor, which is most marked in the hands, is the only morbid symptom and can be referred to no known cause. This form of tremor is sometimes seen in

comparatively young people, and even in children. A distinct hereditary predisposition is often present, so that several "tremblers" are found in the same family.

We very often find trembling in "nervous" persons, which is at once increased by any emotion. There is also a pure hysterical tremor.

4. *Single contractions*, either sudden twitchings, or in the form of a slow contraction of the muscle, are seen with especial frequency in diseases of the cord. They are either single, or frequent and persistent. Their mode of origin is not always plain. They may depend on direct motor irritation or they may have a reflex origin.

5. *Fibrillary muscular contractions* are little contractions in the separate muscular bundles, which may be seen on a close examination of the muscles, but which do not have any special influence on motion. If the fibrillary contractions in a muscle are very pronounced, there may develop an actual "wave" in the muscular substance. We see this symptom especially in atrophied muscles, particularly in spinal progressive muscular atrophy (*vide infra*).

6. *Choreic movements* are either slight contractions or quite complicated and extensive movements, which usually appear in the face, in one limb, or sometimes over the whole body, without regard to rule. In severe cases they are almost continuous, but in milder cases they are interrupted by shorter or longer pauses. They form the chief symptom of chorea proper, but they are also present in other cerebral affections, such as symptomatic chorea, post-hemiplegic chorea, etc.

7. *Movements of athetosis* is the name we give to peculiar involuntary and usually quite slow movements, which are seen especially in the arm and hands, but also in the head, the trunk, etc. The fingers make slow but often very extensive movements, are extended, spread apart, flexed, and moved over and around one another in the most remarkable way. This form of motor irritation occurs as a special disease, "*athetosis*," or as a symptom in certain central nervous diseases, especially the cerebral paralysis of children (*vide infra*).

8. *Constant or co-ordinated spasms* are symptoms of motor irritation in which the patient performs complicated movements by compulsion—forced movements. Among these are classed the compulsory going forward or moving in a circle, the turning about the axis of the body (forced attitudes), and also certain peculiar complicated forms of spasm, such as spasms of jumping, laughing, screaming, with all sorts of spasms of the respiratory, pharyngeal, and laryngeal muscles, associated with hiccoughing and belching sounds, etc. They are seen most frequently in severe cases of hysteria, but epilepsy may also occur exceptionally in the form of co-ordinated spasms. The forced movements and attitudes mentioned above are seen chiefly in affections of the cerebellum and the cerebellar peduncles.

9. *Tonic spasm*, as has been said, is the name for all morbid muscular contractions that continue for a long time. Tonic spasm in the muscles of mastication, the masseters, is termed trismus. Tonic spasm in the muscles of the back and neck, by which the whole body is drawn backward, and the vertebral column is bent into an arch with the convexity in front, is called opisthotonos. Tonic rigidity of the whole body is termed tetanus. Tonic spasms are seen in tetanus, tetany, hysteria, etc.

10. *Cataleptic rigidity* is the name of that tonic condition of the muscles in which the limbs are deprived of the influence of the will, but are held in position by the muscles in any position given to them passively. It is seen chiefly in certain cases of hysteria, but cataleptic states are also present in other cerebral diseases, such as meningitis (see the chapter on catalepsy).

11. *Associated movements* are abnormal movements which appear, while mak-

ing voluntary movements, in muscles which have no connection with the movement willed. Thus in hemiplegia associated movements sometimes take place in the arm when the patient wills to move the leg alone. In spinal cases, as we have seen, the movement of one leg is accompanied also by an unintentional movement of the other leg. Associated movements are commonest in the muscles of the same limb. Thus we often see in hemiplegia or in spastic spinal paralysis that patients can not draw the leg up on the body without at the same time producing a marked dorsal extension of the foot as an associated movement. In old peripheral facial paralysis (*q. v.*) we very often see associated movements in the facial muscles.

Besides the conditions of motor irritation, other attendant nervous symptoms often occur at the same time. Symptoms of motor paralysis and irritation are very often combined with each other, since the different forms of spasm may appear not only in groups of muscles whose motion is otherwise normal, but also in paretic or paralyzed muscles. In general convulsions the state of the consciousness deserves special attention. Genuine epileptic attacks are usually associated with complete loss of consciousness, but in most of the other forms of spasm the consciousness is unaffected. Finally, it is worthy of mention that tonic spasms especially are attended by a feeling of decided pain, which is probably due to an irritation of the intra-muscular sensory nerves. Such painful tonic muscular contractions are termed cramps. Among them are the well-known painful spasms in the calves after physical exertion.

### 3. ATAXIA.

In executing all normal complicated movements we need the simultaneous action of several muscles. Consider the numerous muscles which must be put in activity in walking, in grasping, and in all the manifold employments of the hands. Hence, in order to perform such movements correctly, it is not only necessary that all the muscles concerned should be innervated by the will—that is, that they be not paralyzed—but that we should also be able so to modify the innervation of each individual muscle that its contraction corresponds precisely to the special part of the work belonging to it. A prescribed voluntary motion can take place only when, first, all the muscles requisite for it come into no less but also no greater action; secondly, when each individual muscle contracts only so far and so much as its special task requires; and, third, when the conditions in the time of innervation take their normal course—that is, when all the muscles involved contract at the same time or in the proper order after one another. A movement which is executed in such a prescribed manner we call a co-ordinated movement, and the process of modifying properly the innervation of the different muscles necessary for a complicated movement we call the co-ordination of motion. We must especially bear in mind that the simultaneous action of several muscles is so far necessary, even for what seem to be the simplest movements, that muscles antagonistic to those moved must also come into activity. Only by the aid of the ever-ready antagonistic muscles can we grade our movements as finely, or check or hasten them as rapidly, as is demanded for the execution of almost all complicated movements.

Nervous pathology is rich in facts which can make the idea and the necessity of the co-ordination of motion clear to us. We often see disturbances of motility which make the patient incapable of any fine motor acts, and yet which do not depend at all upon any motor weakness or paralysis, but only upon a disturbance in the co-ordination of motion. Such a disturbance we call ataxia, and we speak of an ataxia of the arms, of the legs, etc., when the parts named can perform all

the motions and retain their full strength, but these movements show, usually at once, a striking, disordered, uncertain "ataxic" character.

Many theories have been advanced as to the precise cause of ataxia, upon which we must enter in the special chapters. We can remark here only that ataxia is seen both in cerebral diseases, especially in affections of the cerebellum (cerebellar ataxia), and in diseases of the spinal cord (spinal ataxia). Among the latter, degeneration of the posterior columns especially (locomotor ataxia, tabes dorsalis) has ataxia as one of its chief symptoms. Therefore we will discuss the character of the symptoms and the cause of ataxia more fully in describing this disease.

#### 4. GENERAL REMARKS UPON TESTING THE REFLEXES AND UPON THE CONDITION OF THEM.

In testing the reflexes, which should never be omitted in any case of nervous disease on account of its frequent great diagnostic importance, we must distinguish the two chief groups of reflexes from each other: the cutaneous reflexes, and the "tendon reflexes."

**Cutaneous Reflexes.**—We term the muscular contractions, excited reflexly by irritation of the sensory centripetal cutaneous nerves, cutaneous reflexes. These are usually present only to a slight degree in the upper extremities; but we can sometimes excite reflexes even here by pricking or pinching the skin, especially that of the fingers. The very marked reflex in many people caused by tickling the axilla is well known. The test of the cutaneous reflexes in the lower extremities is much more important. The soles of the feet are the most sensitive parts for exciting a reflex. Simply tickling the soles with the finger is a sufficient irritation (the tickling reflex), and so is the prick of a pin (the prick reflex), or striking the skin hard with a blunt object, usually the handle of a percussion-hammer (the blow reflex). Thermal irritants are also very suitable for exciting a reflex, especially bits of ice held to the skin (cold reflex). It is often advisable to try all these methods, since with diminished reflex irritability a reflex contraction in the leg can often be excited only by some one of them. We should also examine the reflex irritability of the rest of the skin, as well as the soles of the feet, by a pin-prick, by pinching a fold of the skin, etc. We should especially remember that in nervous diseases there is often a delay in the reflex, so that the reflex contraction appears only when the irritation has lasted for a certain time. Thus in many diseases of the cord, as we have repeatedly seen, the reflex follows only after we have pinched a fold of skin continuously for several (ten or fifteen) seconds, a delay which has a connection with the fact of the "summation of reflex irritation" known from physiology. The fact also deserves mention that in many patients the reflexes are easily excited in certain parts of the skin, but in other parts with difficulty or not at all—the "place of easiest reflex irritability."

In general, the reflex contractions are confined to the limb irritated. On pricking the sole of the foot, a dorsal extension of the toes or of the foot follows, or a greater or less flexion of the leg. The reflex rarely involves the rest of the body, but under pathological conditions there is such an increased reflex irritability that, on irritating the soles of the feet, both legs, or even the whole body, fall into contraction. Such a condition is sometimes seen in hysteria, in tetanus, in hydrophobia, in strychnine poisoning, etc.

We must also mention two special forms of cutaneous reflex which are often examined: the abdominal reflex, consisting of a contraction of the abdominal muscles on the same side, when we stroke the skin of the abdomen with the finger or the handle of the percussion-hammer; and the cremaster reflex—that is, the reflex retraction of the testicle, when we stroke the internal surface of the thigh,

or exert a marked pressure a hand's breadth above the internal condyle. The cremaster reflex appears first on the side irritated, but not very infrequently on both sides at once. Other cutaneous reflexes, such as the gluteal reflex, the mammillary reflex, etc., have less significance and are often absent.

Judgment in regard to any pathological condition of the cutaneous reflexes is rendered difficult by the fact that their intensity varies considerably even under normal conditions. Many healthy people have much livelier reflexes than others. Hence we may judge most accurately of a patient if, in unilateral affections, we can compare the reflex symptoms in the two halves of the body with each other. The precise condition of the reflexes in the different forms of disease will be spoken of in the special chapters. We can state here only that a diminution or a complete absence of the cutaneous reflexes must, of course, be seen where the reflex conduction—through the centripetal nerve, the gray matter, the special anterior cornu, and the motor nerve—is interrupted at any point, as may be the case both in diseases of the peripheral nerves and of the spinal cord. On the other hand, however, the cutaneous reflexes may lose their intensity, or even disappear entirely, if the reflex centers lose their irritability from an irritation of the reflex-inhibitory centers or fibers. We see an abnormal increase of the cutaneous reflexes when either the irritability of the parts that aid in producing the reflex is increased, as in many cases of cutaneous hyperæsthesia, in strychnine poisoning, and in many general neuroses; or when the inhibitory processes which normally act upon the reflex centers are abolished, as in certain diseases of the brain and spinal cord. The increase of the cutaneous reflexes is shown partly by the fact that the reflex movements are particularly lively, and appear with a comparatively slight irritation of the skin, and partly by their extension to more distant groups of muscles than usual.

**Tendon Reflexes.**—Of almost greater practical importance than the investigation of the cutaneous reflexes is the test of the phenomena classed under the name of the "tendon reflexes," and first carefully investigated and described by Erb and Westphal in the year 1875. We understand by these those muscular contractions which arise from the mechanical irritation of the tendons and analogous parts, such as the periosteum and fasciæ. By this the sensory nerves of the tendon are irritated, and excite a reflex muscular contraction by means of the spinal cord. If we give a quick blow to the ligamentum patellæ (the tendon of the quadriceps extensor) with the ulnar side of the hand, or, better, with a percussion-hammer, while the leg hangs down laxly, or, if the person examined be in bed, while the leg is in a passive position of slight flexion, it is followed almost invariably in healthy persons by a more or less vigorous contraction of the quadriceps, by which the leg is extended. This is termed "patellar reflex," "knee phenomenon" (Westphal) [or "knee-jerk"]. In order to produce it, it is especially necessary for the person examined to avoid all active muscular tension in the leg, especially in the extensor. If we examine patients who are not in bed, we can test the patellar reflex by making the patient cross the leg to be tested over the other, and by striking the patellar tendon as the leg hangs loose; but it seems to us more convenient to direct the patient to extend the leg until it forms an obtuse angle with the thigh with the opening of the angle below. If the sole be set fully on the floor the extensor cruris is made tense in this position, and we can very easily and plainly excite the contraction of the quadriceps by striking the patellar tendon. If the patellar reflex be weak and hard to detect, we should try the proceeding advised by Jendrassik, which consists in testing the reflex while the patient grips the two hands together, and tries with all his strength to pull them apart. By this ingenious tension of the muscles of the upper extremities the muscles of the legs are probably greatly relaxed, while any voluntary innervation is avoided, and

thus is explained the increase of the reflex, which is often pronounced. If by the help of this "Jendrassik's test" no reflex is to be elicited, we may regard it as absent.

The second important tendon reflex to be provoked in the lower extremity is the Achilles' tendon reflex. If we give to the foot of the person examined a passive position of slight dorsal extension, so that the tendo Achillis is a little tense, and then strike the tendon a quick blow, a marked contraction of the gastrocnemius follows. Under normal conditions this reflex is often absent. Where the tendon reflexes are abnormally increased, however, it is very vigorous, and then we can very often produce it in the following especially characteristic manner. If we make a sudden, short, vigorous, passive, dorsal extension of the foot, the tendo Achillis is suddenly made tense, and thus is irritated mechanically. As a result of this, there is a reflex plantar flexion of the foot. If now, by persistent passive dorsal extension of the foot, the tendo Achillis is again made tense, there follow by turns new plantar and dorsal movements of the foot, so that the foot is thus put into a vigorous tremor. This symptom, which can only exceptionally be provoked in healthy persons, is termed ankle clonus (foot clonus), or "foot phenomenon" (Westphal). Where there is a very great increase of the tendon reflexes the tremor is sometimes not confined to the foot, but the whole leg falls into a vigorous clonus, a symptom which was once given the unsuitable name of spinal epilepsy. We can also obtain the patellar reflex in the form of a clonus if we pull the patella firmly down with the finger and force it downward by a sudden blow on the finger.

The two symptoms described—the patellar reflex, and the Achilles' tendon reflex or foot phenomenon—are practically the most important, and are the most often tested, but they are by no means the only reflexes in the lower extremity. Besides the reflexes from the special tendons, we also frequently obtain muscular contractions by striking the periosteum and the fasciæ, which have been termed the periosteal and fascia reflexes. Thus a contraction in the quadriceps often follows a blow on the anterior surface of the tibia. We also see contractions frequently in the adductors of the thigh on striking the internal condyle of the femur, contractions in the muscles of the posterior aspect of the thigh in striking the calves, etc.

Under normal conditions the tendon reflexes in the upper extremities are often insignificant or entirely absent, but where the irritability is abnormally increased we see even here the most various and vigorous reflexes. The most important and most constant are the periosteal reflexes in the supinator longus, biceps, and deltoid, from a blow on the lower end of the radius and ulnar, and also the tendon reflex in the biceps from a blow on the biceps tendon at the elbow-joint, or in the triceps from a blow on the triceps tendon above the olecranon. A persistent clonus in the hand upon passive volar flexion sometimes occurs, but it is rare.

In many places in the special chapters we shall go more fully into the exact conditions and diagnostic significance of the tendon reflexes. We shall see that the absence of tendon reflex is characteristic of certain spinal diseases, such as poliomyelitis and tabes dorsalis, and also of most peripheral paralyses (traumatic paralyses and neuritis). We see an abnormal increase of tendon reflex in many diseases of the cord, especially in that form of spinal paralysis which is termed spastic spinal paralysis, and very often, too, in cerebral paralyses. The increase of the reflex in these cases is probably always due to a disappearance of certain influences which normally inhibit the reflex.

Although we have so far tacitly assumed the reflex nature of the symptom termed "tendon reflex" as certain—a theory first propounded by Erb, and now shared by most nervous pathologists on the ground of many clinical and experimental facts—we can not conceal the fact that the reflex nature of the phenomena

in question is not recognized by another party, headed by Westphal. Westphal holds the "tendon phenomena" to be the result of a direct mechanical irritation of the muscle provoked by the jarring or stretching of the muscle. Since, however, careful experimental investigations, repeatedly performed, have of late almost without exception decided in favor of the reflex nature of the phenomena in question, and since many clinical facts, such as the occurrence of contractions in distant muscles, crossed contractions, etc., can be explained only in this way, we will hold in the sequel to the term "tendon reflex."

**Mechanical Muscular Irritability and Paradoxical Contraction.**—In addition to the description of tendon reflexes we must make brief mention here of two symptoms which must also be considered in the examination of nervous patients. "Direct mechanical irritability of the muscles" is shown by the occurrence of contractions from a direct blow on the belly of the muscle, in which, of course, we can not definitely separate the direct muscular irritation from some mechanical irritation of the muscular nerves. Sometimes the muscular contraction is perhaps also a reflex, arising from the mechanical irritation of the fascia drawn over the muscle; but it is worthy of mention that in cases where the tendon reflex has wholly disappeared, as in *tubercles dorsalis*, the direct mechanical muscular irritability is usually retained. The so-called *idio-muscular* contractions must be especially distinguished. We see these most plainly if we give a vigorous blow with the ulnar side of the hand to the belly of a muscle, like the biceps. A circumscribed muscular swelling forms at the point struck, and gradually disappears again. The test for mechanical muscular irritability has not yet attained any special practical importance.

"Paradoxical contraction" is the name which Westphal has given to a symptom seen especially in the *tibialis anticus*, and rarely also in the flexors of the leg and forearm. It is when the foot, after being put in passive dorsal extension, remains in this position even after the expiration of a considerable time (several minutes), and a marked prominence of the tendon of the *tibialis anticus* is usually visible. We can not at the present time give an explanation of this phenomenon, which so far has been observed in different spinal and cerebral diseases, multiple sclerosis, paralysis agitans, etc.

##### 5. GENERAL REMARKS UPON THE CHANGES OF ELECTRICAL EXCITABILITY IN THE MOTOR NERVES AND MUSCLES.\*

Electricity, since the investigations of Duchenne, Remak, Benedikt, Moritz Meyer, von Ziemssen, Brenner, Erb, and others, has become not only one of the most prominent therapeutic aids in the treatment of nervous diseases, but it also plays an extremely important part in the examination of nervous patients, since the test of the electrical excitability of diseased nerves and muscles gives us a large amount of valuable information in regard to diagnosis and prognosis.

Every complete electrical examination must be made with both currents—the faradic or induction current (usually the secondary current), and the galvanic or constant current. One "indifferent" pole is usually put on the sternum or the back of the neck, and the other "testing" pole on the nerve or muscle to be tested. The excitement of the muscle from the nerve is called indirect; the excitement from placing the electrode on the muscle itself (where, of course, the excitement of the intra-muscular nerves can not be excluded) is called direct. Those points on the human body where the different nerves and muscles are most easily

\* In regard to all the details of electrical diagnosis and electro-therapeutics we would refer to Erb's "*Handbuch der Elektrotherapie*," Leipzig, Vogel, 1882. [Translated by De Watteville. New York: Wm. Wood & Co., 1887.]

accessible to the electrical excitement are to be found in Figs. 68 to 73, taken from Erb's hand-book.

In faradic examination the rule is that we can provoke marked muscular contractions both from the nerves and from direct excitement of the muscles at the points generally accessible to excitement. We designate the strength of the current required by the distance between the two coils of the induction apparatus (coil distance, *Rollenabstand*) at which the first minimal contraction of the muscle occurs. On increasing the current, the minimal contraction gradually passes into a vigorous tetanic contraction of the muscles.

Galvanic examination is performed by the aid of a "current reverser," by which the testing pole can be made either the negative pole (the cathode or zinc pole) or the positive pole (the anode or copper or carbon pole). By this

FIG. 68.

"polar method of investigation" (Brenner) the following law of contraction is obtained, which holds equally for the normal motor nerves and for the muscles.

With a weak current no noticeable excitement takes place. If we gradually increase the strength of the current, the first weak contraction of the muscle occurs at the closure of the cathode—that is, when the current is closed so that the cathode is made the testing pole. On opening the cathode, or on closing or opening the anode, nothing follows. If we increase the strength of the current still more, the cathodic closure contractions become stronger, and the anodic closure and anodic opening contractions appear, now the one being earlier and stronger, and now the other. Opening of the cathode has still no effect. Only with a very strong current, in which the cathodic closure contractions have

in question is not recognized by another party, headed by Westphal. Westphal holds the "tendon phenomena" to be the result of a direct mechanical irritation of the muscle provoked by the jarring or stretching of the muscle. However, careful experimental investigations, repeatedly performed, have almost without exception decided in favor of the reflex nature of the phenomenon in question, and since many clinical facts, such as the occurrence of contractions in distant muscles, crossed contractions, etc., can be explained only in this way, will hold in the sequel to the term "tendon reflex."

**Mechanical Muscular Irritability and Paradoxical Contraction.**—In addition to the description of tendon reflexes we must make brief mention here of two symptoms which must also be considered in the examination of nervous patients. "Direct mechanical irritability of the muscles" is shown by the occurrence of contractions from a direct blow on the belly of the muscle, in which, of course, can not definitely separate the direct muscular irritation from some mechanical irritation of the muscular nerves. Sometimes the muscular contraction is perceived also as a reflex, arising from the mechanical irritation of the fascia drawn over the muscle; but it is worthy of mention that in cases where the tendon reflex is wholly disappeared, as in *tuberculous dorsalis*, the direct mechanical muscular irritability is usually retained. The so-called idio-muscular contractions must be especially distinguished. We see these most plainly if we give a vigorous blow on the ulnar side of the hand to the belly of a muscle, like the biceps. A circumscribed muscular swelling forms at the point struck, and gradually disappears again. The test for mechanical muscular irritability has not yet attained special practical importance.

"Paradoxical contraction" is the name which Westphal has given to a symptom seen especially in the *tibialis anticus*, and rarely also in the flexors of the arm and forearm. It is when the foot, after being put in passive dorsal extension, remains in this position even after the expiration of a considerable time (several minutes), and a marked prominence of the tendon of the *tibialis anticus* is usually visible. We can not at the present time give an explanation of this phenomenon, which so far has been observed in different spinal and cerebral diseases, multiple sclerosis, paralysis agitans, etc.

##### 5. GENERAL REMARKS UPON THE CHANGES OF ELECTRICAL EXCITABILITY IN THE MOTOR NERVES AND MUSCLES.\*

Electricity, since the investigations of Duchenne, Remak, Benedikt, Moynier, Meyer, von Ziemissen, Brenner, Erb, and others, has become not only one of the most prominent therapeutic aids in the treatment of nervous diseases, but it also plays an extremely important part in the examination of nervous patients, since the test of the electrical excitability of diseased nerves and muscles gives us a large amount of valuable information in regard to diagnosis and prognosis.

Every complete electrical examination must be made with both currents—galvanic or induced (usually the secondary current), and the galvanic constant current. The "testing" pole is usually put on the sternum or the back of the head, the "testing" pole on the nerve or muscle to be tested. The excitation of the muscle from the nerve is called indirect; the excitation of the muscle itself (where, of course, the excitation of the nerves can not be excluded) is called direct. The results of the examination where the different nerves and muscles are most easily tested.

American writers on electricity use letters **closure, and contraction.** A and O have **-ter harmony to retain the German**

already become tetanic—that is, they still persist after the closure of the current—can we provoke weak cathodic opening contractions. Expressed in the abbrevia-

FIG. 69.

tions now in general use in electrical diagnosis, the law of contraction for normal muscles and nerves in man is as follows:\*

1. Lowest degree with weak currents: **KaSz**, KaO—, AnS—, AnO—.
2. Middle degree with stronger currents: **KaSZ**, KaO—, **AnSz**, AnOz.
3. Highest degree with very strong currents: **KaSTe**, **KaOz**, **AnSZ**, AnOZ.

\* Ka signifies cathode, An = anode, S = closure, O = opening, z (Zuckung) = weak contraction, Z = stronger contraction, Te = tetanus. Sometimes the increasing strength of the contractions is

The variations from the normal state seen under pathological conditions consist of quantitative and also of qualitative changes in the law of contraction. We term the simple increase or diminution of the electrical excitability in nerves or muscles, without simultaneous changes in the quality and order of the occurrence of muscular contractions, quantitative changes. The discovery of increased or diminished irritability of nerve and muscle can be made most easily in unilateral diseases, where we can compare the strengths of current required to obtain the minimal contraction on the diseased and healthy sides with each other. If we are

FIG. 70.

dealing with bilateral or general diseases this is much harder to make out. We must then draw our comparisons from the conditions of excitability in normal individuals, where the different obstacles to conduction can be carefully estimated by the aid of a galvanometer, or by comparing the excitability of the nerve-trunks in the different parts of the body with one another. For this purpose we are

abbreviated by the signs Z, Z' and Z''. [Many English and American writers on electricity use letters derived from the English names. Thus C stands for cathode, closure, and contraction. A and O have the same meaning. It seems to us clearer and conducive to greater harmony to retain the German abbreviations, which are simple and definite.—TRANS.]

usually content (following Erb's example) with comparing the superficial nerves, such as the frontal, accessory, ulnar, and peroneal, which are easily excited. An increase of electrical excitability is found in many fresh peripheral paralyses, and also in tetany. A diminution of electrical excitability is found quite frequently in bulbar and spinal paralyses, in progressive muscular atrophy, etc.

FIG. 71.

A significant advance in the investigation of the quantitative conditions of excitability has been rendered possible by the introduction of the "absolute galvanometer" (Hirschmann, Edelmann, etc.), by which the strength of the current can be read off directly in milliampères. By extensive investigations on healthy persons Stintzing has found certain limits within which the normal excitability of the different nerves varies. Deviations from these figures above or below accordingly permit us to recognize an increase or a diminution of the galvanic excitability. These limits are, for instance, for the frontal nerve, 1-2.5 milliampères; for the accessory nerve, 0.1-0.44 ma.; for the ulnar nerve (at a point one or two inches above the olecranon), 0.2-0.9 ma.; for the peroneal nerve, 0.2-2.0 ma. In these cases it is necessary, in order to obtain results that may be compared, always to use electrodes of the same area ("unit electrode" of 3 sq. cm).<sup>\*</sup> An accurate measure of the absolute strength of the faradic current has not yet been found. We therefore content ourselves with the statement of the position of the outer coil [of the DuBois-Reymond apparatus] over the inner (coil distance, *Rollenabstand*), at which the first perceptible contraction occurs. Stintzing found as an average position for the frontal nerve, 128.5 mm.; for the accessory nerve, 137 mm.; for

[<sup>\*</sup> This is Stintzing's unit. Erb has proposed a larger one, a "normal electrode" of 10 sq. cm.—K.]

the ulnar nerve, 130 mm.; and for the peroneal nerve, 115 mm. We must refer to the special works for further details.

Much more important, however, than the simple quantitative changes of electrical excitability are those not merely quantitative but also qualitative deviations from the normal law of contraction, which were first discovered in certain forms of paralysis by Baierlacher in 1859, and were soon generally confirmed. Erb has given these the name of the "reaction of degeneration," because they are closely connected with the progress of certain anatomical changes in the paralyzed muscles and nerves.

In order to make the relations of the reaction of degeneration clear, let us select as an example any fresh peripheral paralysis and follow the changes in excitability to the two currents in the nerves and muscles. In a short time (two or three days) after the onset of the paralysis a gradually increasing decline in the faradic and galvanic excitability in the nerve begins. After one or two weeks

FIG. 72.

the excitability is completely lost, so that from the nerve we can no longer provoke any trace of muscular contraction with the strongest faradic or constant current. During this time the excitability of the paralyzed muscles to the faradic current has also rapidly diminished, and finally has wholly disappeared. The case is quite different with direct galvanic excitement of the mus-

cles. Here we find at first a slight diminution, which in the second week passes to a decided increase of the galvanic muscular excitability. We now obtain marked muscular contractions with relatively very weak currents. Besides that, two other very important peculiarities are to be noted: 1. The muscular contractions are not short and lightning-like, as under normal conditions, but they seem quite sluggish, protracted, "worm-like," and often persist during the whole duration of the closure of the current. 2. The muscular contractions occur not only chiefly at cathodic closure (KaS), as under normal conditions, but the anodic

FIG. 73.

closure contractions are as strong as the cathodic closure contractions (KaSZ), or even plainly exceed them. The cathodic opening contraction (KaOZ) is also frequently stronger. 3. It may also be mentioned here that the mechanical irritability of the muscles in such cases is usually increased.

This second degree of the reaction of degeneration lasts from four to eight weeks. If the paralysis be severe and long continued, or incurable, at the end of this period comes a decline of the galvanic muscular excitability. The contractions become weaker, the strength of current necessary to produce them greater, and, finally, in incurable cases, even with the strongest currents, we can obtain only a little slow anodic closure contraction, or none at all. It is different, however, in the milder, curable cases. In these the passage to the normal condition gradually follows either the increase of the galvanic muscular excitability, or, in more protracted cases, its secondary decline. The contractions become more vigorous and shorter, the cathodic closure contraction (KaSZ) again predominates, the faradic muscular excitability and the faradic and galvanic excitability of the nerves

finally return, and with them the old normal conditions are restored. A fact to be observed in these cases is of great interest, namely, that the voluntary motion in such cases often returns decidedly earlier than the electrical excitability of the peripheral nerves. We see, then, that a diseased nerve may be capable of conducting irritations coming from the brain, while the taking up of irritation, its direct excitability, is still completely lost.\* In such cases we can obtain a muscular contraction by electrical irritation of the nerve above the point of lesion.

Besides the complete reaction of degeneration just described, there is also a so-called partial reaction of degeneration, which is not infrequent in milder cases. This may show itself in several forms, but it is chiefly when the diminution of the faradic and galvanic excitability in the nerves and the diminution of faradic excitability in the muscles is only of a slight degree, while the characteristic changes in the direct galvanic excitement of the muscles—increased excitability, slow contractions, and predominance of anodic closure contractions—are fully developed. In some cases the occurrence of slow contractions on faradic excitement of nerves and muscles has lately been observed—"faradic reaction of degeneration." In the course of atrophic paralyses we often see that the different varieties of reaction of degeneration pass into one another as the process advances or improves (Stintzing).

**Anatomical Changes of the Nerves and Muscles in the Reaction of Degeneration; its Significance in Diagnosis and Prognosis.**—As we have seen on page 538, all paralyses may be divided into two great groups—into atrophic paralyses, and paralyses without marked atrophy of the affected muscles. We have learned to recognize the necessary hypothesis of the "trophic" influence of the ganglion-cells in the anterior cornua of the spinal cord as the foundation of this distinction. In all cases where the disease affects these ganglion-cells, or is situated in the peripheral nerves, so that the trophic influence of the ganglion-cells on the muscles can no longer be of influence, we have a degenerative atrophy of the peripheral portion of the nerve, and of the muscle belonging to it. This degenerative atrophy is the anatomical cause of the symptoms of the electrical reaction of degeneration.

If we have to do with a peripheral paralysis, such as a traumatic lesion of a nerve-trunk, the portion of the nerve peripheral to the point of lesion is separated from its "trophic center" in the cord, and begins to undergo secondary degeneration. The first anatomical sign of the degeneration is a breaking down of the medullary sheath into large and small flakes and drops. The axis cylinder is also soon destroyed, so that the sheath of Schwann finally incloses only homogeneous fluid contents, which are in great part rapidly absorbed. At the same time there is an increase of the nuclei in the sheath of Schwann, and this increase, when the process is long continued, leads to a decided increase of the interstitial connective tissue in the nerve. The diminution and final loss of electrical irritability in the nerve are perfectly parallel to these anatomical changes, as we can easily understand.

The degeneration of the nerve involves its finest terminal branches in the muscles; but the muscle itself does not remain unchanged. The muscular fibers undergo a marked atrophy. They become much smaller, their transverse striation is less distinct, and they show in part a fatty and "granular" degeneration of their contents. The motor end-plates of the nerves in the muscles are spared for a com-

\* This is also connected with the repeated observations by Erb, Bernhardt, and others, that in lesions of peripheral nerves, and perhaps also in spinal diseases, reaction of degeneration can sometimes be made out even in those muscles which show no essential limitation of their voluntary mobility. In these cases the electrical examination points to finer anatomical disturbances which have not led to the loss of voluntary excitability.

paratively long time, and they disappear only when the degeneration of the muscles has reached the highest degree. In regeneration, however, the end-plates are already completely restored at a time when the nerve-fibers themselves are still found destroyed (Gessler). Some fibers show that peculiar yellow homogeneous character which we call "waxy degeneration." In addition to this, there is a considerable increase of the muscular nuclei, and in the later stages a great new growth of interstitial connective tissue, often associated with a marked deposit of fat. These muscles, thus altered, now react only to the galvanic current, and in the manner above described. The particular cause of this remarkable fact is, of course, still completely unknown to us.

In the incurable cases the processes of degeneration just described gradually advance, but, in the cases that recover, a number of processes of regeneration begin sooner or later. We can not here go into the finer details, which are still, in many respects, the subject of controversy; but it is certain that new nervous and muscular fibers are formed, and that, hand in hand with the anatomical processes of regeneration, first the voluntary motion, and later the electrical excitability of the paralyzed parts, gradually return again.

The same anatomical changes, which we have just described as a secondary degeneration in lesions of the peripheral motor nerves, also develop, if the primary disease has its seat in the anterior cornua of the gray matter of the spinal cord—that is, in the trophic centers themselves. In these cases, of course, the form of the disease has nothing to do with it. Both in the different forms of inflammation and of primary atrophy, and also in new growths, which affect the anterior gray matter of the cord, a secondary degeneration, with pronounced reaction of degeneration, develops from the anterior roots of that portion of the cord affected to the ends of the peripheral nerves, and even to the corresponding muscles. We shall also learn to recognize a number of primary degenerations of the peripheral nerves, such as primary neuritis, diphtheritic and toxic paralyses, etc., which likewise show the same anatomical changes, and likewise give, as a result of these, electrical reaction of degeneration. In all cerebral paralyses, however, and in those spinal paralyses where the cause of the paralysis is situated above the part of the anterior gray cornua concerned, the degenerative atrophy, and also the reaction of degeneration, are entirely wanting.

We thus see that the reaction of degeneration, in regard to diagnosis, at once permits us to decide that the disease is situated in the gray matter of the cord, or in the peripheral nerves. It does not permit any further distinction. In regard to prognosis, it teaches us that anatomical changes have taken place in the nerves and muscles, from which a restoration is still very possible, but at all events it can take place only after the lapse of a longer time, at least two or three months. We will soon learn to recognize a number of mild peripheral paralyses in which there is generally no reaction of degeneration. From the absence of reaction of degeneration we can then draw the conclusion, with certainty, that no coarse anatomical changes are present in the nerve, and that we may expect after the trouble a much more rapid recovery, perhaps in three or four weeks. The partial reaction of degeneration, above mentioned, is also an important symptom in regard to prognosis. It shows that severe anatomical changes have taken place in the muscles but not in the nerves, and hence it always permits a more favorable prognosis as to time than in the cases with complete reaction of degeneration.

---

## CHAPTER II.

## THE DIFFERENT FORMS OF PERIPHERAL PARALYSIS.

## 1. PARALYSIS OF THE OCULAR MUSCLES.

**Ætiology.**—The largest part of all the ocular paralyses arise from affections which involve either the peripheral nerves or their nuclei in the brain-stem. We accordingly make a distinction between peripheral and nuclear paralyses of the ocular muscles. As we shall take up the latter more fully in the description of chronic bulbar paralysis, we have here to mention only the most important and most frequent causes of the peripheral ocular paralyses. These are as follows:

1. Traumatic injuries, which directly affect the nerve-trunks or their branches: blows on the eye, knife-stabs, fractures of the skull involving the orbit or the base of the skull, and the like.

2. Compression of the nerves from morbid processes in their neighborhood. Tumors of the base of the skull, especially, very often lead to ocular paralyses. Periostitis at the base of the skull or in the orbit may also cause similar symptoms, and so do syphilitic diseases of the nerves and their surroundings, the meninges or periosteum, aneurisms of the basilar artery, acute or chronic meningitis in its different forms, etc. In all these cases we usually have to do with a pure mechanical compression of the affected nerves by the morbid new growths in their immediate vicinity. More rarely the pathological process directly invades the nerves themselves.

3. The so-called rheumatic ocular paralyses are quite common. These arise after some decided exposure to cold, such as a draught from an open window, and are in all probability very largely of a peripheral nature. They depend, as is supposed, upon an acute neuritis of the affected nerve, and hence are to be regarded as completely analogous to the other rheumatic paralyses, like rheumatic facial paralysis. Among the "rheumatic paralyses" we usually class the paralyses which apparently come on spontaneously and completely recover, for which no other special cause can be made out.

4. The ocular paralyses that sometimes arise after certain acute diseases are also of a peripheral nature, and are due to a degenerative neuritis of the affected nerves. They are most frequent as a result of diphtheria, and are much more rare in typhoid, acute rheumatism, etc. Of chronic diseases, diabetes mellitus may sometimes give rise to ocular paralyses, especially to paralysis of accommodation.

A fuller account of the very important ocular paralyses in *tabes dorsalis* will be found in the description of that disease.

**Symptoms.**—Since we must refer to the text-books of ophthalmology in regard to the more precise symptomatology, and the more special methods of ophthalmic investigation, we will here give only a brief review of the chief symptoms of ocular paralyses which are important in nervous pathology.

The disturbance in the mobility of one eye is noticed by the patient himself from the appearance of double images—double vision, or *diplopia*. These arise because, on looking to one side, the eye on the paralyzed side can not be brought into the corresponding position, and consequently the retinal images no longer fall upon the same spots. In pathological convergence of the visual axes homologous double images arise, in pathological divergence crossed images—that is, in the first case, on closing one eye, the image disappears on the same side, in the second case it disappears on the opposite side. By alternately fixing the gaze on one or the other of two fingers held in line with each other, and by regarding the disappearance, on closing one eye, of the double image of the finger not fixed, we can easily demonstrate this on ourselves. If, then, crossed double images arise,

for example, on looking to the right, we must have a divergent strabismus—that is, an imperfect function of the left internus; but if there are homonymous double images, there must be a convergent strabismus, and consequently a weakness in the right abducens. It makes it much easier to test the double images if we put a colored glass before one of the patient's eyes. False projections of the visual field arise, as a result of the double images and of the abnormal strength of innervation which the patient exerts, so that the patient's judgment of the position of external objects is uncertain. In the more extensive ocular paralyses this often leads to a pronounced feeling of dizziness. In order to avoid this unpleasantness many patients confine themselves to monocular vision, close the affected eye, or put their heads in a position to avoid the double images.

Physical examination gives the following results, according to the extent of the paralysis:

In complete paralysis of one **oculo-motor nerve** (the levator palpebrae superioris, the superior, inferior, and internal recti, the inferior oblique, the sphincter of the iris, and the ciliary muscle) the first thing that is noticed, besides the disturbance in the movements of the eye, is the more or less complete drooping of the upper lid—ptosis. If we ask the patient to follow with his eyes the motion of any object, like the finger, held before him, keeping his head still, we notice at once that the affected eye does not move upward, downward, or inward. The pupil is dilated (mydriasis) and no longer contracts to light. Accommodation is lost, and distinct vision for near objects is impossible. As a rule, the whole eye seems rather prominent (paralytic exophthalmus), because the backward traction of the recti is very largely absent. In old oculo-motor paralysis there is often a secondary contracture in the unparalyzed external rectus (and superior oblique), by which the eye is persistently drawn outward. Partial oculo-motor paralyses are not infrequent, especially isolated ptosis, isolated paralysis of the internal, inferior, or superior rectus, or isolated paralysis of accommodation, and they may usually be easily recognized from what has been said.

Paralysis of the **abducens** is characterized by the inability to move the external rectus. The eye can no longer be moved, or it can be moved only imperfectly, outward beyond the median line. In old paralysis the eye is drawn inward from a secondary contracture of the internal rectus, and convergent strabismus arises. Paralysis of the abducens may be isolated, bilateral, or combined with other ocular paralyses.

Paralysis of the **trochlear nerve**, the superior oblique muscle, is not perfectly easy to recognize; but it is rarely of special practical importance. The action of the superior oblique coincides with that of the inferior rectus. The paralysis of the former, therefore, is soonest recognized by the retardation of the eye in movements downward and also inward, and sometimes by the failure of the eye to revolve, which rotation normally takes place on looking downward, and is due to the superior oblique muscle. This latter movement takes place in each eye inward, toward the nose, about a sagittal axis, in such a way that the left eye is turned from the left and up to the left and downward, and the right eye from the right and up to the right and downward. In regard to diagnosis it is also characteristic that the double images in trochlear paralysis appear only in the lower half of the field of vision, and especially on looking downward. Hence it happens that the disturbance of vision is especially manifest in going up or down stairs.

Finally, we must mention a symptom to be observed in almost every ocular paralysis—the so-called secondary deviation of the healthy eye. If, after the sound eye has been covered, we have the parietic eye fix itself upon a point which it can not reach at all, or which it can reach only after the utmost exertion, we

see, when the covering hand is taken away from the sound eye, that the latter has been moved much too far in the corresponding direction. The abnormal exertions of innervation with the affected eye, somewhat after the analogy of certain associated movements, pass over to the associated muscle of the healthy side and cause in it too extensive a contraction.

The following must be added in regard to the separate forms of ocular paralysis: Rheumatic ocular paralysis affects the abducens most frequently, and not infrequently the oculo-motor or one of its branches, as in isolated ptosis. A case observed by us a short time ago is, at any rate, rare, in which exposure to severe cold had been followed by a complete paralysis of all the muscles of the right eye, with complete ptosis, and almost absolute immobility of the eye in any direction. The rheumatic ocular paralyses are almost always acute in their onset, and they are often during the first period associated with sensations of pain about the eye and in the head. Vomiting (of reflex origin?) is also not rare at the beginning of the affection. The course of most cases is favorable, since they usually completely recover in a few weeks, though sometimes not for months. In some cases the paralysis may remain stationary. The diphtheritic ocular paralyses usually appear, like the other diphtheritic paralyses, a week or two after the termination of the disease. They most frequently affect the muscles of accommodation, so that the patient complains chiefly of indistinct vision for near objects; but we sometimes see paralyses of the external ocular muscles also, the abducens or the internal rectus. The prognosis of diphtheritic paralyses is almost invariably favorable. Finally, we must mention here the "periodical oculo-motor paralysis," to which Möbius and others have lately called attention, and whose nature is still almost wholly inexplicable. In the cases of this sort repeated paralyses of one oculo-motor nerve, often associated with headache and vomiting, just as in migraine, come on at longer or shorter intervals (in women sometimes at the menstrual period) in the same individual, who has often had them since childhood. The individual attack sometimes lasts only a few days, but often some weeks. The attacks usually become gradually more severe later on.

Nothing generally applicable can be said as to the course and prognosis of the other forms of ocular paralyses, since in them everything depends upon the form of the underlying disease.

**Treatment.**—In regard to the fulfillment of any possible causal indication we must remember especially that a syphilitic origin of ocular paralysis is not very rare. Iodide of potassium and energetic mercurial inunction may sometimes give very good results in such cases. Hence these remedies must also be tried in doubtful cases.

Of other remedies galvanic treatment gives the speediest relief. We pass weak currents transversely through the temples, or, what is usually better, put the anode to the back of the neck and apply the labile cathode to the closed eye, especially to the region corresponding to the paralyzed muscles. Great caution, weak currents, and the avoidance of any great variations in the currents are of course necessary. We may also try preparations of strychnine internally, or, better, subcutaneously in the vicinity of the eye. We must refer to special treatises with regard to a correction of the double images by prismatic spectacles, or in regard to operations, such as tenotomy, that are sometimes performed.

## 2. PARALYSIS OF THE MOTOR BRANCH OF THE TRIGEMINUS.

*(Paralysis of the Muscles of Mastication.)*

Paralysis of the muscles of mastication, the masseters and temporals, supplied by the third branch of the trigeminus, is a rare affection. It is most frequently seen in diseases of the base of the skull which compress the motor branch of the

fifth. We shall also learn later on to recognize paralysis of the muscles of mastication as a rare symptom of chronic bulbar affections.

The chief symptom of motor paralysis of the trigeminus is the difficulty or impossibility of chewing. In unilateral paralysis the patient can chew only on the healthy side; in bilateral paralysis he can no longer chew at all. The lower jaw hangs loosely down and can also no longer be moved sideways, from the co-existing paralysis of the pterygoids. There are often sensory disturbances in the distribution of the trigeminus at the same time.

The prognosis and treatment depend upon the primary disease. Local faradization or galvanization of the paralyzed muscles is to be tried.

### 3. FACIAL PARALYSIS.

(*Mimetic Facial Paralysis. Bell's Palsy.*)

**Etiology.**—Facial paralysis is one of the commonest peripheral paralyses, as we can understand from the exposed position of the nerve and its course through the narrow Fallopiian canal. The most important causes of it are: 1. Exposure to cold, draughts, sleeping by an open window, riding in the cars with the window open, etc. The paralyses arising in this way are termed "rheumatic," and we also include in this class those peripheral paralyses which are apparently spontaneous—that is, those without any marked exposure to cold that can be discovered. In all these cases we probably have to do with a neuritis of the nerve-trunk, which comes on in a way as yet unknown. [In a recent autopsy of a case of so-called "rheumatic" facial paralysis, Minkowski found a simple degenerative parenchymatous neuritis, without any swelling of the nerve sheath or increase of connective tissue.—K.] 2. Diseases of the middle ear and caries of the petrous bone. As the facial passes through the Fallopiian canal, which is in the

immediate vicinity of the tympanic cavity, we can easily understand how, in caries of the petrous bone and in purulent affections of the middle ear, inflammation may often invade the trunk of the facial, or how the facial may be compressed by inflammatory exudations, etc. 3. In rare cases a pressure paralysis of the facial nerve arises in swelling of the parotid gland or tumors in its vicinity. 4. Diseases of the base of the skull or brain, tumors, syphilitic new growths, and acute or chronic inflammations, often give rise to the development of a facial paralysis by invasion of the trunk of the facial or compression of it. 5. We shall have to speak repeatedly of the frequent implication of the facial nerve in diseases of the brain and medulla in the following sections.

**Symptoms and Course.**—The manifold character and different functions of the nerves, which unite in the trunk of the facial, are the cause of the quite

FIG. 74.—Right facial paralysis (after SEELIGMULLER). The folds are smoothed out and in part entirely absent on the paralyzed side, while they are strongly marked on the left. The mouth and nose are drawn to the left.

large array of symptoms in facial paralysis. The paralysis of the facial muscles of expression is the most striking and characteristic (see Fig. 74). The paralyzed half

of the face is lax and expressionless, the wrinkles in the forehead are obliterated, the eye is abnormally wide open and waters (epiphora), the naso-labial fold is obliterated, the corner of the mouth droops, and saliva frequently flows from it. The paralysis becomes still more marked on any movement of the face, on wrinkling the forehead, turning up the nose, laughing, talking, whistling, or inflating the cheeks. The eye can be only partly closed. On attempting it, the upper lid sinks down from its weight (a weakening of the levator palpebrae superioris), the eye is turned upward, so that the pupil is covered, but quite a wide space is left between the eyelids (lagophthalmus). This defective closure of the lids facilitates the entrance of dust, etc., into the eye, and sometimes gives rise to conjunctivitis, or even to severer inflammation of the eye. Speech is rendered difficult and indistinct from defective movements of the lips, and mastication becomes impaired from the imperfect movement of the cheeks. In many cases we also find a paresis of the soft palate on the affected side; the fibers from the facial pass through the superficial petrosal nerve to the sphenopalatine ganglion, and thence to the soft palate. It droops more, and on phonation the soft palate is raised obliquely to the healthy side. No general rule can be given as to the position of the uvula, as this varies very much even under normal conditions.

Disturbances of taste in the anterior two thirds of the tongue have been repeatedly found on the paralyzed side, but they usually attain only a slight degree. They are explained by an affection of the fibers of the chorda tympani, which run for some distance in the facial, as has been described on page 533. At the beginning of the paralysis many patients complain of subjective sensations of taste. Later on the dullness of taste may often be discovered by careful testing. Tactile sensibility in the tongue is only exceptionally diminished (sensory fibers in the chorda?). There is sometimes a diminished secretion of saliva (fibers in the chorda), which produces an abnormal feeling of dryness in the patient's mouth on the paralyzed side. Disturbances of hearing are frequent, but they are usually due to some complicating aural trouble (*vide supra*), or to a co-existing affection of the acoustic nerve. Paralysis of the stapedius muscle, however, sometimes seems to cause symptoms, including a marked sensitiveness to all loud sounds, and even an abnormal acuteness of hearing, especially for low notes (hyperacusis oxyokoia). This symptom is due to the fact that in paralysis of the stapedius its antagonist, the tensor tympani, causes a greater tension of the membrana tympani. Reflex movements, winking, etc., are, of course, lost in complete peripheral facial paralysis. For the special reflexes, which are often seen in the later stages of facial paralysis, *vide infra*.

By testing all the symptoms described, in most cases we can decide with accuracy upon the place where the break in conduction in the facial must occur. If we examine the accompanying plan of the facial (Fig. 75), devised by Erb, we can easily understand the following chief symptomatic forms of facial paralysis:

1. Paralysis of the facial muscles; but taste, secretion of saliva, hearing, and soft palate normal; seat of the affection in the portion between 1 and 2, usually the trunk of the facial below the Fallopian canal.
2. Paralysis of the facial muscles, disturbance of taste, and eventually diminished secretion of saliva; but hearing and soft palate normal; seat of the affection within the Fallopian canal between 2 and 3.
3. Paralysis of the facial muscles, disturbance of taste, diminished secretion of saliva, abnormal acuteness of hearing; but soft palate normal; seat between 3 and 4.
4. Paralysis of the facial muscles, disturbance of taste, diminished secretion of saliva, abnormal acuteness of hearing, and paresis of the soft palate; seat in the geniculate ganglion between 4 and 5.

5. Paralysis of the facial muscles, diminished secretion of saliva, abnormal acuteness of hearing, paresis of the soft palate, but no disturbance of taste; seat above the geniculate ganglion between 5 and 6. [Gowers doubts whether there be

paralysis of the soft palate in lesions of the facial nerve. If it exist at all it is very rare. Consequently the conclusions just given can hardly be accepted in full.—K.]

The changes in electrical excitability, and some other changes, may be best described in connection with the course of facial paralysis. The paralysis usually begins quite suddenly; less frequently it is more gradual. Sometimes there are, for a short time, subjective prodromata, such as abnormal sensations of taste, slight ringing in the ears, and above all painful sensations in the ear and face, which symptoms may be referred to the beginning of acute inflammatory processes in the nerve. In a few cases the occurrence of herpes vesicles has been observed in the distribution of the affected facial, a condition which may be soonest explained, in accordance with what was said on page 525, by reference to the numerous anastomoses between the branches of the facial and those of the trigeminus.

In regard to the further course we distinguish the three following forms:

1. *The mild form of facial paralysis*, to which especially many rheumatic paralyses belong. The affection is usually referred only to the facial muscles, disturbances of taste, etc., being wholly absent. Electrical excitability in the facial and the paralyzed muscles remains entirely normal. Recovery is rapid, usually in two or three weeks. In these cases we may certainly suppose that there are no severe and deep-seated anatomical changes in the nervous or muscular fibers.

2. *The middle form of facial paralysis* (Erb). In this there is no complete reaction of degeneration, but only a partial one. The excitability of the nerve is somewhat diminished, but it is not lost. In the muscles, however, in about two or three weeks, there appears a decided increase of galvanic excitability to direct excitement. The anodic closure contraction (AnSZ) is also greater than the cathodic closure contraction (KaSZ), and the contractions are slow. In regard to prognosis we may decide from this that the recovery will still be quite rapid. It usually follows in from four to six weeks.

3. *The severe form of facial paralysis* is that in which there is a complete reaction of degeneration in the nerve and muscles, the details of which we have

FIG. 76.—Schematic representation of the trunk of the facial from the base of the skull to the pes anserinus. Different localizations of the lesion in paralysis. *N.f.* Facial nerve. *N.p.s.* Great superficial petrosal. *N.c.c.p.t.* Nerve communicating with the tympanic plexus. *N.st.* Stapedius. *Ch.t.* Chorda tympani. *Cf.* Fibers of taste. *Sps.* Nerve governing the secretion of saliva. *N.a.* Acoustic nerve. *G.g.* Geniculate ganglion. *F.st.* Stylomastoid foramen. *N.a.p.* Posterior auricular nerve.

learned in the previous chapter, loss of faradic and galvanic excitability of the nerve, loss of faradic excitability of the muscles, and quantitative and qualitative changes in the galvanic excitability of the muscles. In this form there are always course processes of degeneration in the nerve and muscles, so that recovery follows, if at all, only after two to six months, or even later, because the processes of regeneration require at least as much time for their accomplishment. We often see in the later stages of these cases special symptoms of motor irritation (Hitzig). These consist, first, of a more or less marked tonic contracture of the paralyzed muscles, which is sometimes very striking; second, of single spasmodic contractions of the muscles; third, of special associated movements—if the patient closes his eyes, winks, etc., there always follows a marked distortion of the corner of the mouth, which can not be suppressed; fourth, of an increased reflex irritability—on pricking the skin, or blowing on it, vigorous muscular contractions follow. We have often ourselves seen contractions in the affected facial muscles following a blow on the bridge of the nose, on the nasal bone, or on the forehead on the healthy side. These reflexes come from the skin, or perhaps in part from the periosteum and the fasciæ also. All these symptoms may last for a very long time—for years in incurable or in imperfectly cured cases. The above-described associated movement in the angle of the mouth on shutting the eyes we have repeatedly seen in students who have had an injury of a peripheral branch of the facial in a duel.

**Prognosis.**—The prognosis of facial paralysis depends, of course, in the first place, upon the primary disease, if any exists. Paralysis in tumors of the base of the brain, caries of the petrous bone, etc., is almost always incurable. The course of the paralysis in affections of the middle ear depends upon the curability of the latter disease. Very important data for the accurate prognosis of rheumatic paralysis are given by the electrical examination, as has been carefully described above. Of course, we can never form a definite judgment from this at the beginning of the paralysis, but only at the end of the first week. If, at the end of the first week or fortnight, the electrical excitability of the nerve still remains normal, we can almost certainly prophesy a rapid and favorable course. If reaction of degeneration appears, we can not count upon recovery in the most favorable cases before two or three months. As a rule, relapses do not occur, but we saw a man of about thirty who had a peripheral facial paralysis four times within a few years, which disappeared each time after a few weeks—a condition which possibly is to be regarded as analogous to the "periodical oculo-motor paralysis" (see page 557).

**Diagnosis.**—The symptoms of facial paralysis are so pronounced that the paralysis itself can always be easily recognized. In regard to the precise form of the paralysis and its cause, we can often decide only by considering the ætiological factors, such as injuries, exposure to cold, or aural affections. In distinguishing between peripheral and central (bulbar or cerebral) paralyses, the other co-existing bulbar or cerebral symptoms must also be considered. We shall learn to recognize more accurately later the different modes in which, in these cases, facial paralysis may be combined with paralysis of the other cerebral nerves, or the nerves of the extremities. In doubtful cases electrical examination is often of decisive value. Reaction of degeneration can be present only in peripheral paralysis, or in such bulbar paralyses as affect the fibers of the facial below the facial nucleus or affect the nucleus itself. In all the genuine cerebral paralyses the electrical excitability is perfectly retained. It may also be mentioned here briefly that in all cerebral facial paralyses the frontal portion of the facial is usually unaffected, while in peripheral paralysis it also is paralyzed. The power to close the eye is usually not affected in cerebral facial paralysis.

**Treatment.**—The treatment of the underlying disease is of the greatest impor-

tance in all cases where any aural affection, any removable compressing swelling, as of the parotid, or syphilis, lies at the bottom of the trouble. The methods of treatment indicated in such cases are self-evident. In other cases electricity is the only remedy which can give sure results, although we must not overestimate its efficiency. In fresh facial paralysis we may recommend the stable conduction of a weak constant current through the auriculo-mastoid fossæ, four to six times a week for two or three minutes, at first the anode, then the cathode, to the affected side. Later on the chief treatment is peripheral galvanization, or eventually faradization of the muscles. We place the anode in the auricular fossa and slowly stroke the different nerve-branches and the muscles with the cathode. We can often confirm the fact, immediately after each sitting, that the eye closes better after galvanization of the orbicularis. Faradization perhaps excites a reflex irritation of the nerves from irritation of the skin, and hence is of service.

Of other remedies we may mention subcutaneous injections of strychnine, seven to fifteen minims of a one-per-cent. solution of the sulphate three or four times a week, although it is only rarely of use. In secondary contractures we may obtain favorable results by methodical stretching of the muscles by wooden wedges inserted under the cheeks and by massage.

#### 4. PARALYSES IN THE REGION OF THE MUSCLES OF THE SHOULDER.

Isolated paralyses of these muscles are rare, with the exception of the practically important paralysis of the serratus. Disturbances in their functions are more frequent, as one symptom in complicated paralytic states, especially in progressive muscular atrophy. The diagnosis of these paralyses in detail is often very difficult.

**PARALYSIS OF THE STERNO-CLEIDO-MASTOID** (*spinal accessory nerve*).—The chin is somewhat raised and turned toward the affected side in consequence of the antagonistic contracture of the other sterno-mastoid. Motion in the opposite direction is difficult. In bilateral paralysis of this muscle it is very difficult to turn the head with the chin raised, and it can be done only imperfectly.

**PARALYSIS OF THE TRAPEZIUS** (*spinal accessory nerve*).—The shoulder sinks downward and forward so that the supra-clavicular fossa becomes deeper. The median border of the scapula is not parallel to the vertebral column, as under normal conditions, but it runs obliquely from below and inward, upward and outward. Voluntary raising of the shoulder, "shrugging the shoulder," is impaired, and it can be done only by the levator scapulæ. The drawing back of the shoulder, approximating it to the vertebral column, is difficult, and can be done only by the rhomboidei. Raising the arm above the horizontal is also affected, from the impaired fixation of the scapula.

**PARALYSIS OF THE PECTORALIS MAJOR AND MINOR** (*anterior thoracic nerves*).—Abduction of the upper arm is difficult or impossible. The hand can no longer be placed on the shoulder of the healthy side.

**PARALYSIS OF THE RHOMBOIDEI AND THE LEVATOR ANGULI SCAPULÆ** (*dorsalis scapulae nerve*) can be certainly recognized only when the trapezius is also paralyzed. Then the approximation of the scapula to the vertebral column (rhomboidei) and the raising of the scapula (levator anguli scapulæ) are completely abolished.

**PARALYSES OF THE LATISSIMUS DORSI** (*subscapular nerves*).—There is no deformity when at rest, but the arm can not be strongly adducted, and the hand can not be placed on the sacrum.

**PARALYSIS OF THE ROTATORS OF THE HUMERUS INWARD AND OUTWARD.**—In paralysis of the inward rotators, the teres major and subscapular, innervated by the subscapular nerves, the arm, when rotated outward, can not be brought back

again to its normal position. All manipulations, too, which the paralyzed arm tries to make on the opposite side of the body, are considerably impaired. In paralysis of the outward rotators—the infra-spinatus, innervated by the supra-scapular nerve, and the teres minor, innervated by the axillary—rotation of the arm outward is abolished. In writing and sewing (using the needle), the paralysis causes very marked disturbance.

**PARALYSIS OF THE SERRATUS ANTICUS MAJOR** (*paralysis of the long thoracic nerve*).—This paralysis is quite common, and therefore is of practical importance. Its most frequent cause is traumatic action on the nerve; therefore it is especially common in porters, soldiers, etc. Besides this, serratus paralysis sometimes arises from exposure to cold, "rheumatic serratus paralysis," and also as a result of infectious diseases, such as typhoid, and as one symptom of progressive muscular atrophy, especially in the juvenile form.

As the arm hangs down quietly, the scapula on the paralyzed side stands out a little from the chest-wall, from the action of the antagonists (the rhomboidei, the levator anguli scapulae, and the trapezius), its lower angle is a little approximated to the vertebral column, and therefore its median edge runs obliquely upward and outward. If the patient tries to raise his arm, he can raise it only to the horizontal position, and we fail to see the projection of the tense indentations of the

FIG. 76.—Paralysis of the right serratus. (From a photograph by DUCHESNE.)

serratus on the lateral wall of the chest; but as soon as we seize the scapula firmly and push it forward—that is, supply the missing action of the serratus—the patient can at once raise the arm. If the arm is raised upward to the horizontal

line, the scapula approaches the vertebral column; if it is raised forward, there appears a very characteristic wing-like projection of the inner border of the scapula, so that we can touch with the hand the inner surface of the scapula (see Fig. 76). Adduction of the arm and laying the hand on the other shoulder are also disturbed. The cutaneous sensibility of the chest is, as a rule, normal.

The course of serratus paralysis is usually tedious. Recovery does not take place for several months, as a rule. Many cases are incurable. Treatment consists chiefly in the application of electricity to the paralyzed nerve and muscles.

##### 5. PARALYSES OF THE MUSCLES OF THE BACK.

Of the paralyzes of the muscles of the back, which are rarely seen except as a complication of more extensive paralyzes, paralysis of the extensors of the spine in the lumbar region (the erector spinæ and its divisions, the sacro-lumbalis and longissimus dorsi) is the only one that has a practical interest. This is seen comparatively often in the muscular atrophy or pseudo-hypertrophy of children (*vide infra*), and causes a remarkably characteristic and easily recognizable picture. If we make the little patient stand up, the peculiar carriage of the body strikes us at once. The lumbar vertebrae are arched forward in lordosis, the belly is very prominent, and the upper part of the body is bent backward. The trunk is balanced on the hips and the gait is waddling. The paralysis of the erectors appears most plainly if the child has stooped to get any object and tries to straighten up again. He can bring the upper part of his body into the erect posture only by supporting himself with his hands on his knees, and slowly climbing up his thighs.

##### 6. PARALYSES IN THE REGION OF THE UPPER EXTREMITY.

**PARALYSIS OF THE DELTOID MUSCLE** (*axillary [circumflex\*] nerve*).—Deltoid paralysis occurs either as one symptom of complicated paralyzes arising from the brachial plexus, or as an isolated traumatic and rheumatic paralysis: that is, neuritic, beginning with pains in the region of the shoulder. It may be recognized by the impossibility of raising the upper arm at all. We can easily distinguish it from an ankylosis of the shoulder-joint by passive motion. If the paralysis lasts a long time there is a very marked atrophy of the muscle, and there is the electrical reaction of degeneration in it. Paralysis of the teres minor, which is also innervated by the axillary, can not be diagnosed with certainty.

**PARALYSIS OF THE BICEPS AND BRACHIALIS ANTICUS** (*musculo-cutaneous nerve*) is only exceptionally isolated, but is quite often seen combined with other paralyzes. The forearm, when in supination, can not be flexed, but in pronation the supinator longus it can still display its action of flexion. The action of supination by the biceps, which it exerts when the forearm is flexed, is also absent. We sometimes see at the same time a disturbance of sensibility on the radial side of the forearm from an affection of a cutaneous branch of the musculo-cutaneous nerve.

**Radial [Musculo-spiral] Paralysis.**—The anatomical course of the radial nerve causes pressure paralysis of this nerve to be among the commonest peripheral paralyzes. It is seen especially when the nerve is pressed against the humerus during sleep by the body or head lying on it, in drunkenness, sleeping with the arm hanging over the arm of a chair, etc. The paralysis is usually noticed immediately on waking. Other traumatic influences, direct injuries of the nerve, compression in dislocation of the shoulder, in fractures of the humerus, in pressure from crutches, in bandaging the arm, etc., are also frequent causes of radial

\* We have followed Henle's nomenclature for the peripheral nerves.—TRANS.

paralysis. Exposure to cold, rheumatic radial paralysis, plays a very subordinate part. For lead paralysis, which is localized chiefly in the distribution of the radial, *vide infra*.

The radial innervates the triceps and the muscles on the extensor side of the forearm. Paralysis of the triceps is present only in the cases where the point of lesion is situated quite high up, as in crutch paralyses, dislocation paralyses, plexus paralyses, etc., but it is absent, or at least it is only faintly manifest, in most of the ordinary pressure paralyses, in which the place where the radial turns about the humerus is the point of compression. Triceps paralysis is readily recognized by the impossibility of extending the forearm, but we must always make the experiment with the upper arm raised, so as to exclude the action of gravity in extending the forearm.

Paralysis of the muscles on the extensor side of the forearm may at once be recognized, since the hand hangs down in a flexed position (see Fig. 77). Any dorsal extension by the extensor carpi ulnaris and the extensor carpi radialis longus and brevis is impossible, and the lateral movements of the hand in abduction and adduction are rendered difficult. The fingers are flexed, the first phalanx can not be extended by the extensor communis digitorum, extensor indicis, and extensor minimi digiti; but if the first phalanges be extended passively and supported, the extension of the terminal phalanges is perfectly normal, from the action of the interossei which are supplied by the ulnar nerve.

The thumb is flexed and adducted, and can neither be abducted nor extended actively (extensores ossis metacarpi et primi et secundi internodii pollicis).

If the forearm be extended and pronated it can not be supinated (supinator brevis), but the flexed forearm can be supinated by the biceps. Flexion of the

FIG. 77.—Position of the hand in paralysis of the radial nerve.  
(FROM SEELIGMÜLLER.)

forearm in supination, which is done by the biceps and brachialis anticus, is retained, but flexion when half pronated ("middle position") is weakened, from the paralysis of the supinator longus. If we have the patient make short and rapid movements of flexion of the forearm in this position we do not see the characteristic normal prominence of the tense supinator longus. The very characteristic prominence of this muscle is also wanting if the patient tries to hold his pronated and semi-flexed forearm firm against forcible attempts at extension.

The functional disturbance of the hand in radial paralysis is very considerable. The action of the flexors is also weakened, since their points of insertion are approximated, on account of the constant drooping of the hand. We often see, too, sensory disturbances as well as motor in the distribution of the radial, but these are usually slight. The chief seat is on the radial half of the back of the hand and the dorsal surface of the thumb, and index and middle fingers (compare Fig. 61). The electrical excitability of the paralyzed parts corresponds to the laws that generally obtain. At the onset, and in mild cases, it is normal; at a later period, in severe cases, there are pronounced atrophy and reaction of degeneration. It is worthy of note that in all forms of radial paralysis, especially in lead paralysis, we very often find a peculiar chronic thickening and swelling of the tendons

on the back of the hand, the chief cause of which is probably the mechanical tension of the tendons.

**Ulnar Paralysis.**—Except from the frequent implication of the muscles supplied by the ulnar nerve in extensive paralyzes and atrophies, especially in progressive muscular atrophy, ulnar paralysis arises chiefly from traumatic influences, pressure, wounds, fractures of the humerus, dislocations of the shoulder-joint, etc. Neuritic paralyzes are more rare.

Flexion of the hand, and especially its lateral movement to the ulnar side, is disturbed (flexor carpi ulnaris). Flexion of the last three fingers is imperfect from partial paresis of the flexor profundus digitorum, and the little finger can not be moved at all (hypothenar muscles). Paralysis of the interossei is most striking, by which flexion of the primary phalanges and extension of the terminal phalanges of the fingers becomes impossible. Spreading the fingers, and still more bringing them together again, is also much impaired (interossei, lumbricales). The thumb can not be firmly adducted against the metacarpal bone of the index-finger (adductor pollicis).

In almost all old cases of ulnar paralysis a very characteristic position of the hand is developed, besides the muscular atrophy which is especially noticeable in the interosseal furrows of the back of the hand. By the contraction of the muscles antagonistic to the paralyzed interossei (extensor and flexor communis digitorum), the first phalanges are put in marked dorsal extension, but the terminal phalanges are completely flexed, so that the hand assumes an actual clawing position—"claw-like hand," *main en griffe* (see Fig. 78).

The disturbance of sensibility, if it be present at all, affects the volar surface of the last two fingers, the dorsal surface of the last three fingers, and a portion of the back of the hand (see Figs. 59 and 60).

**Median Paralysis.**—Median paralysis is seen chiefly as a traumatic paralysis. It is often, too, one symptom of more extensive paralyzes, in progressive muscular atrophy, etc.

The disturbances of motion are very striking. Pronation of the forearm is almost wholly abolished (pronator radii teres and quadratus). The hand can be

flexed only toward the ulnar side by the flexor carpi ulnaris (paralysis of the flexor carpi radialis). The terminal phalanges of the fingers can no longer be flexed (flexor sublimis digitorum and a part of the profundus), but flexion of the primary phalanges is normal by means of the interossei. The patient can grasp an object only by the last three fingers, which can still be

FIG. 78.—Claw-shaped hand, *main en griffe*. (FROM DUCHENNE.)

partly flexed by the flexor profundus digitorum (ulnar nerve). The thumb can no longer be flexed or opposed (flexor longus pollicis et brevis, opponens), and usually lies on the hand.

If there is any disturbance of sensibility, it is found on the volar surface of the thumb and the two adjacent fingers, and also on the dorsal surface of the terminal and middle phalanges of the index and middle fingers, and the radial side of the ring-finger (see Figs. 60 and 61). We quite frequently see in severe cases trophic disturbances, vesicles on the fingers, a shining atrophic skin, and changes in the nails.

**Combined Paralysis of the Arm.**—Combined paralysis, in which the affected muscles belong to the distribution of several nerves, occur in various forms, especially as a result of injuries which affect the brachial plexus in the neck—plexus paralysis. To this class belong also a great part of the paralysis following dislocation of the humerus—dislocation paralysis.

A combined plexus paralysis, first described by Erb, and since then repeatedly observed, deserves special mention. In this the deltoid, biceps, brachialis anticus, and supinator longus (muscles whose nerves all rise from the roots of the fifth and sixth cervical nerves) are paralyzed at the same time. The arm hangs down relaxed, and can not be raised at all, the forearm can not be flexed at all, but the hand and fingers have their normal mobility. The cause of the paralysis must have its seat at the point where the nerve-fibers for the muscles mentioned lie near one another (see Fig. 68). Sometimes the infra-spinatus is also paralyzed, so that when the arm is rotated inward it can not be rotated outward.

This same combination of paralyzed muscles is found in a part of the delivery paralysis first described by Duchenne. These are sometimes seen in infants after hard labor, and are the result of traumatic injuries of the brachial plexus in turning, in the Prague method, in extracting the child by the shoulders, etc.

In some cases of complicated paralysis of the brachial plexus, which are usually traumatic (Seeligmüller and others), co-existing symptoms on the part of the sympathetic have been observed, consisting of contraction of the pupil, narrowing of the opening of the lids, and a retraction of the eyeball on the paralyzed side. These symptoms, pointing to a paralysis of sympathetic nerves (*vide infra*, page 591), probably depend, as follows from clinical and experimental investigations (Klumpke), always upon a lesion of the ramus communicans of the first dorsal nerve. Vaso-motor symptoms in the face are usually absent, but we sometimes find a peculiar flattening of the cheeks, which has not yet been correctly explained.

**General Prognosis and Treatment of the Peripheral Paralysis of the Upper Extremity.**—In the prognosis of the peripheral paralysis of the arm the same points hold good that have been spoken of in the prognosis of facial paralysis. In this, too, there are mild and severe cases, the latter having complete reaction of degeneration, and a course that lasts at least several months before recovery. A number of traumatic paralysis can be cured only up to a certain point, or they may be even entirely incurable.

The treatment can fulfill a causal indication only in comparatively rare cases, when we can succeed in removing by operation any compressing tumors, cicatrices, splinters of bone, formations of callus, etc.

In other cases the electrical treatment of paralysis promises the best success. We use the galvanic current chiefly, although we generally employ the faradic current at the same time. In regard to the method of application, we may employ the stable action of the constant current on the very point of the lesion, especially in fresh cases, but the chief method is the electrical irritation of the paralyzed nerves and muscles. We treat the nerve above the point of the lesion in order to act in some degree against the hindrance to conduction from above and to overcome it. The muscles are irritated by galvanism by stroking the cathode over the separate paralyzed muscles. If there is reaction of degeneration, with anodic contractions predominating or exclusively present, we use the anode for the testing pole. The other pole is placed on the back of the neck or on the seat of the lesion. Faradization of the muscles may also be of service, especially if the muscles react to faradism; but, even if this is not the case, the sensory faradic irritation has perhaps a favorable influence, since it produces a reflex irritation of the motor nerves. The single sittings should last five or ten minutes, and should take place

daily or three or four times a week. The fresher the paralysis, the more favorable, comparatively, is the prognosis, but even in old and severe cases we may sometimes obtain noticeable results by patience and perseverance. The treatment must in such cases be kept up for months, and even longer, with occasional interruptions.

Embrocations with spirits and with similar substances must often be prescribed in practice, but they act favorably only when associated with methodical massage of the paralyzed muscles. We sometimes see a certain advantage, too, from local warm bathing, or from the use of the baths in Teplitz, Wiesbaden, Wildbad, etc.

#### 7. PARALYSES OF THE DIAPHRAGM.

Isolated paralysis of the diaphragm occurs but rarely, in wounds of the phrenic nerve in the neck, as a "rheumatic" paralysis, and finally in hysteria. Muscular paresis of the diaphragm seems to develop sometimes as a result of inflammation of the serous layer of the diaphragm. The paralysis of the diaphragm which comes on as one symptom in more extensive paralyses, is more frequent and practically more important. In diseases of the upper cervical cord, in ascending myelitis, in progressive muscular atrophy, in multiple neuritis, etc., the development of paralysis of the diaphragm is the cause of the rapidly fatal termination which follows the appearance of disturbance of respiration.

The symptoms of paralysis of the diaphragm are readily recognized, especially in the ordinary bilateral affection. We detect the modification of the respiratory movements at the first glance. While we are struck by the marked upper thoracic respiration, which becomes very labored on the slightest cause, the visible and palpable protrusion of the epigastrium on inspiration is entirely absent. Instead of this there is usually an inspiratory retraction in the epigastric region. The respiration is but little accelerated in simple paralysis of the diaphragm as long as the patient is perfectly quiet; but in other cases the development of a severe bronchitis, from the defective respiration in the lower lobes of the lungs, causes constant dyspnoea. The cause of the bronchitis may be found in the fact that the action of abdominal pressure is very much diminished in the constant high position of the diaphragm, which may be made out by percussion, and consequently the cough and the expectoration of secretion are very imperfect.

The prognosis is favorable only in hysterical and rheumatic paralyses; otherwise it is usually very unfavorable. In regard to treatment, the only thing that can be tried is to excite the diaphragm from the phrenic in the neck by faradism or galvanism, while the other pole is placed on the region of the insertion of the diaphragm in the thorax. A transverse conduction of the constant current through the diaphragm, associated with changes of the current, may also have a favorable influence.

#### 8. PARALYSES IN THE REGION OF THE LOWER EXTREMITY.

**PARALYSIS OF THE CRURAL NERVE.**—Crural paralysis is but rarely isolated. It is seen after injuries, after compression of the nerve by tumors of the pelvis or thigh, in disease of the vertebræ, psoas abscess, etc.

The symptoms are readily recognized. The thigh can not be flexed on the trunk, and the trunk can not be raised from the recumbent position (ilio-psoas muscle). The leg when flexed can not be extended (quadriceps extensor). Walking and standing are very difficult or almost impossible. Paralysis of the sartorius and pectineus causes no special symptoms. If there is any disturbance of sensibility it is found in the lower half of the anterior surface of the thigh and on the inner side of the leg down to the great toe (saphenous nerve, see Figs. 62 and 63).

**PARALYSIS OF THE OBTURATOR NERVE** is very rarely seen as an isolated phenomenon. The chief symptom is the defective adduction of the thigh (the adductor magnus, longus, and brevis, and the gracilis), and the impossibility of crossing one leg over the other. Rotation of the thigh outward is also disturbed (obturator externus). Some disturbance of sensibility may be found on the inner side of the thigh.

**Paralyses in the Distribution of the Gluteal Nerves** are not uncommon. We have seen them in progressive muscular atrophy and in multiple neuritis. Paralysis of the gluteus maximus is rendered noticeable by the fact that this muscle extends the thigh on the pelvis. It is therefore especially called into play in going up-stairs, climbing mountains, and rising from a sitting position. All these movements are rendered nearly impossible when the muscles are paralyzed. The gluteus medius and gluteus minimus are abductors of the thigh, and also fix the thigh on the pelvis. If they are paralyzed the patient has a very characteristic waddling gait. On account of the predominance of the adductors the feet are then advanced near each other or even one over the other. Rotation of the thigh inward is also due in part to fibers of the gluteus medius, but chiefly to the obturator internus.

**Paralyses in the Region of the Sciatic** are quite frequently seen. They come from traumatic lesions, from compression of the separate nerve-branches in diseases of the vertebrae, in pelvic tumors, in hard labors, rarely from rheumatic influences, sciatic neuritis etc.

**PARALYSIS OF THE PERONEAL NERVE**, which is also frequently isolated, may at once be recognized by the flaccid drooping of the foot. On walking, this becomes very marked, and the tip of the foot often sticks to the floor. The patient, therefore, has to raise the thigh higher, and to put the foot down awkwardly, toe first. Dorsal extension of the foot (tibialis anticus) and of the toes (extensor communis digitorum longus and extensor hallucis longus), and also abduction of the foot and raising its outer border (the peronei), are almost impossible. In old cases a permanent toe-drop (talipes equinus or varo-equinus) develops, usually as a result of secondary contracture of the muscles of the calf.

**PARALYSIS OF THE TIBIAL NERVE** makes plantar flexion of the foot impossible (gastrocnemius and soleus). The patient can no longer rise on his toes. Adduction of the foot (tibialis posticus) and plantar flexion of the toes (flexor communis digitorum and flexor hallucis longus) are also abolished. As a result of secondary contractures, talipes calcaneus sometimes develops, and also a claw-like position of the toes, with dorsal extension of the first and plantar flexion of the last phalanges from paralysis of the interossei.

In **PARALYSES OF THE TRUNK OF THE SCIATIC** there is added to the symptoms mentioned the inability to flex the leg backward on the thigh (to be tested when the patient is lying on his side or standing), which is due to a paralysis of the biceps, semi-membranosus, and semi-tendinosus. In unilateral paralysis of the sciatic, walking is still possible, since the leg is fixed at the knee by the quadriceps extensor and is rigid like a wooden leg.

The distribution of the disturbance of sensibility on the posterior surface of the whole leg is given in Fig 63. Vaso-motor and trophic disturbances, cyanosis and coldness of the skin, and atrophy of the muscles, are often present.

Treatment follows the same rules as are given for the management of peripheral paralyses in the upper extremity.

#### 9. TOXIC PARALYSES.

**Lead Paralysis.**—Of all the toxic paralyses, that from lead poisoning is practically the most important. It is a common symptom of chronic lead poisoning.

and is seen chiefly in those people whose occupation gives rise to a long-continued taking of small amounts of lead into the system, especially, therefore, in type-setters, type-cutters, and type-founders; in artists and house-painters, from lead colors; in potters, from lead glaze, etc.

As to the special anatomical causes of lead paralysis, we have not yet reached a complete harmony in our theories. While some seek the starting-point of the paralysis in the muscles themselves, most authors at present assume, as a cause of the paralysis, an affection of the nervous system excited by the toxic action of the lead. Since lead paralysis belongs to the genuine atrophic paralyses (*vide supra*), as we shall soon see, we have to do only with a disease of the anterior gray cornua in the cord, or with a degeneration of the peripheral motor nerves. The positive lesions found at present do not fully agree, but there can be scarcely a doubt, after the discoveries of Leyden, Zunker, and others, that, at least in most cases, the degenerative atrophy of the peripheral motor nerve-fibers is primary, and that the degenerative atrophy of muscles supplied by the nerves follows secondarily in the ordinary way. In many cases, however, there is perhaps, besides the peripheral degeneration, an affection of the cord, especially in the anterior gray cornua, caused by the toxic action of the lead.

Lead paralysis shows an extremely typical localization in the great majority of cases, and it affects by far the most frequently a part of the radial distribution. A paralysis of the extensor communis digitorum comes on rapidly or slowly. Extension of the primary phalanx of the middle and ring, and later of the index and little fingers, becomes impossible, but the extension of the terminal phalanges by the interossei remains normal. There often follows later a paralysis of the extensor longus pollicis and the extensor brevis, and of the abductor pollicis and the extensors of the wrist, while the supinator longus and the triceps almost always remain free in a remarkable way. In much rarer cases lead paralysis affects the deltoid, biceps, brachialis anticus, and supinators. Paralysis of the lower extremities is also very rare.

Lead paralysis is usually bilateral. In all severe cases a pronounced atrophy and electrical reaction of degeneration develop in the paralyzed muscles. It is an interesting point that the latter may sometimes be made out in muscles which can be perfectly well moved by the will (see page 553). The sensibility is almost invariably perfectly normal, so that the sensory nerves are manifestly unaffected by the lead.

Lead paralysis permits a favorable prognosis in the cases where the patient can be removed from the injurious influence of the poison. Recovery takes place after several weeks, or in severe cases after some months. Relapses and complications with other morbid results of chronic lead poisoning, however, are, of course, frequent.

The treatment is the same as in all other peripheral paralyses. Electricity is first to be considered. Local sulphur baths and the internal use of iodide of potassium are also recommended.

[It is well to mention here that chronic lead poisoning may give rise to symptoms closely resembling those of almost every chronic disease of the nervous system. It is often so difficult to detect the source of the lead that it is well in all obscure nervous diseases to test the urine for the metal after iodide of potassium has been administered in five- to ten-grain doses thrice daily for a week. For the precautions to be observed in carrying out this test the reader is referred to works on medical chemistry. If large doses of the iodide are administered there is danger lest the lead be liberated too rapidly and cerebral symptoms supervene. J. J. Putnam has shown, however, that lead is often found in the urine of persons in apparent good health. Lead may also cause simple anaemia, and it is occasionally

found in the urine of patients with degenerative diseases of the spinal cord, especially combined sclerosis, ataxic paraplegia, and chronic myelitis.]

**Arsenical Paralysis.**—Arsenical paralysis is much rarer than that from lead. In distinction from that it comes on especially after acute poisoning with arsenic, and usually, though not always, it follows immediately the other symptoms of poisoning. The localization of the paralysis is not as typical as in lead paralysis. The paralysis is sometimes very extensive over the arms and legs, but it usually chiefly affects only the lower extremities. The paralyzed muscles rapidly atrophy. It has not yet been certainly decided whether reaction of degeneration occurs. The accompanying disturbances of sensibility are very characteristic, either anaesthesia, or especially paresthesia and severe pains in the sacrum and legs. Trophic disturbances in the nails, hair, etc., have been repeatedly observed. Nothing certain is known as to the anatomical cause of arsenical paralysis, but the theory of its peripheral origin is most probable on account of the initial pains.

The course is usually favorable, sometimes rapid and sometimes lasting for months. The treatment is the same as in lead paralysis.

Copper paralysis, zinc paralysis, etc., are very rare, and therefore they will not be described fully here. The essentials in regard to alcoholic paralysis may be found in the chapter on neuritis (*vide infra*). We may mention here briefly that, after subcutaneous injections of ether on the extensor side of the forearm, paralysis of the extensor communis digitorum has been observed in a few cases.

### CHAPTER III.

#### THE DIFFERENT FORMS OF LOCALIZED SPASM.

##### 1. SPASM IN THE MOTOR DISTRIBUTION OF THE TRIGEMINUS.

TONIC spasm of the muscles of mastication is called trismus. As an independent disease it is very rare, but it often occurs as one symptom in complicated forms of spasm and other nervous affections, as in tetanus, in the epileptic attack, in hysteria, meningitis, etc. Both jaws are pressed firmly together, and we can feel through the cheeks the hard and tense masseters. In unilateral spasm of the pterygoids the lower jaw is pushed laterally in the opposite direction.

Clonic spasm of the muscles of mastication—masticatory facial spasm—consists of a paroxysmal and constant movement of the lower jaw, almost always in a vertical, but rarely in a horizontal direction. The single movements follow one another usually in a regular, rapid rhythm, and produce an audible chattering of the teeth. The mucous membrane of the mouth and the tongue is often injured.

The cause of these spasms can not always be established. Sometimes they seem to be of reflex origin, as in affections of the lower jaw, the teeth, or even of distant parts. We once saw a case which lasted for a year which was said to have arisen from a severe fright, and also a case of chronic spasm in the masseters and mylo-hyoids of hysterical origin in a ten-year-old boy.

The treatment, apart from the treatment of the primary affection, must aim at removing the cause of the disease, if there be one, such as decayed teeth. In other respects electricity is of value in many cases, applied either by passing the constant current through the muscles, or by faradizing them, or by using the wire brush.

Of internal remedies we may try narcotics, such as morphine, cannabis indica, bromide of potassium, atropine, arsenic, iodide of potassium, valerianate of zinc, etc.

Artificial feeding is of great importance, if the patient can not take food voluntarily from a persistent trismus. It is best to introduce a small œsophageal tube through the nose into the œsophagus. Rectal feeding is insufficient for a permanent method, but still it is sometimes of service. In some cases a successful attempt has been made to overcome the closure of the jaws gradually by pushing wooden wedges between the teeth.

## 2. CLONIC FACIAL SPASM.

(*Minetic Facial Spasm. Convulsive Tic.*)

We know little that is definite as to the ætiology of facial spasm, the most frequent and practically the most important form of spasm. We can rarely make out any cause for its origin. In some cases, perhaps, the disease is to be referred to a lesion of the trunk of the facial, from exposure to cold, aural affections, or disturbances at the base of the skull, or else to a reflex irritation of the nerve in trigeminal neuralgia, and also in diseases of the sexual organs, etc. It may be that many cases are not of peripheral but of central origin, from the facial center in the cerebral cortex. The disease may also appear after violent mental excitement. Finally, imitation and the habit of grimacing play a part in many cases, especially in children, that is not to be underestimated. Repeated observations have established the fact that the disposition to the disease is heightened by a general hereditary neuropathic taint.

The symptoms of convulsive tic consist of alternating, short, lightning-like contractions in almost all the muscles supplied by the facial. The disease is usually unilateral, often extending over the whole distribution of the facial, but sometimes confined only to individual parts, the partial facial spasm. Sometimes the contractions are almost constant, though varying in intensity, so that the patient involuntarily makes the strangest faces; but they often appear in separate attacks, which last but a short time, and are interrupted by completely free intervals. The attacks arise without any special cause, or they may be excited by talking, voluntary movements, sensory and mental impressions, etc. In some very severe cases the contractions also invade the neighboring territory—the muscles of mastication, the tongue, and the muscles of the neck. Voluntary motion in the muscles is perfectly normal, except for the disturbing influence of the spasmodic movements. All sensory disturbances are also wanting; there is neither anæsthesia nor pain.

A common partial form of facial spasm, which is entirely or almost entirely isolated, deserves special mention—blepharospasm, or spasm of the eyelids—that is, a tonic or clonic spasm in the orbicularis palpebrarum. The tonic form may be of reflex origin in affections of the eye, but sometimes it is excited from other regions of the trigeminus. It is, as a rule, bilateral, and may last for days or weeks, sometimes with occasional interruptions. The pressure points, which are found in this form, and which were first carefully described by Graefe, are very remarkable. They are usually found at the points of exit of the branches of the trigeminus, but sometimes on the vertebral column or on other parts of the body. By pressure on these points the spasm at once ceases, so that the lids “fly up as if by a spring.” Clonic spasm of the lids, nictitating spasm, consists of a spasmodic winking and contraction of the eyes, which is sometimes almost constant. Here, too, we can often make out a reflex origin for the spasm, but frequently we can not find any cause.

Facial spasm, in its severe forms, is always a troublesome disease for the patient, and causes very much disturbance, especially in blepharospasm. The course is often very tedious. Sometimes there are long intervals, as we have seen during pregnancy, and then the spasm begins anew. In not very rare cases the affection becomes habitual and lasts for life.

Treatment is, therefore, usually a difficult and thankless task. The best results may be obtained where we can succeed in removing any reflex cause of the spasm, as in extracting decayed teeth, treating affections of the eye, or, in some cases, resection of the supra-orbital nerve. In applying electricity, our chief attention must be directed to any pressure points, to which we make a stable application of the anode of the constant current. If there are no pressure points, we put the anode on the trunk of the facial and the different branches of the *pes anserinus*. In cases of reflex origin Berger obtained good results by applying the anode to the occiput, just under the protuberance, while the cathode was held in the hand—galvanization of the medulla. The single sitting should last five or ten minutes. The faradic current—a slowly “swelling current” \*—has also been recommended. Of internal remedies we should first try bromide of potassium, and then arsenic, atropine, curare, or oxide of zinc. Their action is always very uncertain. A favorable result, however, has been obtained by nerve-stretching, in a part of the cases operated on, at least so far that the ensuing paralysis troubles the patient less than the constant twitching. When the paralysis ceases the twitchings usually begin again, but in some cases the benefit has been permanent. Finally, we must mention that the use of the red-hot iron has sometimes been followed by a decided improvement of the spasm in old cases. We employ cauterization along the cervical vertebrae, on the trunk of the nerve, or on any existing pressure points, by means of Paquelin's thermo-cautery.

[*Convulsive tic (Maladies des tics convulsifs)*.—Under this term Gilles de la Tourette has described an affection allied to hysteria, which usually begins in young children, especially those with a neurotic heredity. It is characterized by spasmodic twitchings of the facial muscles, and sometimes of the other muscles of the body, and by explosive utterances. These utterances may be a repetition of some word which the child hears (echolalia), or the repetition of some profane or filthy word (coprolalia). Actions may also be imitated. Coprolalia is one of the most distinctive symptoms. Other mental symptoms, particularly certain forms of imperative conceptions, are occasionally observed. The prognosis is bad. The treatment is largely the same as that of hysteria (*q. v.*).—K.]

### 3. SPASM IN THE REGION OF THE HYPOGLOSSAL NERVE. LINGUAL SPASM.

Although the tongue is often implicated in complicated forms of spasm, such as hysterical or epileptic spasms, isolated spasms in it are very rarely seen. They occur, however, either in a clonic or a tonic form, and then they cause a marked disturbance of speech, or even of respiration, if the spasm draw the tongue backward. In the latter case it may be necessary to use inhalations of chloroform, and to draw the tongue forward by force.

### 4. SPASMS IN THE MUSCLES OF THE NECK.

Tonic and clonic spasms in the region of the muscles of the neck are not very frequent, but they appear in very various forms, and are at times a very severe and persistent affection. We can usually discover nothing definite as to the etiology of this condition. Only in a few cases can we make out coarse anatomical

\* A current that begins weak, and is gradually made stronger and then weaker.—TRANS.]

disease of the nervous system or of the cervical vertebræ, rheumatic or other evil factors, reflex influences, etc. Although the spasms in the different muscular regions are often combined with one another, we can still distinguish the chief separate forms.

**SPASMS IN THE DISTRIBUTION OF THE ACCESSORY (CIRCUMFLEX) NERVE.**—In clonic spasm of the accessory there are paroxysmal twitchings of the head, which may attain great severity. Where there is a predominating unilateral spasm of the sterno-mastoid, the head is turned to the opposite side at every contraction of this muscle, and the chin is also somewhat raised. In unilateral spasm of the trapezius the head is drawn backward toward the affected side against the shoulder. In bilateral and combined spasm of these muscles we see severe shaking and nodding movements of the head—the so-called nodding spasms, "salaam convulsions"—which have been observed chiefly in children. They may also be excited in like manner by contractions of other muscles of the neck. In tonic spasm of

the accessory the head is constantly fixed in the abnormal position described above, and it can not be brought back passively to its normal position at all, or only incompletely. The oblique position of the head in unilateral tonic spasm of the sterno-mastoid is called spastic torticollis (*caput obstipum spasticum*), or rheumatic torticollis, if exposure to cold be regarded as the cause.

Tonic and clonic spasm of the splenius (Fig. 79) is also isolated, or combined with spasm of the accessory. In this the head is drawn backward and toward the affected side, and thus we can feel the muscular swelling protruding to the outside of the cervical portion of the trapezius.

Spasm of the obliquus capitis is probably the cause of the so-called rotatory tic, in which there are genuine spasmodic rotatory movements of the head. The recti capitis antici and postici are perhaps implicated in many cases of nodding spasm.

FIG. 79.—Spasm of the right splenius capitis.  
(FROM DUCHENNE.)

The prognosis of the forms of spasm described is usually doubtful. There are many mild "rheumatic" cases which recover in a short time, but, on the other hand, many of these forms of spasm develop into a chronic affection. In these cases any steady occupation, such as reading or writing, is rendered almost impossible by the constantly recurring spasmodic lateral and rotatory movements of the head. Any excitement, a feeling that he is noticed, etc., increase the patient's spasms, while they become milder when he is completely at ease. Many cases of combined tonic-clonic spasm of the muscles of the neck form a very severe affection, which may last for years or for life, which is extremely distressing and painful to the patient, and which may also reduce the strength and the nutrition to the utmost degree.

**Treatment.**—In some cases electricity has brought about recovery, or at least improvement. The method of treatment consists in the application of the anode to the affected nerves and muscles, or in the use of a swelling faradic current, or of the faradic brush to the skin over the affected muscles. Very often we have to change the method, and we must try to find out, by testing, the most efficient way

to employ electricity. Of other remedies, narcotics, such as subcutaneous injections of morphine, are indispensable in severe cases. We may also try bromide of potassium, antipyrine, valerianate of zinc, arsenic, and other nervines. In severe cases we resort to the use of the red-hot iron to the back of the neck. Other observers, and we ourselves, have seen good results from it, but of course benefit does not always follow. We may also advise nerve-stretching, but it is of doubtful advantage. Finally, it must be mentioned, that we may give great relief to many patients by suitably applied mechanical supports, the more so because in some cases the spasms occur only when the head is kept free, but if they lean their heads on anything, as in lying or sitting, the spasms cease at once.

#### 5. SPASMS IN THE MUSCLES OF THE SHOULDER AND ARM.

Clonic spasms in the upper extremity are probably usually of central origin. They are rarely isolated, as in the pectoralis major, but are more frequently combined with other forms of spasm and other nervous symptoms. They sometimes seem to be of reflex origin, as in the clonic spasms associated with brachial neuralgia, and also the spasms sometimes seen in amputation-stumps.

Isolated tonic spasms, in single muscles, or groups of muscles, in the upper extremity, have been repeatedly observed. Tonic spasm of the rhomboidei causes an oblique position of the scapula, so that its inner border runs obliquely upward and outward from below and inward. This makes it hard to raise the arm above the horizontal line, as in serratus paralysis, but the separation of the scapula from the chest-wall, which is so very characteristic of the latter, is wanting. Tonic spasm in the levator anguli scapulae is rare, except in connection with spasm of the rhomboidei or trapezius. In it the shoulder is raised and the head is bent a little to the affected side. Isolated tonic spasms in the pectoralis major, latissimus dorsi, deltoid, etc., are, on the whole, easy to recognize, but they are only of very rare occurrence. Tonic flexor spasms of the hand and fingers are more common. We have ourselves seen several such cases, which lasted for months. In one case the spasm could at once be relieved by placing the anode of a moderately strong galvanic current on the median nerve. In another case the flexor spasm of the fingers had followed a mild acute inflammation of the wrist-joint.

The special causes of all these spasms are still wholly unknown to us. Prognosis and treatment follow the same general rules which are given for other forms of spasm. Most is to be expected from electricity: the stable action of the anode, the faradic brush, or faradization of the antagonistic muscles.

#### 6. SPASMS IN THE MUSCLES OF THE LOWER EXTREMITY.

Clonic spasms in the muscles of the lower extremity are always, with rare exceptions, a symptom of spinal or cerebral disease. Of the tonic spasms the most frequent and the best known are the painful spasms in the calves, or cramps, which are apt to come on after great muscular exertion, mountain-climbing, or dancing. Many persons have an especially marked predisposition to such cramps, which readily come on, especially after making certain movements or holding the foot in a certain position. Similar painful cramps sometimes come in other muscles besides the calves, as in the abductor hallucis, etc. Other tonic spasms in the muscles of the lower extremity are rare, but individual cases of isolated tonic spasm in the abductors, in the ilio-psoas, in the muscles of the calves, etc., have been observed. More extensive tonic contractures of the muscles of the leg are not very rare in hysteria, especially in the hysteria of children.

**Saltatory Reflex Spasm.**—In this place we may mention a peculiar form of spasm, to which Bamberger has given the name of "saltatory reflex spasm."

This shows itself in the muscles of the lower extremities, never when the patient is quiet in bed, but only when he tries to stand or to walk. As soon as the soles of the feet touch the floor, such vigorous contractions are set up in the muscles of the legs as to force the patient to keep up a constant hopping, jumping, or tripping. The heels are also usually raised spasmodically, and in many cases the patient would certainly fall if he were not supported. In the pure forms of saltatory spasm, on physical examination we can usually make out nothing but an extraordinary increase of the reflexes, especially of the tendon reflexes, but in some cases there may also be other nervous symptoms. In general, it seems that saltatory reflex spasm is not to be regarded as a special disease, but as a peculiar symptom, which may arise in different neuroses in consequence of a very decided exaggeration of the reflexes. Many cases especially seem to us to be hysterical.

[Certain similar affections exist as endemic neuroses. In the "jumpers" of Maine the spasms may be produced by any excitement. In other forms the victims are compelled to imitate everything they see or hear. The curious affections observed in Siberia, Java, and elsewhere, known as *latah* or *emeryaki* (*myriachit*), are allied to this trouble. Alcoholism, cold, and privation seem to be important ætiological factors, and they probably have some relation to hysteria.—K.]

**Arthrogryposis.**—As an appendix we would here consider briefly a remarkable disease, the so-called *arthrogryposis*, which occurs chiefly in children in the first years of life, and consists of persistent tonic spasms and contractures of one or often of all four extremities. The disease usually develops quite acutely, and may run its course with fever and rather severe general symptoms. The legs are found either in a position of rigid extension, or they are drawn up spasmodically to the body, and can not be extended passively even with violence. The arms are flexed, and the hands and fingers are also fixed in some position of contracture. The milder cases may recover after a few weeks, but we have also seen two cases which ended fatally, in which the autopsy gave a perfectly negative result. The nature of this quite rare affection is still wholly unknown to us. In regard to treatment, prolonged warm baths are especially to be recommended.

**[Paramyoclonus multiplex.**—Under this term Friedreich has described a peculiar affection consisting of clonic bilateral spasms of several muscles of a physiological group. Hence the movements seem to have a purposive character. The spasms are rapidly repeated from fifty to one hundred and eighty times a minute, and occur in paroxysms. The muscles chiefly affected are those attached at one or both ends to the trunk. Fascicular tremors of the affected muscles are observed in the intervals. The reflexes are exaggerated, and the attacks may be brought on by irritation of the skin or tendons. The nature of the affection is unknown. The prognosis is favorable. The most effective treatment has been the application of strong galvanic currents to the spine and neck.

**Electrical Chorea.**—This term was first applied to an affection met with chiefly in northern Italy. It consists of sudden muscular contractions, resembling those caused by electrical stimulation. With these are associated progressive paralysis and muscular wasting. Many of the cases terminate fatally. Similar sudden contractions are seen in ordinary chorea, hysterical spasmodic conditions, etc., and hence the term has been frequently applied to these. Compare the chapter on hysteria.—K.]

The form of tonic spasm known as tetany will be described in a special chapter.

## 7. SPASMS IN THE RESPIRATORY MUSCLES.

Tonic spasm of the diaphragm has been seen in a few rare cases. The lower part of the thorax is much expanded, the epigastrium is protruded, and the respira-

tion, which shows intense dyspnoea, can be performed only by the upper part of the thorax. The depression and immobility of the diaphragm can be made out on percussion. Many patients have a severe pain in the region of the diaphragm. The condition is not without danger and demands instant interference: inhalations of chloroform, subcutaneous injections of morphine, a warm bath with a cool shower-bath after it, faradization of the skin in the region of the diaphragm, galvanization of the phrenics, etc.

*Clonic Spasm of the Diaphragm.—Singultus.*—The well-known "hiccup" or "sob," due to a sudden spasmodic contraction of the diaphragm, is in its mild forms a very frequent condition, which soon passes off; but it sometimes increases to a persistent, obstinate, and very troublesome affection, which may last for weeks or months. It sometimes comes on after mental excitement, and is a not very rare symptom of hysteria. Persistent hiccup may also be excited reflexly in affections of the stomach, intestines, peritoneum, etc. In some cases the hiccup depends upon a direct lesion of the phrenic nerve, as we have seen in one case of tubercular mediastino-pericarditis. We have also seen hiccup lasting for hours in cerebral apoplexy, and also in chronic myelitis extending to the cervical cord.

In the milder cases hiccup soon passes off without special treatment. Holding the breath, pressure on the closed glottis, blows on the back, etc., are procedures generally known by the laity, and often used to suppress hiccup. In more severe cases we must try narcotics, opium, cannabis indica, or inhalations of chloroform. The faradic brush to the region of the diaphragm, or the direct action of electricity on the phrenic nerve, is sometimes of advantage. In hysterical hiccup we may obtain very rapid results in this way, or sometimes by one of the different nervines, valerian, zinc, atropine, or Fowler's solution.

Complicated respiratory spasms, either in the form of spasmodically accelerated and forced breathing, or spasms combined with all sorts of other symptoms, with many gurgling noises, eructations, etc., are almost exclusively confined to hysteria. We have ourselves counted in one such case over two hundred respirations a minute! The best remedy against most of these forms of spasm, and one which often acts instantly, is a cool bath with energetic cold shower-baths. The yawning spasm (*chasmus, oscedo*), sneezing spasm (*sternutatio convulsiva, ptarmus*), laughing and weeping spasms, coughing spasm, etc., also belong to the respiratory spasms. We once saw a very remarkable example of the latter in a boy ten years old. A peculiar, reflex, hollow, barking cough came on, either spontaneously or on pinching any part of the skin. The affection lasted for some weeks, and then disappeared quite suddenly.

#### CHAPTER IV.

##### WRITER'S CRAMP AND ALLIED PROFESSIONAL NEUROSES.

WRITER'S cramp (*graphospasm, mogigraphia*) is the commonest form of a whole class of peculiar disturbances of motion, to which Benedikt gave the appropriate name of "professional neuroses of co-ordination." Their characteristic feature is that the disturbance in a certain group of muscles appears only when these muscles come into harmonious action, in quite a definite and usually a delicate and complicated occupation. Although the persons who suffer from writer's cramp can move and use the muscles of their right arm and hand for ordinary purposes in a perfectly normal manner, these same muscles at once

refuse their service when the patient begins to write. In this case the disturbance can not lie in the innervation of the individual muscles themselves, but it must be referred to the form of their associated action—that is, it must be a disturbance of co-ordination; but the details of this disturbance are still entirely unknown to us, nor do we know in what part of the nervous system we are to look for the seat of the disease. Over-exertion in writing plays the most important part as an ætiological factor. Writer's cramp is therefore seen chiefly, but of course not exclusively, in those persons whose occupation is connected with continuous writing, especially in secretaries, merchants, bureau officials, etc. A general nervous predisposition seems also to increase the tendency to writer's cramp. Attention has also been called to the fact that bad pens, such as hard steel pens, bad methods of holding the pen in writing, etc., may favor the development of writer's cramp.

**Symptoms.**—The essential symptom of writer's cramp is the appearance of certain disturbances at every attempt to write, which render writing very difficult or entirely impossible. The affection usually begins gradually, but increases quite rapidly. For the precise characterization of the disturbance Benedikt has distinguished three forms of writer's cramp, but they run into one another in various ways. The spastic form is the most frequent. The patient scarcely begins to write when contractions or tonic spasms come on in the different fingers, so that the pen can no longer be held firmly, or it makes abnormal irregular movements, or it is firmly pressed into the paper, etc. We very often see a tonic spasm of the pronators of the forearm set in on each attempt to write. Writing is wholly impossible, or it is done only with the greatest exertion, and the characters are also utterly distorted, unequal, and mingled with false strokes and blots. In the paralytic form\* the disturbance in writing is chiefly a rapidly arising tired feeling, like paralysis, in the right arm, which is often associated with painful sensations. Finally, in the tremulous form of writer's cramp there is such a marked tremor in the right hand at every attempt to write that the letters are completely illegible. We have seen several such cases in children, which we have regarded as distinctly hysterical.

As has already been said, motility in every other respect is perfectly normal, but sometimes analogous symptoms also appear in the same patient in many other fine employments, such as sewing, piano-playing, etc. The sensibility is usually perfectly normal, except for the muscular pains already mentioned, and a frequent feeling of numbness in the forearm and fingers. A few painful pressure-points have sometimes been found on the cervical and dorsal vertebræ. We should also examine the peripheral nerves, since painful thickenings are sometimes to be detected in them, which possibly stand in a causal relation to the disease. If we are dealing with people who are generally neurotic, they often complain at the same time of headaches, mental uneasiness, and general weakness.

The diagnosis of writer's cramp is almost always easy. We must guard against confusing it with other nervous diseases, such as chorea, paralysis agitans, multiple sclerosis, beginning muscular atrophy, or agraphia, which, of course, under some circumstances may lead to disturbances in writing.

The prognosis is always to be given with reserve. Complete recoveries without doubt do occur, but many cases are extremely obstinate and others are incurable. Relapses are also very common even after improvement has set in. Many patients are obliged to choose another calling in consequence of their trouble.

The treatment begins first with the command to give up writing entirely for several weeks or months. If this command can be obeyed, the mere rest may be

---

\* It is particularly illogical to class this disturbance with writer's cramp, since we can not speak of the "paralytic" form of a "cramp."

of service in mild incipient cases. Certain contrivances for writing, which the patient can best test himself, are often of advantage, such as sticking the pen-holder through a cork, using a large pen-holder, a change in the way of holding the pen and in the position of the arm, etc. Nussbaum has lately invented a kind of bracelet to which the pen-holder is fastened, and which is held firmly by the outspread fingers. Learning to write with the left hand, which is often tried by patients, usually leads to no good result, since the cramp very soon appears in the left hand also with remarkable rapidity.

Of the special methods of treating writer's cramp the application of galvanism deserves the first mention. Avoiding all strong currents and variations of the current, we apply the stable anode to the brachial plexus, and also to the different nerves (especially if they be sensitive to pressure) and the affected muscles, for five or ten minutes. The cathode is placed in the vicinity of the cervical vertebrae. If painful points are found, they receive special treatment. We may also use galvanism, as an experiment, through the head. Of late, massage and methodical gymnastics have shown still more favorable results than electrical treatment, but the use of them demands special technical skill, and therefore they have so far obtained excellent results chiefly in the hands of certain specialists. We can very rarely promise success from internal remedies such as subcutaneous injections of strychnine, atropine, etc., but those methods of treatment often act favorably which aid the general strength of the nervous system, such as cold-water cures, sea-bathing, and residence at a mountain resort.

As an appendix we will mention here some other professional neuroses that are occasionally seen. They are the piano-player's cramp, which is seen especially in young conservatory pupils, violin- and cello-player's cramp, telegrapher's cramp, tailor's cramp, milker's cramp, the peculiar disturbances of innervation in the hands which often occur in cigar-rollers, etc. In the lower extremities there seems to be an analogous affection in ballet-dancers, and also in sewing-machine girls, turners, etc. We have seen a professional cramp in the tongue in a clarinet-player. The special points in the symptomatology and treatment of all these forms of cramp are in large part analogous to the conditions described in writer's cramp. In piano-players the neurosis appears chiefly in the paretic form—mild fatigue—and is usually associated with quite severe pains, that come on during playing, in certain parts of the arm. In regard to treatment, the best results are obtained by energetic massage. Finally, it may here be noted that in certain laborious occupations that are persistently practiced, a severe group of nervous symptoms may also arise. For example, B. Hirt has lately described an affection which occurs in sewing-machine girls, and is characterized by disturbances of sensibility, pain, paræsthesia, and in some cases anæsthesia, ataxia, absence of the tendon reflexes, and swaying with the eyes shut. The disease thus recalls very closely the picture of locomotor ataxia, but it is curable with proper treatment. Therefore Hirt suspected an affection of the peripheral nerves. Like symptoms are also seen in other classes of laborers, as in farm-hands after laborious toil in the fields.

## CHAPTER V.

### SIMPLE AND MULTIPLE DEGENERATIVE NEURITIS.

**Ætiology and Pathology.**—We term those changes in the nerves acute neuritis (inflammation of the nerves) where their vessels become very hyperæmic, and where the transudation of fluid and cellular elements takes place from the walls

of the vessels into the surrounding tissue. The inflamed nerve is therefore swollen and thickened, its color is manifestly reddened from the marked vascular hyperæmia, and we can often recognize with the naked eye a few or many small hæmorrhages. Microscopic examination shows an abundant infiltration of round cells into the nerve sheaths and the interstitial tissue, and these may be so numerous that the inflammation in some cases may be recognized, even on macroscopic examination, as a purulent neuritis. The nerve-fibers themselves sometimes show no visible changes, but in more severe neuritis we usually find an evident disintegration of the medullary sheaths and the axis-cylinders, and finally a complete destruction of the nerve-fibers. The "fatty granular cells" which are seen in these cases are probably white blood-corpuscles (perhaps, also, endothelial cells?), which have taken up the fat from the disintegrated medullary substance. The destruction of the nerve-fibers, "parenchymatous inflammation," is partly a mechanical result of their compression by the surrounding exudation, but very largely probably the result of the direct injury which the nerve-fibers undergo from the causes that provoke the inflammation.

In its further course the neuritis advances to the stage of the new formation of connective tissue and the regenerative processes. The nerve appears firmer and denser than normal; a large amount of interstitial connective tissue is formed between the single nerve-fibers that are still preserved, which, if produced in excess, like a sort of callus formation, may lead to quite considerable partial thickenings of the nerve, the so-called *neuritis nodosa*. The capacity for regeneration of the peripheral nerves is relatively very considerable, so that in moderate and even in severe degrees of neuritis we may have a complete *restitutio ad integrum*. There may be a partial regeneration of the nerve-fibers even in the worst cases. Chronic neuritis either proceeds from acute neuritis, or it develops *de novo* in an insidious fashion. In the latter case the first acute stage of hyperæmia and cellular infiltration is entirely absent, and the destruction of the nerve-fibers and the new growth of connective tissue proceed in a chronic manner from the beginning. In such cases the interstitial inflammatory changes in the connective tissues and the vessels are often so subordinate to the degenerative processes in the nerve-fibers themselves that we have almost a genuine parenchymatous degeneration. Such conditions, perhaps, can not be properly termed "neuritis" at all, but rather "primary chronic degenerative atrophy of the nerves." They arise especially as a result of certain infectious and toxic influences (*vide infra*), which have a directly deleterious action upon the nerve-fibers. They often appear in many nerves at the same time, and consist of a slowly progressive disintegration of the medullary sheath, and later of the axis-cylinders also. It is possible that these last-named changes begin in the terminal branches of the peripheral nerves, and gradually advance from them toward the centers, but this has not yet been certainly confirmed; at any rate, the affection often remains confined to the peripheral nerves. The anterior spinal roots and the cord itself in such cases are found perfectly intact, or altered only in a subordinate way. [According to recent observations distinct changes may be found in the cord, chiefly in the white substance, especially in the more chronic forms of neuritis, and the forms of toxic origin.—K.]

In inquiring into the causes of neuritis we encounter first the same injurious influences which play the chief part in the inflammations of other organs. We very often speak of a traumatic neuritis, which is supposed to mean a neuritis produced by various mechanical injuries of the nerve. As far as this implies open wounds—like stabs, cuts, gun-shot wounds, etc.—that involve the nerve, the development of a genuine traumatic neuritis can not be doubted; but in such cases we not only have to do with mechanical lesions, but with an accidental complica-

tion of the wound, with the entrance of organized agents of inflammation through the wound into the nerves. Only in this case can there be an inflammation (ascending neuritis, *neuritis migrans*) advancing continuously or by leaps in the nerve-trunk from the point of lesion in the nerve, whereas, if the wound remains aseptic, as the experiments of Rosenbach and Kast have shown, such a propagation of the inflammation above the point of lesion never occurs. In the subcutaneous injuries of the nerve-trunk from a blow, from pressure, from dislocations of the bones, etc., we are, of course, not justified in speaking of a traumatic neuritis; but in such cases we have a purely mechanical destruction of the nervous elements, which is followed by the regular processes of secondary degeneration (*vide supra*), increase of connective tissue, and final restoration.

Another cause for the origin of a genuine neuritis lies in the extension of an inflammation from the neighboring organs to the nerves. In inflammations of the bones, as in caries of the bones of the skull and of the vertebrae, of the joints and of the different internal organs, the inflammatory process may directly involve a nerve-trunk by contiguity. In this way, perhaps, are developed the atrophy and paralysis of the neighboring muscles which are often seen after affections of the joints. Leyden has also tried to explain a number of the so-called "reflex paralyzes"—that is, paralyzes which sometimes develop as a result of inflammatory affections of certain internal organs, especially the intestines and the urinary and sexual organs—by a neuritis arising from the organ originally affected, and even extending to the spinal cord.

Primary neuritis, however, is of special interest. This may either be caused by some evident agency, or it may develop, apparently spontaneously, without any cause as far as known. We have already learned to recognize one group of these primary neuritides in the preceding chapters: those which, in all probability, underlie most of the "rheumatic" paralyzes on the one hand, and certain forms of neuralgia, such as sciatica, intercostal neuralgia with zoster, etc., on the other. As we have said, little that is definite is known as to the precise cause of these neuritides. Some of them seem to arise from external agencies, such as exposure to cold; others, perhaps, from infectious influences. Certain toxic paralyzes belong to a second group of primary neuritides, among them, for instance, the lead and arsenic paralyzes already described, and the disease of the nerves produced by chronic alcoholism, which will be more fully described below. Finally, the so-called multiple neuritis forms the third recognized group, a special form of disease in which several nerves are usually affected at the same time or soon after one another. As will be stated in the description of the course of the disease, we probably have in these cases a definite form of infectious disease, which is localized exclusively, or at least mainly, in the peripheral nerves. In the acute cases the anatomical changes in the nerves seem to be really of an inflammatory nature, but in the chronic cases a simple degenerative atrophy of the nerves underlies the morbid symptoms. The aetiological position of these chronic cases of multiple neuritis, however, is, in our opinion, to be judged with caution, since at least a part of the cases so far published are certainly to be classed with alcoholic neuritis (*vide infra*).

#### Clinical History of the Different Forms of Neuritis.

1. SECONDARY NEURITIS.—The chief symptom of secondary neuritis, following wounds, inflammations of neighboring organs, etc., is pain, which comes on with great intensity, not only in the region of distribution of the affected nerve, but also along the whole trunk of the nerve. In these cases there is also a marked

sensitiveness of the nerve to pressure. In many cases we can succeed in feeling the thickened nerve plainly through the skin.

Besides these direct symptoms, the inflammation soon renders the necessary results of disturbed nervous conduction apparent. There is a dullness of sensibility in the distribution of the affected nerve, at first in the form of a subjective feeling of numbness, but later as a manifest objective anaesthesia, which, however, rarely reaches a very high degree. The motor symptoms at first show themselves as motor weakness, which in severe cases becomes a pronounced paralysis. It goes without saying (see page 538) that the paralysis, in all severe cases, is followed by a degenerative atrophy of the paralyzed muscles, and the appearance of electrical reaction of degeneration. In the skin, trophic and vaso-motor disturbances have been repeatedly observed, especially slight oedema of the subcutaneous cellular tissue, eruptions of herpes, etc.

The course of simple secondary neuritis may vary. Its onset is usually quite acute, or more rarely it begins gradually. Many cases seem to recover before the severer consequences are reached, while others take a chronic, tedious course, and lead to permanent disturbances of function.

2. PRIMARY SIMPLE NEURITIS.—We must seek for the cause of many primary paralyses (that is, paralyses coming on without special cause or after cold, etc.) in the distribution of individual peripheral nerves in a pure neuritis. For example, "rheumatic" facial paralysis is certainly due to a mild or a severe neuritis of the facial nerve. Precisely similar primary neuritic paralyses occur, although more rarely, in the distribution of other nerves, especially in the upper and more rarely in the lower extremities; thus we see neuritic axillary or deltoid paralysis, ulnar paralysis, peroneal paralysis, etc. All these cases are characterized by the fact that they begin with more or less severe pain or paresthesia in the territory of the affected nerve. Motor paralysis sooner or later develops, which in the severer cases leads to degenerative atrophy of the affected muscles with reaction of degeneration. Sensory disturbances in the skin can usually be plainly detected, at least to a slight degree, on careful examination. The prognosis of these paralyses is, as a rule, favorable; but sometimes permanent disturbances of function remain, and they may also recur.

3. PRIMARY MULTIPLE DEGENERATIVE NEURITIS.—Primary multiple neuritis is probably not a very rare disease, but yet it has been carefully investigated only in the last few years. The first definite observations upon it were made in the years 1864 and 1866 in France by Duménil. Since then a whole series of well-established cases have been published by Eichhorst, Eisenlohr, Joffroy, Leyden, Vierordt, the writer, and others, so that the type of the disease is at present quite accurately known. Probably in former days multiple neuritis was often confused with poliomyelitis and certain cases of "acute ascending paralysis" (*vide infra*). An interesting discovery was first made by Scheube, that the peculiar disease, of endemic occurrence, long known in Japan and the East Indies as "*kak-ke*" or "*beri-beri*," is in its clinical and anatomical relations a well-characterized multiple peripheral neuritis. With us, also, multiple neuritis occasionally shows an epidemic increase in frequency (Eisenlohr). [Cases have been observed among sailors, fishermen, etc., in the seaport towns of New England, where the symptoms resembled those of neuritis and were akin to *beri-beri*. J. J. Putnam thinks that in 1881 and 1889 there were epidemics of this disease in the fishing towns of Massachusetts, characterized by pain, loss of power, numbness, and oedema, the trouble being chiefly in the legs.—K.]

Multiple neuritis usually begins acutely, sometimes almost in an apoplectic form manner, and without any definite occasion, precisely like an acute infectious disease. Febrile symptoms, with temperatures from 102° to 104° (39°–40° C.), come

on in persons previously in good health, usually in adults in youth or middle life, with severe general disturbance, loss of appetite, dullness, headache, and sometimes even mild delirium. In these acute cases albuminuria and a slight enlargement of the spleen have sometimes been observed, which symptoms also point toward the infectious nature of the disease. In other cases the initial symptoms are less severe, but they are almost never entirely absent. The pains, which are hardly ever absent, are very characteristic. They are described as pulling and tearing, are felt chiefly in the loins and the extremities, and sometimes follow approximately the course of the large nerve-trunks. Since in some cases a number of the joints are swollen, the disease at first may be mistaken for acute articular rheumatism. The first symptoms of paralysis, usually in the lower extremities, appear very soon after these initial symptoms, or at the same time with them. The patient notices that he can not readily move one leg, and soon after he notices the same of the other. The paralysis often extends rapidly to one or both arms. If we examine the paralyzed parts more carefully we find a perfectly atonic and more or less extensive paralysis. The legs are often not paralyzed, but distinctly ataxic, a condition which is often seen in alcoholic neuritis (*vide infra*). The reflexes are almost always diminished, the tendon reflexes are usually entirely absent, and the cutaneous reflexes are weak, or they also have almost wholly disappeared. In only a few cases are the reflexes increased—a symptom which is to be regarded as analogous to cutaneous hyperæsthesia. We can usually make out, after a few days, a decided diminution of electrical excitability in the affected nerves and muscles, which finally becomes a pronounced reaction of degeneration. If the paralysis is of longer duration, there is a decided atrophy of the muscles. In these cases the severe initial symptoms of sensory irritation, as a rule, rapidly disappear, although slight pains, paresthesia, and especially a considerable sensitiveness of the paralyzed parts to pressure and to passive motion, often last for a long time. In many acute cases the hyperæsthesia of the skin and of the deeper parts reaches a very high degree, but it is remarkable that the objective disturbances of sensibility are very slight in the great majority of cases. Marked anaesthesia is a rare exception, so that we may rightly suppose that primary multiple neuritis affects chiefly the motor nerve-fibers. We usually find no disturbances in the distribution of the cerebral and bulbar nerves. An affection of the optic nerve has been mentioned in only a few cases. The marked increase in the frequency of the pulse, which is usually present, is important, and probably depends upon a disturbance of the vagus. Trophic disturbances in the skin, hair, and nails are not very rare. Edematous swelling of the affected extremities has also been repeatedly observed. The functions of the bladder and rectum, however, almost always remain undisturbed.

In regard to the course of the disease, in the severest cases it may soon terminate fatally, almost always because the paralysis extends to the muscles of respiration. The inspirations are labored, and are performed with the upper part of the thorax only, while the epigastrium is motionless, or sinks in on inspiration from the paralysis of the diaphragm. There is also paralysis of the other muscles of respiration, the abdominal muscles, etc., so that, after the disease has lasted a week or ten days, death ensues with all the signs of respiratory insufficiency. A second class of cases also begins quite acutely, but then takes a chronic course. The initial acute febrile symptoms cease after a few days, and the paralysis develops to some extent. Then the affection seems to come to a stand-still, and the first signs of improvement gradually begin to appear. Since there is a more or less pronounced atrophy of the muscles in these cases, it always takes quite a long time—usually several months—for recovery. A third class of cases follow a chronic course from the outset, although even in these cases there may be more acute exacerbations of the disease. In these cases quite extensive atrophic paraly-

sis gradually develops in the lower extremities, and usually in the upper extremities also. The reflexes disappear; the sensibility is as a rule somewhat, but very rarely much diminished. Pains are always present at first, but later on in the disease they often become subordinate. The bladder and rectum usually remain intact in their functions. If the disease advance gradually it may terminate fatally even at a late period, after a course of months, usually from a final paralysis of respiration; but, on the other hand, even after a protracted course, the disease may come to a stand-still, and even to a complete or at least to a partial recovery. It is worthy of note that a combination of multiple neuritis and pulmonary tuberculosis has quite frequently been observed; but nothing definite is yet known as to the form of connection between the two diseases.

The diagnosis of multiple neuritis is, as a rule, easy, for one who is acquainted with the disease and notes the different symptoms carefully. In regard to diagnosis, the chief importance should be placed on the generally acute beginning, with pronounced symptoms of sensory irritation, with frequently a very considerable sensitiveness of the nerves to pressure and general cutaneous hyperesthesia; and also on the appearance of a rapidly extending paralysis, whose peripheral nature may be attested by the presence of reaction of degeneration, muscular atrophy, and the absence of the cutaneous and tendon reflexes. Such a paralysis can be produced by nothing but an affection of the peripheral nerves or poliomyelitis (*vide infra*). As we have shown above, this latter disease may, in fact, often be confused with multiple neuritis, but a careful attention to the initial symptoms, especially to the disturbances of sensation, will usually make the differential diagnosis possible.

The prognosis of multiple neuritis is doubtful, as is shown by the description of the course of the disease, but it is by no means very unfavorable. If the first acute stage of the disease has been gone through with without accident, we may hope for recovery, or at least actual improvement, even with extensive paralysis. Such striking results in the way of recovery, after paralysis that has lasted for months, are also important in regard to diagnosis, since such extensive processes of regeneration are possible in affections of the peripheral nerves, but scarcely in spinal diseases; and hence they are sometimes an additional confirmation of the diagnosis of a neuritis.

*Treatment.*—In the first stage of the disease, especially if severe pains, swelling of the joints, or high fever be present, it is advisable to try the exhibition of salicylic acid, from which several observers have seen a favorable effect. We give ten grains (grm. 0.5) of the acid every hour, or a few larger doses, a drachm to a drachm and a half (grm. 4-6) of salicylate of sodium. Instead of salicylic acid we have lately used antipyrine and phenacetine with good results. When the pain is very severe we must use narcotics, such as injections of morphine. Embrocations of chloroform, and sometimes protracted warm baths, have also a palliative effect. In the further course of the disease proper care, a suitable position for the limbs, and diet—nourishing food—are the main things for the patient. The regenerative processes of recovery begin spontaneously, if at all, but we may hasten recovery and make it complete by a subsequent electrical treatment, especially galvanism. For the completion of the recovery, bathing (simple warm baths, salt baths, etc.) is serviceable, and also the baths at Teplitz, Wiesbaden, and Rehme.

#### 4. THE CHRONIC NEURITIS OF ALCOHOLIC SUBJECTS.

(*Pseudotabes of Alcoholic Subjects, Ataxia of Drinkers.*)

It has long been known that peculiar nervous affections often occur in alcoholic subjects (M. Huss, Lendet, and others); but up to the present time a disease

of the spinal cord has been assumed to be the cause of the symptoms, and only of late have we obtained the knowledge that at least a great part of the cases of this class are to be regarded as a special form of chronic multiple neuritis (Lancereaux, Moeli, and others). The practical importance of this alcoholic neuritis is not slight; first, because it may easily be confused with other nervous diseases, especially with *tabes dorsalis*, and, second, because its proper and timely diagnosis is of great significance in regard to treatment.

Alcoholic neuritis occurs chiefly in two forms: in one form actual atrophic paralysis develops chiefly in the lower extremities, but in the other form the paresis is subordinate to the other disturbances of innervation. The first symptom of the disease is usually tearing and drawing pains in different parts of the lower, or, more rarely, of the upper, extremities. The pains are usually quite severe, but sometimes only of moderate strength. Sooner or later, but sometimes not for years, a pronounced disturbance of the gait is added to the pains. More careful examination shows that in such cases there is partly an actual paresis of the muscles of the legs, and partly a form of ataxia—a defective innervation which is manifest by an uncertainty, a staggering and reeling in the gait. If there be marked paresis, the affected muscles are quite atrophic, and electrical examination usually gives a decided diminution of excitability, or even pronounced reaction of degeneration. The patellar reflex is usually lost quite early. The sensibility, too, is very rarely perfectly normal; we find sometimes quite marked anaesthesia, especially in the lower legs, and also in other parts of the skin. The cutaneous reflexes are also often feeble and slow. There is sometimes considerable tenderness on pressure on the deeper parts and over the nerves. The course of the disease is usually chronic. If the cause of the evil—the abuse of alcohol—be removed in time, perfect recovery is possible; but in far-advanced cases the disease may go on to complete paralysis even of the upper extremities, and to a fatal termination. [In women, especially, mental symptoms are often pronounced. It is a characteristic feature of the delusions of alcoholic neuritis, that the patient will tell of walks taken, and of people seen, although at the time he is helpless in bed.—K.]

As may be seen, the disease is decidedly like *tabes dorsalis*, and in the early stages, with pain, ataxia, and absence of patellar reflex, the differential diagnosis has no slight difficulty. In regard to this it must be borne in mind that the reflex immobility of the pupils, the girdle sensation and disturbances of the bladder, seem to be absent in alcoholic neuritis, at least as a rule, while, on the other hand, the development of atrophic paralyses may almost certainly exclude *tabes*.

The treatment demands, in the first place, the entire abandonment of the further use of alcohol, if possible. In mild cases we can obtain a decided improvement by this alone. In more advanced cases electrical treatment and tepid baths do the best service. We would also recommend the internal or subcutaneous use of preparations of strychnine.

## CHAPTER VI.

### NEW GROWTHS IN THE PERIPHERAL NERVES.

THE new growths in the peripheral nerves are usually divided into false and true neuromata. The former are not newly formed nervous tissue proper, but are fibromata, myxomata, sarcomata, etc., which develop on the nerves. Infectious tumors, also, especially syphilitic gummata, and still more frequently the new growths arising in leprosy, may have their seat on the peripheral nerves. The

true neuromata consist of newly formed, usually medullated, nerve-fibers (*neuroma myelinicum* of Virchow), which are imbedded in a frequently very abundant connective-tissue stroma. These neuromata develop most frequently in the cut ends of nerves in amputation-stumps (amputation neuromata), but they may form after other injuries of the nerves, and probably many neuralgias and persistent pains after injuries are due to the formation of such little neuromata. The multiple occurrence of neuromata, which has also been repeatedly observed, is very remarkable. These develop by hundreds in the same individual, chiefly on the spinal nerves, only occasionally and exceptionally on the sympathetic or cranial nerves. In such cases the different tumors are by no means metastases from one original tumor, but are the expression of a general and often hereditary predisposition of the peripheral nervous system to the formation of tumors. Sometimes multiple neuromata are combined with other anomalies of the nervous system, such as cretinism. Besides the medullated neuromata, there are also new growths of non-medullated nerve-fibers (*neuroma amyelinicum*), but their histological diagnosis is always very difficult.

The symptoms of neuromata vary very much in different cases. Many of them cause no symptoms at all, but in other cases they are the cause of extremely severe and persistent neuralgias and neuralgiform pains, which come on with varying intensity, are usually remittent or intermittent, and are often increased by external causes, the influence of the weather, etc. Marked symptoms of pressure, especially anaesthesia and motor paralysis, are only exceptionally developed, but they sometimes do occur, especially in neuromata of the cauda equina. Direct or reflex symptoms of motor irritation, such as tremor or tonic spasms, are somewhat more frequent.

The so-called *tubercula dolorosa* deserve special mention. By this term we mean little nodules which may be felt beneath the skin, and are usually readily movable and very sensitive to pressure. They are not very rare, and are usually associated with drawing pains, which are rarely decidedly neuralgic and are not very strictly localized. They are situated in the extremities, especially in the arms, and in the back, the neck, etc. It is worthy of note that the symptoms are only at times very prominent, and then they disappear again, and that with this disappearance is certainly sometimes associated a spontaneous disappearance of the nodule. The anatomical nature of the *tubercula dolorosa* is not always to be established with certainty. Many of them are true neuromata, but others belong to other kinds of new growths.

The course of neuromata is of course very chronic. In some cases the persistent severe pain may give rise to considerable general disturbance, but a final spontaneous cessation of the symptoms, and even a disappearance of the new growths, have also been observed.

The diagnosis of neuromata is possible only when the tumors can be felt through the skin, and when their seat, as well as their clinical symptoms, correspond to the course and distribution of a nerve. In multiple neuromata the diagnosis has been repeatedly confirmed by the excision and examination of one of the tumors.

The only successful treatment of neuromata is extirpation, which is to be undertaken only when the symptoms are very severe. If extirpation be not practicable, or if we have to do with multiple neuromata, the patient's trouble can be alleviated only by symptomatic means, narcotics, and electricity. If we can compress the nerve above the neuroma, we can often cause by this means a temporary cessation of the pain.

## II.—Vaso-motor and Trophic Neuroses.

### CHAPTER I.

#### PRELIMINARY REMARKS UPON VASO-MOTOR, TROPHIC, AND SECRETORY DISTURBANCES.

BESIDES the disturbances of sensibility and motility described in the preceding sections, we also see in nervous patients frequent anomalies of the vaso-motor and trophic functions, but up to the present time we know comparatively little that is certain as to the precise nature of their occurrence.

Physiology, as is well known, distinguishes two varieties of vaso-motor nerves—the vaso-constrictors and the vaso-dilators; but since experiments have detected the latter variety in only a few places—for example, in the chorda tympani, the nervi erigentes, and the sciatic—they have not acquired a very great significance in human pathology. We are at present much more disposed to refer every abnormal constriction of the vessels to an irritation, and every abnormal dilatation of the vessels to a paralysis of the vaso-constrictor nerves, although perhaps pathological conditions of irritation of the vaso-dilators may not be at all rare. In regard to the precise anatomical course of the vaso-motor nerves, we must first state that vaso-motor irritations may certainly proceed from the cerebrum, as is shown by the well-known symptoms of blushing and pallor from mental emotions. In experiments on dogs, Eulenburg and Landois have succeeded in producing a fall of temperature on the opposite side by irritating certain portions of the cortex in the immediate vicinity of the motor centers, and by extirpation of the same parts they have produced a rise in temperature. Furthermore, we know with certainty that there is an important vaso-motor center in the medulla oblongata (in the region of the upper olivary body in rabbits), the irritation of which, directly or reflexly, is followed by an almost universal vascular constriction, and its destruction by an almost universal vascular dilatation. We must probably seek the further course of the vaso-motor nerves very largely (or exclusively?) in the lateral columns, from which they pass out chiefly by the anterior roots; but there are also experimental data (Stricker) suggesting the presence of vaso-motor nerves in the posterior roots. It is not known with certainty whether there is any decussation of the vaso-motor fibers, or, if there is, where it occurs. The larger part of the vaso-motor nerves collect, at any rate, in the principal trunks of the sympathetic, from which, as is well known, the separate plexuses that surround the vessels arise. It is not improbable, however, that there is also in part a direct passage of vaso-motor fibers from the cord into the peripheral nerves. In conclusion, we must mention that, according to Goltz's experiments, there are reflex vaso-motor centers in the cord for the different parts of the body.

The clinical vaso-motor symptoms are chiefly to be observed in the external skin. We distinguish them as follows:

1. *Symptoms of Vaso-motor Paralysis.*—We conclude that there is a paralysis of the vaso-motors if there is an abnormal redness of the skin. Such a redness is almost always associated with an objective and often a subjective feeling of an increase of temperature. Such conditions are observed either in connection with other nervous symptoms—as in fresh spinal or cerebral paralyses, and also

very often in certain functional neuroses, such as hysteria and neurasthenia—or in the form of independent affections—the pure vaso-motor neuroses, injuries of the cervical sympathetic, etc. There are cases in which the only symptoms are a persistent or paroxysmal redness of the skin, especially of the head, associated with a great feeling of heat, with palpitation of the heart, strong pulsation of the arteries, anxiety, ringing in the ears, and sweating. If the affection be confined to a single extremity, in which there are paroxysmal redness, diffuse swelling, and pain, we have the condition described by Weir Mitchell as *erythromelalgia*. As was stated above, it is at present impossible to decide whether many of the symptoms just mentioned do not perhaps depend upon an irritation of the vaso-dilator nerves.

2. *Symptoms of Vaso-motor Spasm.*—Spasm of the small vessels becomes apparent by a striking pallor and coolness of the skin. There is often, with this, a decided feeling of formication and stiffness in the affected parts, which may even increase to an actual feeling of pain. Such vaso-motor spasms affect the hands especially, and form a chronic trouble that is not very rare. They are usually seen in people who are generally nervous and irritable, and sometimes also in washerwomen. A vascular spasm is sometimes seen in the extremities as one symptom of complicated paroxysms, such as nervous angina pectoris (*q. v.*), especially at the beginning of the paroxysm. A persistent spasm of the small arteries may give rise to considerable subsequent trophic disturbance. At least, the rare cases of so-called "spontaneous symmetrical gangrene" (Raynaud's disease of the extremities), and also certain forms of scleroderma and some similar affections, are referred by many observers to a primary spasm of the vessels. [Other observers are disposed to attribute many if not all the cases of symmetrical gangrene to arterio-sclerosis or syphilitic endarteritis affecting the smaller vessels.—K.] There is a condition, seen especially in the hands, in which, without known cause, the skin becomes dark blue and icy cold, and the epidermis is raised in different parts into bullæ. This condition may even attain to a circumscribed gangrene—spastic gangrene.

We have much less information concerning the trophic nerves than we have concerning the vaso-motor. As is well known, the controversy is still going on as to whether we have any right to assume the existence of special trophic nerves. Clinical facts speak decidedly in favor of this assumption, although we have already stated that many trophic disturbances are probably due to vaso-motor changes, and also that the anaesthesia of many parts is a very favorable circumstance for the occurrence of disturbances of nutrition (compare what was said in regard to anaesthesia of the trigeminus on page 514).

Those changes in the skin which depend essentially upon an abnormally great exudation from the vessels form a transition between vaso-motor and trophic disturbances. Among them are, first, peculiar cases of disease which have been termed "**acute angioneurotic oedema**" (Quinke, Strübing, and others). In these cases oedematous swellings appear suddenly in various parts of the body, and sometimes disappear after a few hours, but they may be very often repeated. Dangerous symptoms may arise if the oedema affect the pharynx or the entrance to the larynx. The patient's health otherwise is sometimes perfectly good, but in other cases it is more or less affected. Gastric disturbances especially (attacks of vomiting and gastralgia) have been observed at the same time in such patients. Acute angioneurotic oedema is manifestly closely allied to urticaria and erythema exudativum. In regard to the occurrence of herpes zoster in nervous diseases, compare what was said on page 525. Vesicle formations analogous to herpes zoster intercostalis may also occur along the track of other nerve-trunks in peripheral, or even in purely spinal (?) nervous affections.

Among those symptoms which chiefly support the theory of the existence of specific trophic nervous influences, we have already learned to recognize the degenerative atrophy of the muscles and nerves (see page 538). Various other sorts of trophic disturbances in the skin and the deeper parts are seen in nervous diseases. Especially after wounds of the peripheral nerves we often notice a peculiar shining, smooth, atrophic condition of the skin—the “glossy skin” or “glossy fingers” of the English authors. In other cases anomalies in the pigmentation of the skin seem to be connected with the nervous disturbances; thus spots deprived of pigment (*vitiligo*) often develop as a result of severe neuralgias. We must also bring to mind here the appearance of changes in pigmentation from nervous causes, especially the ætiology of Addison's disease (*vide infra*) and the occurrence of the so-called nervous nævi. Among the severe neurotrophic disturbances of the skin many observers, especially Charcot, class the appearance of acute bedsores in many spinal and cerebral paralyses, but we have never been able to convince ourselves of the occurrence of a “neurotrophic decubitus,” and we believe that every bedsore is due in the first instance to external influences, uncleanliness, and pressure on the skin.

We may here mention **myxœdema** (*cachexie pachydermique* of Charcot), which was first described in England by William Gull and Ord. The disease has taken its name from a peculiar thickening and swelling of the skin, which is most marked in the face, but which is sometimes seen in the extremities, the trunk, the tongue, and even in the internal organs. This swelling is not cedema, but it is due to the development of a sort of myxomatous new growth, rich in mucine, in the connective tissue. Other trophic disturbances usually co-exist: atrophy of the teeth and nails [spade-like hands, coarseness and] loss of hair, failure in the sweat secretion and consequent dryness of the skin, etc. Besides these there gradually develops a general physical and mental weakness, which may increase to great hebetude or even to complete dementia. Disturbances of the sensory functions may also occur. It is a fact of especial interest that we find quite commonly a diminution and even a complete atrophy of the thyroid gland. It is not improbable that all the symptoms of the disease may arise from the failure of function of the thyroid gland. This hypothesis is confirmed by the repeated experiments of Kocher and others, that after complete extirpation of the thyroid in man almost the same symptoms ensue as in myxœdema (*cachexia strumipriva*). From this we must suppose that certain injurious substances accumulate in the body which can no longer be made innocuous by the thyroid gland.

Besides the trophic disturbances in the skin, we often see analogous changes in the nails and hair in nervous patients. The nails become brittle and cracked, assume a darker color, and often show a considerable thickening (*onychogryphosis*). We also see at times a loss of the nails. A loss of hair is seen in frontal neuralgia, in certain forms of headache, and not infrequently as an apparently independent nervous disease (*alopecia*). A very rapid whitening of the hair after mental excitement is well known to have occurred in some cases.

Among the trophic disturbances of the deeper parts the symptoms sometimes seen in the bones and joints deserve a brief mention. The implication of the bones in atrophic processes is seen chiefly in progressive unilateral facial atrophy (*vide infra*). A retarded growth of bone in the affected extremities is also a symptom frequently seen in the spinal and even in the cerebral paralyses that develop in childhood, which proves most plainly that the processes of growth depend upon the nervous system.

A “trophic disturbance” chiefly of the bones, but also involving the soft parts, forms the basis of that peculiar and rare disease recently termed **acromegaly** (P. Marie, Erb, etc.). The affection develops slowly in women and men, usually

in youth or middle age. Besides the general symptoms of dullness, fatigue, and quite severe neuralgic or rheumatic pains in the head and the extremities, there gradually develops a striking increase in the size of the hands and feet, and thickness and plumpness of the face, due chiefly to enlargement of the nose, chin, and lips, which become puffed out to a considerable size. The hands and feet become actual paws. Later in the disease the legs and forearms also increase in circumference. The hypertrophy seems to affect the bones chiefly, but in some cases the skin also seems thicker, without showing those marked changes characteristic of myxedema. In a case we have lately seen the tongue also showed distinct enlargement; sugar was also occasionally present in the urine, and with this there was a profuse and almost uninterrupted secretion of sweat. The voice was weak, deep, and hoarse, as a result of an evident paresis of the vocal cords. The few autopsies in acromegaly have thus far not been able to contribute much in the way of explanation of this remarkable affection. In all cases hyperplasia of the hypophysis cerebri was a striking lesion, and in the case of Klebs the persistence and hyperplasia of the thymus gland. Erb found in his cases a dullness in the upper sternal region, which he is disposed to attribute to a persistent thymus. In our case this dullness could not be detected. The significance of all these discoveries is still an utter enigma.

Trophic affections of the joints have been repeatedly confirmed in cerebral and spinal diseases, especially in *tabes dorsalis* (*vide infra*). As a special vaso-motor-trophic articular neurosis we may mention here the so-called **hydrops articularum intermittens**. We mean by this a very rare but perfectly typical disease, in which large swellings, usually of the knee-joint, but sometimes of the other large joints, develop at perfectly regular intervals of one to four weeks. They continue without fever, and usually without any great pain, and disappear again in a few days. Such attacks may be repeated at intervals of different lengths, during years and years. Their nervous character is attested especially by the rapid onset and disappearance of the affection, and also by the combination of it with other nervous disturbances, such as angina pectoris, exophthalmic goitre, vaso-motor symptoms, etc., which combination has often been observed. In regard to treatment we may try salicylic acid, quinine, Fowler's solution, and subcutaneous injections of ergotine.

In addition to the trophic disturbances we must consider the disturbances of secretion. These are not infrequent. We have already learned to recognize anomalies in the secretion of saliva in facial paralysis, and of the lachrymal secretion in trigeminal neuralgia. Analogous symptoms are occasionally noticed in other nervous diseases. Disturbances of the sweat secretion are the easiest to confirm. Our understanding of them comes substantially from the discovery of the "sweat nerves," arising mainly from the sympathetic, which was first made by Luchsinger. In nervous patients we have seen quite frequently, on the one hand, an abnormal increase of the sweat secretion (*hyperidrosis*, *ephidrosis*), and, on the other, a diminution or a complete disappearance of it. The former is seen on the paralyzed side in many hemiplegias and in spinal paralyses, the latter in *tabes dorsalis*. Anomalies of the sweat secretion are quite frequent, and are usually combined with vaso-motor disturbances, in certain general neuroses, such as hysteria and neurasthenia. In a few rare cases a genuine hæmatidrosis (bloody sweat) has been confirmed. The condition known as unilateral hyperidrosis (unilateral sweating) is also especially interesting. In this there is an abnormal secretion of sweat, chiefly in one half of the face, more rarely in one arm or over the whole of one side. The affection has usually been observed in connection with hemicrania, exophthalmic goitre, hysteria, etc., and, in at least a number of cases, it seems to be due to direct lesions of the sympathetic. On the other hand, we

have repeatedly seen persons, who were otherwise perfectly healthy, in whom the secretion of sweat, coming on under normal conditions from heat or physical exertion, remained limited to one half of the body, especially the face.

In conclusion, we would briefly mention here the symptoms which have been observed in direct **injuries of the cervical sympathetic**, wounds, pressure of neighboring tumors, etc. If we have to do with a paralysis of the sympathetic, we see almost constantly on the affected side a contraction of the pupil from paralysis of the dilator pupillæ supplied from the sympathetic, in many cases associated with a slow reaction to light. We also frequently see a narrowing of the opening of the lids from paralysis of Müller's muscle, and in old cases a retraction of the bulbus oculi, and occasionally increased redness and warmth in the ear and cheeks from vaso-motor disturbance. In a few cases we see an increased sweat secretion. We may add that, according to Möbius, the normal reflex dilatation of the pupil, from a painful irritation of the skin of the face, is absent in paralysis of the sympathetic. The opposite symptoms are found in conditions of irritation of the sympathetic. In both cases there are sometimes slight trophic disturbances in the cheeks. It is also worthy of note that in tumors of the neck, and after injuries of the brachial plexus, there are sometimes disturbances in the sympathetic, especially changes in the pupils, which are due, as is supposed, to a lesion of the communicating branches between the principal trunk of the sympathetic and the brachial plexus. The occurrence of sympathetic symptoms in certain injuries of the brachial plexus has already been mentioned above (page 567).

## CHAPTER II.

### HEMICRANIA.

(*Migraine*.)

**Ætiology.**—By hemicrania we mean a peculiar form of unilateral headache, due probably to vaso-motor disturbances, or at least almost always associated with vaso-motor symptoms. The affection occurs especially in women, more rarely in men, and almost always begins in youth, generally at the period of puberty, but typical cases of migraine have been repeatedly observed in school-children. Quite frequently, but not always by any means, the disease affects women who must be regarded as "generally nervous," who are anæmic, or who suffer from disturbances of menstruation. Heredity often plays a part, since hemicrania is both hereditary as such, and often appears in families which have suffered from other nervous diseases, such as epilepsy, hysteria, or the psychoses. We may mention as exciting causes, which may be made answerable both for the onset of the disease and quite often for the individual attacks, physical and mental overexertion, great mental excitement, and disturbances of digestion. [Eye-strain (*vide supra*) may be a cause of migraine as well as of other forms of headache, and a careful search for any errors of refraction should be made in every case.—K.]

We do not know the special cause of hemicrania. Considering the accompanying vaso-motor symptoms, which are present in migraine as a rule (*vide infra*), it is almost universally assumed that we must regard the disease, from its chief cause, as an affection of the sympathetic; but we must agree with Möbius that this assumption is by no means confirmed, and that it is possible that the accompanying sympathetic symptoms may be only secondary and of reflex origin, in consequence of the pain. We also have no definite information as to the special seat of the pain in migraine, but it is most probably to be placed in the meninges—the pia and dura mater.

**Symptomatology.**—Migraine always comes on in separate attacks, which are repeated at intervals of varying lengths, although some cases often show a remarkably great regularity. The onset of the attack in women often has some relation to the menses. The left half of the head is much more frequently affected than the right. In some cases it happens that the pain affects the right and the left sides alternately; in others it is not generally very strictly limited to one side.

The attack of migraine usually begins with certain prodromal symptoms, which the patient soon recognizes as sure signs of his approaching suffering. These prodromal symptoms consist of general uneasiness, discomfort, pressure in the head, vertigo, at times tinnitus, spots before the eyes, chills, malaise, abnormal yawning, etc. In a short time the pain begins. It is felt most either in the anterior frontal region or in the temporal or parietal region; it generally shows a continuous character, not intermittent as in neuralgia, and may increase to a very great intensity. Special painful points are usually absent, but the whole skin over the head on the affected side is usually hyperæsthetic. The general malaise continues with it; the patient has absolutely no appetite; there is often great nausea, and almost always a great sensitiveness to external impressions, to any bright light, or to any noise. In many cases of ophthalmic hemicrania ocular disturbances are especially prominent; bright scintillations before the eyes, scintillating scotoma, and quite often a pronounced hemianopsia, may be made out during the attack.

The vaso-motor symptoms are of special interest because they are of value in the theory of the disease. From them migraine is usually divided into two subdivisions—*hemicrania sympathico-tonica* or *spastica*, and *hemicrania sympathico-paralytica* or *angio-paralytica*.

In *hemicrania spastica*, first described by Du Bois-Reymond from observations on himself, the forehead and ear on the affected side are pale, the skin is cool, the temporal arteries contracted, the pupil is often decidedly dilated, the secretion of saliva increased—in short, there are a whole row of symptoms present which all agree in pointing to a condition of irritation in the sympathetic (*vide supra*).

In *hemicrania paralytica*, however, which was first described by Möllendorff, also from observations on himself, the face is reddened on the affected side, it feels hot, the temporal arteries are dilated and pulsate strongly, there is sometimes unilateral sweating of the face, the pupil is contracted—all symptoms which can depend only on a paralysis of the sympathetic.

As has already been hinted, the significance of all these symptoms is not absolutely certain, and we must also add that the cases which occur in practice can not by any means always be inserted into one or the other typical scheme without further ceremony. The vascular symptoms are sometimes but slight, conditions of paralysis and of irritation of the sympathetic sometimes seem to alternate with each other in the same attack, and we may even frequently meet with apparently contradictory symptoms at the same time, such as pallor joined with contraction of the pupil. The peculiar method of the origin of the pain is at present also almost wholly unexplained. If we assume primary vascular changes in *hemicrania*, we must look for the cause of the pain in the disturbance of the circulation, or perhaps, in *spastic hemicrania*, in the spasmodic contraction of the vessels itself.

The duration of the attacks of migraine differs very much in different cases. It usually lasts several hours, or a whole day; then the pain gradually disappears, and there is often considerable vomiting and sometimes a profuse discharge of urine toward the end of the attack. In the intervals between the different attacks most patients are perfectly well and free from pain.

The whole course of migraine is very chronic, and may last for years and

years. It is usually a trouble to which the patient finally becomes accustomed. We must generally be quite guarded in our prognosis, for many cases resist very obstinately all attempts at cure. We can give the patient only the consolation that the trouble generally disappears of itself in advanced life. It is not usually attended with any special danger. In only a few cases has it been noticed that attacks of hemicrania of years' duration have preceded a severe cerebral disease that developed later, or *tabes dorsalis*.

**Treatment.**—Very many patients who suffer from migraine finally renounce any special treatment, after they have exhausted all possible remedies. They withdraw to their rooms when the attack comes on, darken the windows, take nothing but some tea, Seltzer-water, or cracked ice, put a cold compress about the head, perhaps try a foot-bath, and for the rest wait quietly until the attack is over. In fact, our remedies for cutting the attack short are quite uncertain. They sometimes aid, but they often leave us in the lurch, especially if used repeatedly. We must note especially that narcotics, such as morphine, are almost always ill borne in migraine, and do no good; but antipyrine, sodic salicylate (20-30 grains [grm. 1.5-2.0], in strong black coffee), antifebrine, and phenacetine in many cases undoubtedly have a favorable action. Which remedy acts the best must usually be tested in the individual case. We have ourselves seen excellent results formerly from sodic salicylate, and lately from antipyrine; the attacks of migraine, when the remedy was taken immediately upon the onset of the first symptoms, have become distinctly milder and have run their course more rapidly. Of course the action often ceases with time, and we must then try another of the remedies mentioned. Of the other remedies used we may mention guarana (*Paullinia sorbilis*), half a drachm to a drachm (grm 2-4) of the powder, and caffeine, or sodio-salicylate of caffeine, in three- to five-grain doses (grm. 0.2-0.3), which is sometimes very serviceable. On theoretical grounds, inhalations of nitrite of amyl, three to five drops on a napkin, have been used in spastic hemicrania, and subcutaneous injections of ergotine in the paralytic form (aqueous extract of ergot, 2.5; dilute alcohol and glycerine, each 5; or one part of dialyzed ergotine in four parts of distilled water; injections of either, three to fifteen minims). Many other nervines, such as bromide of potassium and Fowler's solution, have been recommended for continued use, and also extract of *cannabis indica*; and, lately, nitrite of sodium, two parts in 120 of water, a teaspoonful one to three times a day. Its action is analogous to that of nitrite of amyl. Nitro-glycerine, in troches containing  $\frac{1}{16}$  to  $\frac{1}{8}$  grain (grm. 0.0005-0.001), also has the same dilating action on the vessels. In ophthalmic migraine the treatment by large doses of bromide of potassium is praised, especially in France, as being very successful.

In many cases the general treatment is very important. Preparations of iron, sea-bathing, a mountain residence, and cold-water cures are often of distinct service. In patients with co-existing gastric symptoms a course at Carlsbad is sometimes of permanent benefit. The persistent application of electricity has also shown some good results, but we must not build very great hopes upon it. In the spastic form the action of the anode on the sympathetic is to be especially tried, and in the paralytic form the action of the cathode, while the other electrode is to be placed on the cervical cord, or as high as possible on the occiput in the region of the medulla. Cautious galvanization of the head, and weak primary faradic currents, may also be used. Specialists in massage praise their mode of treatment in migraine; they massage either certain painful spots in the head, or the gastric region. Finally, we must mention that migraine often seems to be connected with diseases of the nose, especially with hyperplasia of the erectile tissue in the nose, and that in such cases treatment of the primary disease with the galvanocautery may result in the cessation of the migraine.

## CHAPTER III.

**PROGRESSIVE FACIAL HEMIATROPHY.***(Unilateral Progressive Facial Atrophy.)*

UNILATERAL facial atrophy is an extremely rare disease, of which only about ninety cases have been recorded in literature up to the present time. The disease consists in a very slow and gradual but usually constantly progressive atrophy of one half of the face, and affects the skin, and also the fatty tissue, the muscles, and the bones, either in a uniform or a very diverse manner. The affection usually begins in youth. The female sex seems to be more disposed to the disease than the male.

The atrophy, which has its seat much more frequently on the left side than on the right, begins usually in a circumscribed spot either on the cheeks or on the chin.

FIG. 80.—Left facial hemiatrophy.

The skin, as a rule, gradually assumes a whitish or brownish color. The affected part, and finally the whole half of the face, gradually sink in more and more, so that the disease can be recognized at the first glance. The atrophy shows a sharp limitation at the median line. In many cases the muscles apparently remain almost wholly intact, but in some cases they show a marked atrophy, especially the muscles of mastication. The corresponding half of the tongue and the soft palate has sometimes been found implicated. Exceptionally, the atrophy involves the neighboring region of the shoulder and the upper extremity. The bones also atrophy, especially in the cases which arise in early youth. The hair on the affected half of the head often falls out in great amount, and it becomes thin and atrophic. The sensibility remains perfectly intact.

Marked vaso-motor and secretory disturbances have only rarely been observed. The accompanying illustration (Fig. 80) shows a patient who was described by Romberg about thirty years ago, and who at present still frequents the German clinics in order to show himself.

Nothing definite is known in regard to the nature of the affection. Most observers at present agree that it is a trophic neurosis, an affection of trophic nerves or nerve-centers, but where we are to look for the special seat of the disease, whether in the trigeminus or in the sympathetic, we do not know. Mendel lately found in a case which came to autopsy a distinct neuritis in the trigeminus.

The disease is not dangerous in itself, and usually causes no special subjective disturbance, but it seems to be incurable. In cases at their beginning we can at most make an attempt to bring the disease to a standstill by a long-continued application of electricity.

As an appendix it may be briefly mentioned here that there is a unilateral hypertrophy, which is also possibly connected with neurotrophic disturbances. We

have at present under observation a ten-year-old boy, otherwise perfectly healthy, in whom a striking hypertrophy of the left side of his face and of the left arm has gradually developed.

#### CHAPTER IV.

#### EXOPHTHALMIC GOITRE.

(*Graves's Disease. Morbus Gravesii. Basedow's Disease. Morbus Basedowii. Glotzaugenkrankheit.*)

**Ætiology.**—The special group of symptoms to which the name of exophthalmic goitre has been given, and whose three cardinal symptoms are acceleration of the pulse, goitre, and exophthalmus, was first carefully described in Germany, in the year 1840, by the Merseburg physician Basedow, although similar but less precise observations had been published in England by Graves five years earlier. The anatomical cause of this disease is still entirely unknown to us, but the whole type, and almost all the single symptoms of the affection, point definitely to an affection of the nervous system, which, with regard to the most prominent symptoms, is usually considered a "vaso-motor neurosis" or an "affection of the sympathetic"; although, as may be seen from what follows, this hypothesis still lacks any basis in fact.

With reference to the special ætiology of the disease all those factors are prominent which generally play the first part in the ætiology of neuroses. In many cases a hereditary predisposition can certainly be discovered. The disease has been repeatedly seen in several members of the same family. Furthermore, exophthalmic goitre is also quite frequent in those families in which there is a hereditary predisposition to neuroses in general—epilepsy, the psychoses, or hysteria. Among the exciting causes we must first mention great mental excitement—grief, terror, anger. Sometimes real injuries, as well as these "psychical injuries," seem to have an influence on the development of the disease—that is, great general bodily concussion, such as a fall. Many authors have laid considerable weight on diseases of the female sexual organs, but the importance of this factor seems to us to be exaggerated. It is certain, however, that the first symptoms of exophthalmic goitre often develop at the period of pregnancy.

The influence of sex upon the origin of the disease is plain, since women, especially somewhat anæmic, "nervous" women, are much more frequently affected than men. Exophthalmic goitre usually appears in middle life, while it is seen only exceptionally in children and old people.

**Symptomatology.**—Of the three cardinal symptoms of exophthalmic goitre named above, of which, of course, one or another is often absent or only slightly developed, the acceleration of the pulse is the most constant and usually the earliest. The frequency of the pulse averages 100 to 120, sometimes only 80 or 90, but in other cases even 140 or 160. It is not alike at all times, but has many variations—the symptoms lasting for long periods and coming on in single paroxysms. A very vigorous action of the heart, and as a rule the subjective feeling of palpitation, are usually associated with the acceleration of the pulse. There is a vigorous pulsation of the carotids, and sometimes of the smaller arteries. We do not discover any qualitative changes of the pulse. The pulse is usually quite regular, but arrhythmia has been repeatedly observed. In some cases the patients suffer from pronounced angina pectoris.

Physical examination of the heart in many cases shows nothing particular, except an accelerated and violent action of the heart, but we sometimes find, as we can affirm from several cases in our own experience, a manifest hypertrophy

of the left ventricle, and also dilatation of the heart, and even actual valvular disease. In the diagnosis of the latter some caution is necessary, because functional heart murmurs are often present in exophthalmic goitre.

The goitre usually develops somewhat later than the first symptoms in the heart. In many cases it is entirely absent, or present only in a slight degree. The swelling of the thyroid gland is generally only exceptionally very marked. There are sometimes marked variations in it in the course of the same case. The comparative softness of the tumor, the frequent and strong pulsations in it, and the loud vascular murmurs, which are often but not always heard, and which arise in the dilated vessels of the thyroid gland, are characteristic of the goitre in Graves's disease. By laying the hand on it we can often feel the thrill and pulsation.

The exophthalmus, the protrusion of the eyeballs from their orbits, is always bilateral, although it is sometimes more marked on one side than on the other. In many cases it is entirely absent; in others it may attain so high a degree that an actual "dislocation of the eyeball" has been described. In the marked degrees of exophthalmus there is often a peculiar staring expression to the countenance. A peculiar symptom, first described by Graefe, is also worthy of mention. On raising and lowering the eyes, the corresponding associated movements of the upper eyelid, which are always present under normal conditions, are absent. This "Graefe symptom" may sometimes be one of the earliest signs of the disease, and may therefore be of diagnostic value; but we must lay stress upon the fact that, in our own experience, this symptom is at any rate only rarely pronounced. Sometimes severe inflammatory processes have been seen in the eye, which are probably to be referred to the impaired protection of the eye by the upper lid as a result of the exophthalmus. Disturbances of the pupils and of accommodation are unknown in exophthalmic goitre, but we have ourselves repeatedly observed anomalies in the movements of the eyeball, especially temporary strabismus. We might mention one symptom, which Möbius has first noticed, and which we also have repeatedly but not constantly seen, especially in patients with more marked exophthalmus. It consists in the fact that one eye very soon deviates outward if we have the patient converge the eyes strongly, as in fixation of a near object—"insufficiency of convergence."

Besides the chief symptoms of exophthalmic goitre thus far described, we must also mention a list of other symptoms which come to our observation, both in the typical cases and still more often in anomalous cases—the so-called "*formes frustes*" of the French. Among them are some other nervous symptoms, especially a peculiar tremor to which Marie in particular has lately called attention. This tremor affects the whole body, or the extremities alone; it shows at times temporary remissions and exacerbations, and it may be so severe as to form the patient's chief complaint. In a case under our observation marked tremor was one of the first symptoms of the disease. It may become so violent at times that there are even spasmodic twitchings in the extremities and in the muscles of the face. We have repeatedly seen lesser degrees of tremor, especially in the hands and we regard it, indeed, as quite characteristic. We may also mention among the nervous symptoms which are sometimes present, headache, vertigo, weakness of memory, and sleeplessness. The peculiar nervous anxiety and the irritable disposition of the patient are, however, very frequent, and in fact very characteristic, in many cases of the disease. The anxiety and the haste in all movements, in speaking, etc., often show themselves, even during the physician's examination, in so striking a way that they must be regarded as not unimportant factors in diagnosis. Exophthalmic goitre is sometimes complicated with other neuroses—with actual hysteria, epilepsy, chorea, the psychoses, etc. The marked subjective feeling of heat, from which many patients suffer, is probably due to vaso-motor dis-

turbances. Objective elevations of temperature up to  $100^{\circ}$  or  $101.5^{\circ}$  ( $38^{\circ}$ - $38.8^{\circ}$  C.) have also been repeatedly confirmed by others (Eulenburg) and by ourselves. A marked increase of the sweat production, which in rare cases is only unilateral, is often associated with the feeling of heat. On the other hand, one of our patients complained of a constant dryness in the mouth.

Of symptoms which are referred to other organs we must first consider some disturbances on the part of the respiration. The respiration is usually moderately accelerated, and many patients complain of dyspnoea and of a feeling of oppression in the chest. In one case we saw at times deep spasmodic inspirations; in other cases a peculiar dry, "nervous cough" appears. There are also symptoms on the part of the digestive organs. Vomiting is common, and in severe cases it may become so persistent, distressing, and uncontrollable as to constitute one of the chief dangers of the disease. It is sometimes associated with peculiar paroxysmal sero-mucous or even bloody diarrhoea. Icterus may also develop. Finally we must mention certain disturbances in the skin: vitiligo has often been observed, and also diffuse brownish pigmentation of the skin or chloasma-like pigment-spots and urticaria. A very rare but dangerous occurrence, of which we ourselves have seen a striking example, is an apparently spontaneous gangrene of the extremities. In our case, which ended fatally, the gangrene affected the right leg. Not the slightest anomaly could be made out in the vessels at the autopsy. This gangrene in exophthalmic goitre recalls decidedly the so-called "spontaneous symmetrical gangrene" (*vide supra*), for which we also must assume a neurotic origin.

The general nutrition of the patient suffers in most cases; a certain degree of anæmia and emaciation is often present. In severe cases, especially in those of rapid development, there is often in a very short time a high degree of emaciation associated with much general weakness. Muscular atrophy frequently develops, chiefly in certain regions—the arm or leg muscles. [The electrical resistance of the body is said to be diminished.—K.]

**Pathological Anatomy and Pathogenesis.**—Although all the symptoms of exophthalmic goitre point to an affection of the nervous system as a cause of the disease, as we see from the symptomatology, the results of pathological investigations are still very meager. There is a class of cases in which changes in the sympathetic, and especially in the lowest cervical ganglion, are said to have been present; but the pathological significance of the discovery is not placed beyond all doubt; and in other cases nothing abnormal at all could be found in the sympathetic. The theory that all the symptoms of exophthalmic goitre are derived from a disturbance of the sympathetic also meets many difficulties and contradictions. If we regard only the three cardinal symptoms, we can bring the acceleration of the pulse, and perhaps the exophthalmus, into harmony with the theory of irritation of the sympathetic: but not the goitre, which is due to a dilatation of the vessels. The theory of a paralysis of the sympathetic explains the goitre, and also the exophthalmus—if we assume as the cause of the latter a dilatation of the vessels in the back of the orbit—but again the acceleration of the pulse remains unexplained. The experiments by Filehne, interesting in themselves, in which symptoms similar to those of exophthalmic goitre were produced by dividing the restiform bodies in young rabbits, have had up to the present time no bearing upon human pathology. We must therefore admit that the cause of exophthalmic goitre is still completely unknown. Possibly the recent experiments on the significance of the thyroid gland (*vide supra*) may throw some light on the origin of this remarkable affection.

**Course and Diagnosis.**—The course of the disease is in most cases very chronic, and may extend over years and years, but there are also more acute cases with a rapid development of all the symptoms and a comparatively unfavorable course.

We may often see considerable variation in the intensity of the symptoms. All the symptoms of the disease may often almost wholly disappear, to recur after the lapse of years. In general, the cases beginning in youth give a more unfavorable prognosis than those arising in later years. Complete recoveries have certainly been observed, but they are at all events rare. The disease sometimes terminates fatally with the signs of general marasmus, but more frequently from complications in the heart or lungs. We would note especially, however, that mild and to some extent rudimentary cases of the disease are not rare, and that these in no way endanger life; and even in severe cases we sometimes see marked improvement, or at least an arrest of the disease. The diagnosis of undeveloped cases is difficult at times, since the three cardinal symptoms are not always by any means fully developed. We must then pay careful and especial attention to the other symptoms of the disease, chiefly to the general nervous irritability, the tremor, the subjective feeling of heat, and the tendency to sweating. In well-developed cases, however, the diagnosis is almost always to be made with certainty and without difficulty. The peculiar expression of the face, altered by the emaciation and the exophthalmus, often permits us to recognize the disease at the first glance.

**Treatment.**—In the first place we must consider the general treatment of the patient. Physical and mental rest, good food, and the avoidance of all stimulants—such as alcohol or strong coffee—and the cautious use of cold-water cures, especially sponging, may cause an actual improvement of the condition. For anæmic patients we prescribe iron, alone or in combination with small doses of arsenic. A course at the springs at Franzensbad, Schwalbach, Pyrmont, Elster, and Cudowa, is also sometimes attended with good results. Residence in mountainous regions or by the sea often seems to act still more favorably.

Of other remedies, electricity is first to be mentioned, especially the application of galvanism to the neck—the so-called galvanization of the sympathetic at the inner border of the sterno-mastoid. The slowing of the pulse, which sometimes comes on at once (vagus irritation?), is striking. Vigouroux praises faradization of the sympathetic and of the goitre as the best method of treatment. Among internal remedies we may recommend atropine or tincture of belladonna, and ergot or ergotine. We believe we have repeatedly seen good results from the latter. Digitalis has often been prescribed for the palpitation, but usually without any good result. The use of iodine preparations against the goitre is also almost always unavailing. With great exophthalmus the eyes must be protected from external injuries. The occasional severe symptoms on the part of the digestive organs (vomiting, diarrhœa) must be treated symptomatically, by ice, opium, and champagne.

In some cases the extirpation of the goitre has been practiced, and favorable results have been claimed for it. Should the above-mentioned relation of the morbid symptoms to the functions of the thyroid gland be confirmed, further advance in this direction would perhaps be worthy of trial.

### III.—The Diseases of the Spinal Cord.

#### CHAPTER I.

##### DISEASES OF THE SPINAL MENINGES.

###### 1. ACUTE INFLAMMATIONS OF THE SPINAL MENINGES.

**Ætiology and Pathology.**—Isolated acute inflammation of the spinal meninges is very rarely primary, so far as we know, but inflammatory processes in the neighborhood quite frequently involve the meninges, or a spinal meningitis. occurs as one symptom of a general cerebro-spinal meningitis. This latter condition is seen chiefly in the idiopathic, generally epidemic, cerebro-spinal meningitis, which is a specific infectious disease, and has already been described in detail in a previous chapter. A tubercular spinal meningitis is also very often combined with tubercular inflammation of the cerebral meninges, but, since the symptoms of the latter are usually in the foreground of the picture, we will treat of tubercular cerebro-spinal meningitis in the section on diseases of the cerebral meninges. Secondary cerebro-spinal meningitis is sometimes seen in the course of certain other infectious diseases, and is then probably to be regarded as a special localization of the specific poison of the disease. This is the explanation of the occurrence of acute spinal and cerebral meningitis as a sequel of croupous pneumonia, and also of its occurrence in pyæmic and septic diseases, and, very rarely, in typhoid and the acute exanthemata. We must mention, finally, the occurrence of a purulent cerebro-spinal meningitis as a sequel of empyema, pulmonary gangrene, etc., which, although very rare, we have repeatedly noticed. In these cases the infection of the meninges also results from the primary foci of disease, but the channel of infection is not yet exactly known. Perhaps the intercostal nerves are the media of communication.

In all the cases so far mentioned we have chiefly an inflammation of the pia mater, a so-called *lepto-meningitis*; the dura mater is not implicated in the disease at all, or only to a slight degree. The condition is different in those inflammatory processes which gradually invade the meninges from the neighboring parts outside the cord. Thus we very often see circumscribed inflammations on the outer surface of the dura (pachymeningitis) in caries of the vertebrae, and these inflammations often invade the inner surface of the dura, or more rarely reach the pia mater. Acute purulent peripachymeningitis is a very rare disease; it is a purulent inflammation of the connective tissue between the dura mater and the vertebral column, which in almost all cases is of secondary origin. We have seen a very characteristic case of this sort in the course of a puerperal pyæmia. The inflammation had spread from a purulent inflammation of the pelvic cellular tissue, through the foramina of the vertebral canal, and had finally set up a purulent inflammation on the outer surface of the dura, extending up to the cervical cord. We meet with an affection of the pia mater from an extension of the inflammation, chiefly in diseases of the spinal cord, since the pia takes part in the process to a greater or less extent in many cases of myelitis.

We do not know with certainty whether other influences, especially injuries and exposure to cold, can lead directly, as has often been claimed, to inflammation of the spinal meninges.

We need to say but little in regard to the pathological anatomy of acute spinal meningitis. The changes in purulent inflammation of the pia mater have been described in the chapter on epidemic meningitis. Precisely the same conditions are found in the other forms of acute leptomeningitis. The changes in pachymeningitis are completely analogous. The dura mater is traversed by dilated vessels, and therefore is reddened; it is also thickened, and on its internal or external surface (*pachymeningitis interna* or *externa*, or *peripachymeningitis*) there is usually found a purulent or a sero-purulent exudation.

**Symptoms.**—An accurate distinction between acute inflammations of the pia mater and those of the dura mater can not be made clinically. The symptoms of the disease include the symptoms of any primary disease present, the general symptoms, such as fever, etc., and in addition the necessary consequences which the presence of a disturbance of the meningeal circulation and of the meningeal exudation exerts on the cord and nerve-roots. These consequences are due both to a mechanical compression of the parts named, and often probably to an invasion of the substance of the cord itself by the inflammation. To these is added the frequent combination of spinal symptoms with the symptoms of a co-existing cerebral meningitis.

Those symptoms which occur in acute spinal meningitis, and are especially referred to it, are all of them already known to us from the description of epidemic meningitis (see page 103). Recapitulating them briefly, we may mention chiefly the very severe pain in the back, the great sensitiveness of the vertebral column, and its stiffness. To these may be added usually symptoms of irritation on the part of the nerve-roots: eccentric pains in the trunk and the extremities, hyperæsthesia of the skin and of the deeper parts, symptoms of direct or reflex motor irritation, muscular tension, contractions, etc. The cutaneous and tendon reflexes are often, but not always, much diminished or abolished in consequence of the lesion of the nerve-roots. There are at times disturbances in the passage of urine and feces. If, in the later course of the disease, there are actual paralysis and anæsthesia, they are usually a sign of a more marked implication of the cord itself.

**Diagnosis.**—From the symptoms named, we can in many cases make a diagnosis of spinal meningitis. Of course a meningitis is found often enough on the autopsy-table whose symptoms during life were completely obscured by other severe general symptoms, while, on the other hand, with severe constitutional symptoms the symptoms of meningitis may be illusory, as in typhoid or pyæmia. Fuller information as to the seat and the extent of the inflammation is afforded by considering the most painful parts of the vertebral column, the predominance of pain and cutaneous hyperæsthesia in the arms (cervical region) or legs (lumbar region), etc. When the meningitis involves the upper portion of the cord and the medulla there may also be disturbances of respiration, symptoms in the pupils, and anomalies in the innervation of the heart. We can decide as to the form of the meningitis, whether purulent or tubercular, only by a consideration of the history, the other morbid symptoms, and the course of the disease.

**Prognosis.**—We have seen an undoubted recovery, in severe cases, only in epidemic cerebro-spinal meningitis, and in the sporadic cases of idiopathic meningitis, which are probably identical in ætiology. In all other cases reported with a favorable termination the diagnosis may be doubted, for in general the rule is certain that, in extensive, acute purulent leptomeningitis and pachymeningitis, the prognosis is almost absolutely unfavorable, whether it be secondary to another infectious disease or arise from propagation from some neighboring focus of inflammation. We may, perhaps, make an exception of certain mild, circumscribed cases, which do not come to suppuration, but these are always uncertain in regard to diagnosis.

**Treatment.**—In regard to treatment we must refer entirely to what has been said under epidemic and tubercular meningitis.

## 2. CHRONIC SPINAL LEPTOMENINGITIS.

Although chronic leptomeningitis (usually wrongly termed chronic spinal meningitis) once played quite a large part in the diagnosis and pathology of diseases of the spinal cord, we must at present assert that its occurrence as an independent disease may justly be doubted. Almost all the cases reported come from a time when the diagnosis of many diseases of the cord itself was still perfectly impossible, and when the thickenings and opacities of the meninges were much more striking at the autopsy than the far more essential changes in the substance of the cord itself, which could not be made out with the naked eye, but only by a careful microscopic examination. At any rate, we may say that a case of primary chronic leptomeningitis, which can be surely and convincingly proven clinically and anatomically, does not exist, and that our present clinical experience also by no means favors the assumption of the existence of mild and curable forms of it. Among many cases of spinal disease we shall scarcely be induced even to assume the probability of the existence of primary chronic meningitis. It goes without saying that we can not dispute the possibility of its occurrence, although even for this we can scarcely find an analogy.

The case is different with secondary chronic leptomeningitis. This, in the first place, in rare cases, is the termination of an acute meningitis. Secondary leptomeningitis may be certainly made out, especially in epidemic meningitis. We also find chronic meningitis frequently as a secondary affection in primary diseases of the cord and the vertebræ. Thus, for example, in old cases of chronic spinal disease, associated with atrophy, such as *tabes dorsalis*, progressive muscular atrophy, etc., the pia is almost always quite opaque, thickened, and often united to the cord and the dura by very many firm adhesions, while a cloudy sero-gelatinous exudation is found in the meshes of the arachnoid. All these anomalies, however, are of a secondary nature, and have no clinical significance, for the same changes, though rarely so marked, are quite often found in old people, where they are analogous to the equally frequent opacities of the cerebral meninges, the pleuritic adhesions, etc., and where, during life, they have not caused the slightest symptom of spinal disease.

The symptoms which have been set down as characteristic of leptomeningitis correspond precisely to those of acute meningitis, except, of course, that they are relatively less intense, and that the course of the disease is more protracted. Pain and stiffness in the back and neck, abnormal painful sensations and paræsthesia in the extremities, a girdle sensation, and finally paresis, anæsthesia, and vesical disturbances, are the leading features of the type of disease as constructed, in whose fabrication there have been, at any rate, many confusions with myelitis, spondylitis, beginning *tabes*, multiple neuritis, etc.

It is clear that under such circumstances no special rules for the treatment of chronic spinal meningitis can be given. Given a case, we would try local applications to the vertebral column; painting with iodine; dry, or, exceptionally, in strong patients, wet cups; also protracted tepid baths, 90° to 95° (26°-28° R.), or cautious cold-water treatment; and finally the use of the galvanic current. Of internal remedies, iodide of potassium would be most indicated. We may refer to the description of the treatment of myelitis in regard to all further details.

## 3. PACHYMEINGITIS CERVICALIS HYPERTROPHICA.

*Pachymeningitis cervicalis hypertrophica* was first fully described, as a special form of disease, by Charcot in 1871, and later by his pupil Joffroy. Little is known as to its origin; it has been attributed to exposure to cold and the abuse of alcohol.

Anatomically, the disease is characterized by a chronic and often very considerable thickening of the dura, almost always, as it seems, in the cervical portion of the cord, while the pia takes but a comparatively small part in the affection. The dura may attain a thickness of six or seven millimetres, and usually appears composed of a number of concentric layers. Histologically, the hypertrophy consists of a new growth of dense connective tissue. The clinical symptoms of the disease arise from the fact that, first, the penetrating nerve-roots, and later on the cord itself, undergo a considerable mechanical compression. If this is of high degree and persistent, there are, as a necessary result, secondary degenerations of the motor nerves and muscles, and a secondary descending degeneration of the pyramidal tract in the cord.

The clinical symptoms are easily understood from this. The disease almost always begins with severe pain, which shoots from the neck into the occiput and the arms. Besides this, there are paræsthesia and a numb feeling in the arms and hands. Rarely there is an eruption of herpes. All these symptoms depend upon the irritation of the posterior roots.

After this first period of the disease (*période douloureuse* of Charcot) has lasted some two or three months, the second period begins—the period of paralysis. An atrophic paralysis in the upper extremities gradually develops, mainly as a result of the compression of the anterior motor roots. This affects, in a remarkable manner, chiefly the distribution of the ulnar and median nerves, while the distribution of the radial on both sides usually remains free. The hand, therefore,

assumes a characteristic position (Fig. 81), as a result of the contracture of the antagonistic extensors. The paralyzed muscles rapidly become atrophic and show a marked reaction of degeneration. In this stage there may also be partial anæsthesia of the skin.

If the compression of the cord advances, the motor fibers for the lower extremities, which pass through the cervical cord, must necessarily at last be involved sympathetically—

FIG. 81.—Position of the hand in pachymeningitis cervicalis hypertrophica. (From CHARCOT.)

the third period of the disease. The result of this is a spastic paralysis of the lower extremities—that is, a paresis or paralysis with increased tendon reflexes, but of course without muscular atrophy, because the trophic centers for the muscles of the legs, in the anterior cornua of the lumbar cord, remain perfectly intact. The compression of the cervical cord, however, may finally lead also to anæsthesia of the lower extremities, to paralysis of the bladder, and bedsores, under which symptoms death ensues; but, on the other hand, it must be mentioned that probably cases of recovery, or at least of actual improvement in pachymeningitis cervicalis hypertrophica, may occur even after it has lasted for years.

The diagnosis of the disease is based first upon the fact that the affection begins with pains in the arms, and upon the later appearance of the characteristic

paralyses. It may easily be confused with tumors in the cervical cord and with cervical spondylitis. Amyotrophic lateral sclerosis is distinguished, however, by the absence of disturbances of sensibility, by the final appearance of atrophy in the lower extremities, by the bulbar symptoms, and by the fact that the functions of the bladder remain intact.

Treatment can do little directly, and must be chiefly symptomatic. Baths, iodide of potassium, and electricity are most used. Joffroy recommends the use of the hot iron to the neck.

#### 4. HÆMORRHAGE INTO THE SPINAL MENINGES.

(*Hæmorrhachis. Meningeal Apoplexy. Pachymeningitis spinalis hæmorrhagica interna.*)

Large hæmorrhages into and between the spinal meninges are of rare occurrence. They arise chiefly from traumatic influences, from concussion or fracture of the vertebral column, or from direct injuries of the meninges, such as stabs or gun-shot wounds. In a few cases great physical exertion may also lead to a meningeal apoplexy. Diseases of the vertebrae, caries, and carcinoma, may also lead to a hæmorrhage from the erosion of a vessel. The frequent little meningeal hæmorrhages which appear as a complication of meningitis, in hæmorrhagic diseases, in the course of severe general infectious diseases, septic infections, typhoid, and small-pox, and as a result of severe general convulsions, very rarely have any clinical significance. Finally, it may be mentioned that aneurism of the aorta or its branches may rupture into the vertebral canal.

The clinical symptoms of meningeal hæmorrhage are almost always sudden and "apoplectiform," but are unattended by any disturbance of consciousness. Their intensity depends entirely upon the degree of compression which the nerve-roots and the cord undergo from the effused blood. The symptoms of irritation usually predominate—severe pain in the back, paræsthesia, and neuralgic pains in the extremities; and also symptoms in the motor distribution, tension, tremors, and contractures of the muscles. With large hæmorrhages, symptoms of paralysis, partial anæsthesia, disturbances of the bladder, symptoms of unilateral lesion, etc., may ensue. Therefore the different types of the disease, depending upon the seat of the hæmorrhage, follow the same general rules which are to be considered in judging of the seat of any other affection of the cord (*vide infra*). On the whole, the diagnosis of meningeal hæmorrhage can but rarely be made with any certainty, unless suggestive ætiological factors precede and the symptoms and manner of beginning are especially characteristic.

The course is quite favorable in many cases if the blood be rapidly reabsorbed, but sometimes a permanent disturbance of function is left.

In regard to treatment, complete rest and the energetic local use of ice are chiefly to be recommended, and also local bloodletting—dry cups, or leeches, where there are severe initial symptoms of irritation. If permanent disturbances be left, they should be treated by the ordinary methods—iodide of potassium, baths, and electricity. [When the diagnosis of hæmorrhage into the meninges is reasonably certain, an attempt should be made to relieve the condition by opening the spinal canal and removing the clot.—K.]

We must here speak of **pachymeningitis interna hæmorrhagica** as a special form of disease, which usually occurs at the same time with hæmatoma of the cerebral dura mater (*vide infra*), and is precisely analogous to it in its ætiology and pathological anatomy. Encapsulated collections of blood are found on the inner surface of the dura; these may have quite a considerable circumference, and contain blood already disintegrated, detritus, hæmatoidin crystals, etc., since they are usually of old standing. Besides this, there are also the signs of a fibrinous

inflammation—as in the cerebral dura—which, according to the opinion of most observers, is the primary process, so that the hæmorrhages into the newly formed false membrane are secondary. The symptoms of the affection—which has been observed chiefly in the chronic insane (general paralytics) and drunkards—are rarely pronounced, and consist chiefly of pain in the back, stiffness of the vertebrae, and some signs of compression on the part of the nerve-roots and the cord; but we can very rarely make a definite diagnosis.

## CHAPTER II.

### DISTURBANCES OF CIRCULATION, HÆMORRHAGES, FUNCTIONAL DISTURBANCES, AND TRAUMATIC LESIONS OF THE SPINAL CORD.

1. **Disturbances of Circulation.**—Our knowledge as to the occurrence and as to the clinical significance of pure disturbances of circulation in the spinal cord is very slight. All that is stated in regard to it in the descriptions of the pathology of the spinal cord corresponds much more to theoretical hypotheses than to the actual objective facts.

It goes without saying that a complete anæmia of the spinal cord must destroy its function; this fact is best illustrated by the well-known experiment of Stenson: if we compress the abdominal aorta of an animal, and thus cut off the blood-supply to the lumbar cord almost completely, a paralysis of the posterior portion of the body very rapidly ensues. Some precisely analogous observations have been made in man in the rare cases of obstruction of the aorta by emboli or thrombi. Pronounced spinal symptoms in general anæmia, which may be referred to a co-existing anæmia of the cord, are rare, and at any rate are of much less clinical prominence than the important results of a co-existing cerebral anæmia (*vide infra*). In only a few cases has paraplegia been seen after a great general loss of blood, as after metrorrhagia or intestinal hæmorrhage.

Any statement which may be made as to the occurrence of hyperæmia of the spinal cord is still more uncertain. We do not know whether active hyperæmia of the cord has in itself any clinical significance. The hyperæmia from stasis, in general disturbances of the circulation, in which certainly the spinal cord often takes part, causes no especially marked symptoms.

2. **Hæmorrhage into the Substance of the Spinal Cord—Spinal Apoplexy—Hæmatomyelia.**—Primary hæmorrhage into the spinal cord is as rare as hæmorrhage into the brain is frequent. In some cases it may arise from traumatic influences, but in others we are disposed to assume a primary disease of the spinal vessels. Perhaps there are occasionally aneurismal dilatations in the cord, similar to those found in the smaller vessels in the brain, and these may give rise to hæmorrhage. Finally, the sudden onset of spinal paralysis has been seen after great physical exertion, and this perhaps is due to a spinal apoplexy. The small spinal hæmorrhages which are seen as a complication in tumors of the cord, and in inflammatory affections such as myelitis, epidemic meningitis, etc., and in the general hæmorrhagic diathesis, as in scurvy or severe general infectious diseases, but rarely have any special significance.

Anatomical experience in regard to primary spinal apoplexy is still extremely slight, but the conditions met with do not differ materially, at any rate, from similar processes in other organs. If the hæmorrhage be abundant, we find the substance of the cord destroyed to a great extent. The apoplectic center usually

extends principally in the long axis of the cord. The blood is still fluid in fresh cases. Later on it undergoes all those changes which are fully described in the chapter on cerebral apoplexy.

The symptoms of spinal apoplexy must in the first place depend entirely upon the seat and extent of the hæmorrhage. The sudden, apoplectiform beginning of the symptoms is always characteristic. Usually in a very short time a more or less complete paralysis, with a severe pain in the back, comes on; the paralysis being usually in the lower extremities, or rarely in the muscles of the trunk and the upper extremities also. There are usually at the same time anaesthesia and paralysis of the bladder; but in this respect, as also in regard to the condition of the reflexes, there are of course many variations according to the seat of the hæmorrhage. Hæmorrhage into one half of the cord sometimes produces the symptoms of unilateral lesion. We need not go into a precise description of the details, since they will follow of themselves from the general rules in regard to the localization of affections of the cord.

The course of hæmorrhage of the cord may in many cases be comparatively favorable. If the blood be absorbed, and essential paths of conduction be not permanently destroyed, the symptoms of paralysis gradually pass away, and recovery or at least improvement and an arrest of the symptoms follow. In many cases, of course, the severe type of spinal paralysis develops, with bedsores, cystitis, etc., and this, after a longer or shorter time, leads to death.

We must always be very guarded in making a diagnosis of spinal hæmorrhage. We can do so with some probability only when the symptoms begin in a pronounced apoplectiform manner, and when definite ætiological factors are to be made out; but we should never forget that many forms of multiple neuritis (*vide supra*), acute myelitis, and even chronic spinal affections, may also show a remarkably sudden onset, or at least may suddenly become worse. The distinction between genuine spinal apoplexy and meningeal hæmorrhage can hardly ever be made with certainty.

*Treatment.*—If we have the rare opportunity to be able to interfere at the beginning of the symptoms, we should prescribe a perfectly quiet position in bed, local use of ice, and eventually ergotine. Later on the treatment should be directed according to the methods generally in use in spinal paralysis.

**3. Functional Disturbances.**—In practice we very often see cases where the patient complains of a set of symptoms which are in all probability of spinal origin; but since all the objective signs of a severe spinal affection are entirely absent, and since the whole development and further course of these cases oppose the theory of a coarse anatomical disturbance in the cord, we have a right to regard them as mere "functional disturbances," and thus to express their relation to certain injurious ætiological influences, and their comparative freedom from danger. We know nothing at all definite as to whether the symptoms are based upon unknown disturbances in the nervous mechanism itself, or whether circulatory disturbances, on a basis of abnormal vaso-motor influences, play a part here; but the types of disease met with clinically are very characteristic, are usually easy to be recognized, and, on account of their frequency, have the greatest practical significance. As a rule, the spinal symptoms are joined to certain cerebral symptoms, since the morbid phenomena present are an expression of a disturbance of the whole central nervous system. The type of disease which is briefly described in what follows, for which the names of spinal irritation or spinal neurasthenia are most in use, is often, then, only a complication of a general neurasthenia, to the description of which we must therefore refer for the details.

The ætiology of the disease is often easy to discover. We have to do with patients upon whom one or more of those injurious influences have acted, which

have an undoubted influence in the development of almost all the neuroses: severe and persistent emotional excitement, mental and physical overexertion, improper methods of living, toxic influences, such as alcohol and nicotine, sexual excesses, such as onanism, etc. Beside these there is very often a hereditary predisposition, a congenital weak resistance of the nervous system, which is often increased by a poor state of the general nutrition. Finally, a hypochondriacal disposition is of great aetiological significance, as it causes not only an abnormally increased attention to the symptoms, but also an abnormal hyperaesthesia to all subjective sensations. The constant anxiety about the dreaded results of any excesses committed is often much more injurious than the excesses themselves. Hypochondriacal dread, too, usually plays the largest part in the neurasthenic conditions frequent among physicians.

The symptoms of the morbid conditions in question usually begin gradually. The patient begins to complain of weakness and fatigue in walking, and also very often of pains in the back and loins, and not infrequently in the extremities also. In spite of the vivid description which the patients give of their pain, they usually have to admit, if questioned about it closely, that the intensity of the pain is really not very great. Besides the pain there are usually many forms of paraesthesia—numbness, formication, cold feelings, etc. The more the patient knows, or at least believes he knows, of the symptomatology of spinal diseases from reading and from associating with other patients, the more detailed are his complaints. Disturbances of the bladder are usually present only in a slight degree, but still they do occur. They often depend merely upon the disturbance of the involuntary reflex mechanism, due to the added factor of increased voluntary attention. There are very often sexual disturbances, which are usually to be referred to former excesses, especially to onanism or to the hypochondriacal condition of the patient.

If we make a physical examination of the patient we can not discover definite signs of a spinal affection. In some of the cases we find an increased sensitiveness of the vertebræ on pressure, which may be limited to a few definite spots, a symptom to which the name of "spinal irritation" is often given; but we often fail to find this tenderness of the vertebræ. Nothing abnormal is to be discovered in the pupils or the reflexes. The tendon reflexes are sometimes quite lively and sometimes weak. The sensibility is objectively perfectly normal; neither can we discover actual paresis or atrophy of the muscles. Vaso-motor disturbances, however, are often seen: abnormal coldness, pallor or redness of the hands, tendency to sweating, etc. The manifold cerebral symptoms, that are usually present at the same time, will be mentioned in the description of neurasthenia. The condition of the general nutrition in many patients remains unchanged, but, of course, some become pale, thin, and weak.

The diagnosis of functional disturbances of the spinal cord is usually not difficult, as we have said, and it may often be made from the history, from the patient's whole outward behavior, and from the manner of his complaints; but we can not lay too much stress upon the injunction that a careful physical examination should always be made, in order to avoid confusion with an incipient serious disease. We shall repeatedly call attention in what follows to the symptoms which must chiefly be observed for this purpose.

In regard to prognosis and treatment we will refer to what is said in the chapter on neurasthenia.

#### 4. Traumatic Lesions of the Spinal Cord.\*—In spite of the protected position of

\* "Spinal concussion" (commotio spinalis) will be considered later, in the chapter on the "traumatic neuroses."

the spinal cord, it is often the seat of severe acute traumatic lesions. Fractures and dislocations of the vertebræ are the most frequent, and these may give rise to considerable injury of the spinal cord by the dislocation of the vertebræ, or by the projection of a fragment of bone. In many cases the cord is injured, not by the affection of the bones directly, but by the occurrence of traumatic hæmorrhage. Gun-shot wounds of the cord are quite frequent, in which the bullet either penetrates the cord itself or produces injury of the vertebræ and hæmorrhage, which involve the cord indirectly. Stabs and incised wounds of the cord have been repeatedly seen. The point of a knife or sword may penetrate the spinal canal through the intervertebral disks and cause a partial section or at least a contusion of the cord. As in all other traumatic lesions of the cord, a secondary "traumatic inflammation" (*vide infra*), with its results, may be added to the direct injury in such cases.

We need not go into all the details of the pathology and symptomatology of the traumatic lesions of the spinal cord, since the number of special conditions is, of course, almost inexhaustible; but it is usually not particularly difficult to judge of a given case, if we follow the rules which generally obtain in the pathology of the cord. We can easily tell when the cord is involved in injuries in its vicinity by the appearance of pronounced motor and sensory disturbances, which, however, differ very much according to the seat and the extent of the affection of the cord. There is usually at first a pronounced and often complete motor paralysis of the lower extremities, and sometimes, when the cervical vertebræ are injured, of the upper extremities also. There is also anaesthesia, differing very much, of course, in extent and intensity in the different cases; and there is very often vesical and rectal paralysis. In many severe cases the secretion of urine seems at first much diminished or wholly wanting. If the spinal roots be affected there are severe shooting pains and paraesthesia. The reflexes are usually diminished at first, but, later, if the injury be above the reflex arc, they are increased; but if the arc itself be broken, they are permanently absent. We often see in men a more or less complete and persistent erection of the penis, which is probably due to a direct or reflex irritation of the nerves of erection. In injuries of the cervical cord we often see a great and general increase of temperature, up to 110° or 112° (43°-44° C.), especially in severe and rapidly fatal cases; this is of physiological interest, and agrees with the results of experiments. On the other hand, there are also, especially in injuries of the dorsal cord, as it seems, great falls of temperature, down to 90° or 86° (32°-30° C.).

The further course of the affection differs very much. In the worst cases death ensues in a few hours or days. In other cases the patients recover from the first "shock," but permanent paralysis remains, which may sooner or later lead to death from the ensuing sequelæ, cystitis and bedsores; but we often see partial improvement and a cessation of all the symptoms. Although certain functional disturbances remain permanently, life is not further endangered. Finally, in one class of comparatively mild cases, there may be a complete recovery.

The treatment of the primary affections belongs to the domain of surgery; especially any attempt to trephine the vertebral column, in order, if possible, to relieve the existing pressure on the cord by reducing the dislocation of the vertebræ or the splinters of bone. In most cases we have to confine ourselves to putting the patient in a proper position on a water-bed, and guarding as carefully as possible against bedsores and cystitis. Locally, the constant application of ice is most to be recommended. We can expect but little from local blood-letting, inunctions with mercurial ointment, etc. If the first acute stage pass off favorably, the treatment of any paralytic symptoms remaining follows the ordinary rules (baths and electricity).

5. **Diseases of the Spinal Cord after a sudden Reduction of the Atmospheric Pressure [Caisson Disease].**—In bridge-builders and others, who have worked for hours under water in the so-called "caissons," under an external pressure of two or three atmospheres, we sometimes see the appearance of peculiar symptoms after leaving the caisson—that is, on the sudden reduction of the atmospheric pressure. Besides the frequent mild symptoms of pain in the ears and hæmorrhage from the ears, articular and muscular pains in the back and the extremities, slowing of the pulse and vomiting, there are also severe disturbances of motility and sensibility, which point unequivocally to an affection of the spinal cord. Usually the lower half of the body is alone affected. The legs are more or less completely paralyzed, the skin is usually anæsthetic up to the trunk, and there is generally retention of urine. The patient sometimes recovers in a few weeks, but in other cases the condition terminates fatally in a comparatively short time—in a few weeks or months. The first special anatomical investigations in question (Leyden, F. Schultze) gave in such cases a disseminated but extensive affection in the dorsal cord, chiefly in the posterior columns and the posterior portions of the lateral columns. The nervous tissue in the diseased parts was completely destroyed, and instead of it was found detritus and a collection of large, round, finely granular cells (fatty granular cells?). Hæmorrhages into the cord, which might perhaps be expected, have up to the present time not been found.

Nothing definite is known as to the precise process in this form of spinal disease. Leyden suspected that there was a development of gas from the blood which caused a rupture of the surrounding tissue, under the influence of the rapidly diminished barometric pressure, as Hoppe-Seyler and P. Bert have discovered by experiment; but the circumscribed limitation of the affection to the dorsal cord, and the lack of any signs of vascular hæmorrhage, speak against this theory.

The treatment is the same as in acute myelitis.

### CHAPTER III.

#### THE PRESSURE PARALYSES OF THE SPINAL CORD.

(*Slow Compression of the Spinal Cord, especially in Caries and Carcinoma of the Vertebra.*)

**Ætiology.**—Many pathological processes which develop in the vicinity of the spinal cord may exert a gradually increasing pressure upon it, and thus, on the one hand, inhibit the conduction of nervous irritation, and, on the other, cause coarse mechanical injuries in the substance of the cord. The seat of such affections is in the first place in the membranes of the spinal cord. In the chapter on meningitis we have already mentioned the compressing action of the masses of inflammatory exudation on the nerve-roots and the cord, and we have learned to recognize, especially in pachymeningitis cervicalis hypertrophica, a characteristic example of a gradually increasing compression of the cervical cord. Precisely similar conditions are found in the rare meningeal tumors, whose special pathology will be described in connection with the tumors of the cord itself.

By far the most frequent pressure paralyse of the spinal cord, and hence the most important practically, are caused by certain diseases of the vertebrae, and first of all by chronic caries of the vertebrae (spondylitis, Pott's disease, spondylarthrocace).\* There is no longer any doubt at present that certainly the greatest

\* In the kyphoscolioses of the vertebral column, not due to spondylitis, there are practically never any symptoms of compression in the cord, even in very pronounced cases. In these cases the cord manifestly shows quite a great adaptability.

part, if not all, of the cases of vertebral caries are of tubercular origin, that vertebral caries is a local tuberculosis of the vertebræ. Although these facts were formerly rendered very probable by the histological conditions of the process, and by its frequent relation to other unquestionable tubercular diseases, such as phthisis, miliary tuberculosis, and tubercular meningitis, they have of late been confirmed beyond a doubt by the discovery, which can usually be made, of tubercle bacilli in the cheesy nodules of the vertebral caries. Tubercular spondylitis occurs at almost any age; it is rare only in old people. It often develops in children, but it is almost as frequent in adults. The ætiological significance of injuries, such as a fall or a blow, which are often mentioned by the patients themselves or their parents, is in most cases doubtful; but we can very often succeed in finding ætiological factors for the onset of tubercular disease in general—the tubercular habit, hereditary tendency, or tubercular disease elsewhere, such as phthisis, pleurisy, other affections of the bones, etc.

Cancer of the vertebræ, as well as caries, leads to pressure paralyse of the spinal cord; but it is relatively much rarer than caries, it develops chiefly in older persons, and it occurs both as a primary new growth and also as secondary to cancer of other organs—the breast, the stomach, or the œsophagus.

We must mention here briefly, as very rare causes of compression of the spinal cord, aneurism of the aorta, which gradually erodes the vertebræ, echinococci in the vertebral canal, exostoses of the vertebræ, and syphilitic new growths.

**Pathological Anatomy.**—Vertebral caries is most common in the dorsal portion of the vertebral column (dorsal spondylitis), somewhat rarer in the cervical portion (cervical spondylitis), and rarest in the lumbar portion (lumbar spondylitis) and in the sacrum (sacral spondylitis). It usually extends over several adjacent vertebræ, or more rarely two separate foci of disease are seen. The process itself, the details of which can not be discussed here, probably always begins in the spongy substance of the bodies of the vertebræ. We see here, on section, in incipient cases, roundish, pale reddish, or yellowish nodules, which consist of newly formed fungous tissue—that is, tubercular granulation-tissue. The bony substances become more and more destroyed by the invasion of the new growth, which itself shows the characteristic tendency of all tubercular new growths to cheesy degeneration. Thus there is often an extensive destruction of the bodies of the vertebræ, which later on also involves the vertebral processes, the intervertebral disks, and the other articular connections between the different vertebræ.

There are essentially two factors to be considered in regard to the question which chiefly interests us here—that is, in regard to the occurrence of compression of the spinal cord. In the first place, it is clear that the complete or partial destruction of the bodies of one or even more vertebræ, and of their articular connections, can not remain without influence upon the position of the other adjacent vertebræ. In fact, we very often see dislocations of the vertebræ as a result of it, usually by the pushing backward of the partly destroyed vertebra by the movements of the vertebræ above and below the diseased portion on one another (see Fig. 82). There arises, on the one hand, a contraction of the vertebral canal, and with it often a very considerable limitation of the space for the cord; and, on the other hand, that characteristic projection of the spinous processes in the region of the diseased portion of the vertebral column which forms the so-called Pott's boss—the angular kyphosis. In very slight degrees of the disease there is only a slight

FIG. 82.—Schematic representation of vertebral displacement in spondylitis. The point of compression of the cord, at the level of the second dorsal vertebra, is at C.

projection of one or more spinous processes, but in other cases it gradually becomes an extensive deformity of the vertebral column, which strikes us at the first glance. It goes without saying that, under some circumstances, the Pott's boss may be entirely absent in vertebral caries.

The second factor, which is often to be considered in the mechanism of compression of the cord, is the formation of foci of cheesy pus on the posterior surface of the bodies of the vertebrae. Since the inflammatory tubercular new growth involves the periosteum, there are often formed here large collections of cheesy pus, which are situated beneath the periosteum, raise it, and push it out far into the vertebral canal. In other cases, the tubercular new growth still further directly involves the outer surface of the dura, and forms here extensive cheesy masses which of course may also cause a compression of the cord. The inner surface of the dura at the corresponding parts is usually markedly injected, but a direct invasion of the pia by the tubercular process through the dura is rare.

If now a considerable contraction of the vertebral canal have arisen from dislocation of the vertebrae, or from the projection inward of the cheesy purulent masses into the canal, the necessary mechanical consequences in the spinal cord itself are usually to be recognized with ease. The cord appears smaller at the point of compression. If the narrow part correspond to a bend in the vertebral column, we can very often see a marked angle of bending on the anterior surface of the cord. The consistency of the cord at the part affected, the extent of which seldom exceeds a few centimetres, is usually diminished; the cord is soft and may be easily bent. In old cases only do we find the cord itself harder than normal and sclerosed (*vide infra*). It is very remarkable, however, that often, as we have repeatedly seen, marked symptoms of compression may be present during life without finding any coarse mechanical lesion of the cord in the cadaver, so that the cord may show an almost perfectly normal appearance. As in the peripheral nerves, so in the spinal cord, a moderate pressure is manifestly enough to excite a partial break in the conduction, without being at the same time necessarily associated with an actual mechanical destruction of nervous elements. On careful microscopic examination of the cord, we find in such cases, in spite of the existence of a complete paraplegia during life, that most of the nerve-fibers are still completely preserved, and that there are only here and there a few lacunae, corresponding to single fibers, which have been destroyed. This discovery is especially interesting because it makes us understand the possibility of recovery, even in apparently severe cases (*vide infra*).

Even where we can find considerable histological changes in the spinal cord, however, where the softness of the cord points to a coarse lesion of it, and where the microscope shows the destruction of a great part of the normal tissue at the point of compression, all these changes are merely the necessary results of the purely mechanical pressure on the spinal cord. As we must maintain, against the theory generally received at present, on the ground of many of our own investigations, we have not the slightest reason to refer the occurrence of paralysis in spondylitis to a secondary myelitis. Such a "compression myelitis"—that is, an inflammation of the spinal cord arising from the pressure as such—is to be rejected from general pathological reasons; and the microscopic examination of the cord also shows nothing which points to an inflammation, or which may not be entirely the result of mechanical compression. If we take a portion from the soft place of compression for fresh examination, we find sometimes many, sometimes only a few, granular cells, according to the amount of disintegrated nerve-medulla, the remains of which are taken up by the white blood-corpuscles—the wandering cells. If we make stained cross-sections of the hardened cord, we see under the microscope no signs of vascular changes, of hyperæmia, of accumula-

tion of cells about the vessels, and only exceptionally a little traumatic hæmorrhage; but we do find, besides many still preserved nerve-fibers, other fibers, which are involved in the disintegration or are already destroyed. Very commonly the changes are distributed in the form of nodules. We find groups of greatly swollen axis-cylinders, which have wholly, or almost wholly, lost their medullary sheaths, and in other places we notice already the signs of their disintegration, or the already empty lacunæ in the meshes of the neuroglia. If the destruction of the nervous tissue have advanced to a certain degree, there is in the later stages, as in all analogous processes, a secondary implication of the neuroglia. Now follows an increase of the interstitial connective tissue. Its proliferations, which take the place of the destroyed nervous tissue, seem diffuse—at first loose, but later firm and fibrillary. Thus it happens that in old cases we find nothing at the point of compression but a loss of nerve-fibers in the cord, and instead of it there is a firm fibrous tissue. All the changes mentioned are always much more developed in the white matter of the cord than in the gray.

Finally, after a more protracted compression of the cord we find an ascending and descending secondary degeneration of certain systems of fibers in the cord (*vide infra*).

We need not go more fully into the details of compression of the cord from other causes, since the results, as far as they are of a purely mechanical nature, are precisely the same. In cancer of the vertebræ there may also be dislocations of the vertebral column after the destruction of some of the vertebræ, but usually the compression depends upon the direct growth of the newly formed tissue into the dura. In these cases the compression of the nerve-roots in the intervertebral foramina is also of importance.

**Clinical History.**—Many cases of spondylitis run their course without involving the cord, or at least involving it only in quite a subordinate fashion. In other cases the symptoms of disease of the vertebræ exist for a long time alone, until at last, slowly or suddenly, the signs of compression of the cord are added to them. Finally, in a third group of cases, the vertebral disease is so latent that only the cord symptoms are prominent in the type of the disease, and the disease of the vertebræ may easily be entirely overlooked.

Usually the symptoms of the developing primary disease, the affection of the vertebræ, precede the appearance of the first cord symptoms by some time. The patient feels a dull pain at a definite part of the spine, which is increased by movements of the trunk, by bending or straightening up. Many patients notice the stiffness of the vertebral column of themselves, and sometimes even a beginning deformity. The first cord symptoms usually consist of painful sensations, which are not confined to the place of the disease, but shoot out approximately along the course of the nerve-paths. These pains, which are due chiefly to an irritation of the nerve-roots caused by the compression, extend, according to the seat of the affection, into the shoulders and arms, into the lateral portions of the trunk, or into the lower extremities. They are sometimes very severe, and then they usually have a pronounced neuralgiform character, or they may be more dull and dragging. Besides the special pains, there are also many forms of paræsthesia, such as formication and cold feelings.

The disturbances of motility begin to appear at the same time with these symptoms or soon after them. A stiffness and weakness arise which impede the gait, usually not in both legs at once, but first in one and then in the other. This paresis increases rapidly or slowly, and it may finally go on to a complete motor paralysis. If the seat of the affection be in the dorsal vertebræ, as it usually is, or if it be in the lumbar vertebræ, the paralysis affects the lower extremities only, and the arms, of course, remain intact; but in cervical spondylitis the arms are

usually first and chiefly affected. Only on great compression of the cervical cord is the conduction of the fibers passing through it for the lower extremities impaired, and then there are also disturbances of function in these.

Disturbances of sensibility are often found, independently of the pains and paræsthesiæ above mentioned, but in many cases of pressure paralysis they are present in only a comparatively slight degree. It seems that the sensory nerves resist pressure more than the motor nerves, just as in the pressure paralyzes of peripheral nerves; but possibly their position in the gray matter of the posterior cornua protects them better from mechanical attack than is the case, for example, with the motor fibers in the pyramidal tract (see Figs. 66 and 67). The fact is that often, even in complete motor paraplegia, there is little if any diminution of sensibility, and that marked anaesthesia is rare, and is seen only in the last stages of the disease. We find most frequently a slight blunting of sensibility equally to all forms of sensation, especially to the sense of pain. The different parts of the skin not infrequently act differently, so that we find portions with quite normal sensibility, as well as very anaesthetic portions.

The condition of the reflexes is interesting. If the seat of the compression be above the reflex arc, which we must assume to be in the lumbar cord for the reflexes of the lower extremities, we should expect that the reflexes would persist, and in many cases even be increased, corresponding to the decline in the inhibitory influences coming from above. The latter takes place invariably with the tendon reflexes, which are always increased in the lower extremities in the pressure paralyzes arising from the cervical or dorsal cord. The increase of the tendon reflexes may reach so great a degree as to show in the lower extremities the pronounced type of spastic paralysis (*vide infra*). The limbs are then found in a rigid tonic extension, they can only with difficulty be flexed passively on account of the muscular resistance, and they show a very vigorous ankle clonus, sometimes degenerating into a general tremor of the leg, and also marked patellar reflex, adductor reflex, etc.; but even in flaccid paraplegia the tendon reflexes may be quite vigorous. In cervical spondylitis the tendon and periosteal reflexes in the arms are also increased sometimes, but in other cases, if the reflex arc be injured, they are absent. Where the seat of the compression is above the lumbar cord, the cutaneous reflexes sometimes show considerable vigor, but their increase is much less frequently as marked as is the increase of the tendon reflexes. In severe pressure paralyzes in the dorsal cord the cutaneous reflexes are even frequently diminished. They are probably never entirely absent, but one must understand testing them, and must employ long-continued cutaneous irritation, such as pinching and pricking, in different parts of the skin in order to provoke them.

Trophic disturbances are often found in the paralyzed parts. If there be severe symptoms of sensory irritation there may sometimes be eruptions of herpes, corresponding to the course of the nerves. More frequently there are chronic disturbances in the nutrition of the skin in severe and long-continued cases. It becomes dry, the epidermis scales off, and the nails become brittle. Bedsores form very easily in severe cases on the sacrum, on the buttocks, on the inner side of the knees, and on the heels, especially when the patient has insufficient care. The muscles retain their normal volume and their normal electrical excitability in many cases as long as their trophic center remains uninjured; but sometimes, even when the point of compression is above the lumbar cord, there is a great atrophy of the muscles of the legs, although the electrical reaction of the nerves is normal, or at most a little reduced in quantity. If the lesion involve the lumbar cord itself, or the fibers of the cauda equina, in caries of the sacrum, there must, of course, be an atrophic paralysis in the legs, with reaction of degeneration. There may also be an atrophic paralysis in the arms in cervical spondylitis.

Disturbances of the rectum and bladder occur in almost all severe cases of pressure paralysis. The difficulty of micturition is often an early symptom of the disease; later on there is complete retention of urine, and, in the more advanced stages of the disease, there is usually incontinence. With this the danger of the development of cystitis becomes very great. The bowels are usually constipated, but sometimes there is also incontinence of feces.

Thus we see, under some circumstances, in compression of the cord the whole group of symptoms arising which are the necessary consequence of the break in conduction in the spinal cord, and which we shall likewise meet again in various other spinal affections, especially in myelitis and in tumors. The intensity and selection of the symptoms must, of course, vary very much in the different cases. If the compression be quite slight, there are only mild symptoms of sensory irritation and slight paresis. One of the earliest and most constant signs of a compression of the cord, in the dorsal or cervical region, is a decided increase of the patellar reflex. We sometimes find it at a time when there is scarcely a single other cord symptom present. If the compression increases, the paresis becomes more marked, the disturbance of sensibility is greater, and vesical disturbances arise, until finally the complete type of an entire transverse interruption of conduction in the cord is developed; but the latter is but rarely the case, since, as we have said, the conduction of sensory impressions is usually not wholly abolished. The time required for the development of the symptoms of spinal compression differs very much. They sometimes attain a considerable height in a short time, and sometimes they develop only after a course of months. Variations in the intensity of the symptoms are frequent, and they point perhaps to a corresponding variation in the severity of the compression.

In regard to the result of pressure paralyzes, it, of course, depends first upon the nature of the primary disease. In tumors, especially in cancer of the vertebrae, recovery is not to be thought of, but spondylitic processes without doubt can recover, which is by no means in contradiction to their character as a local tubercular process. In this connection the fact is of great practical importance that even the pressure paralyzes may be completely restored, as far as the cause of the compression can be removed by the absorption of inflammatory and tubercular new growths, so that a complete and permanent recovery may take place even after the paralysis has lasted for some months, or a year, or even a year and a half. Such recoveries have been seen in great numbers by others and also by ourselves.

Although, according to this, the prognosis in a part of the cases of pressure paralysis from spondylitis is comparatively good, still many other cases terminate unfavorably. The cause of this lies either in the occurrence of dangerous sequelae of the paralysis, such as bedsores, cystitis, or pyelo-nephritis, with fever and increasing general weakness; or in the development of other tubercular diseases, especially phthisis, or more rarely miliary tuberculosis or tubercular meningitis, which prove fatal.

**Diagnosis.**—The frequency of the pressure paralyzes of the spinal cord admonishes us to examine the vertebral column carefully in every case of spinal disease, especially if the case can not be put under one of the special types of systemic diseases (*vide infra*). We should look especially for the stiffness of special parts of the vertebral column on movements of the head or trunk, and also for the pronounced tenderness of single vertebrae to pressure, and, finally, as a most important and most certain sign, for the deformity of the vertebral column, the marked projection of a single spinous process, or the formation of an evident angular kyphosis. If we find such a Pott's boss the diagnosis is easy, and we can then at any rate refer the existing cord symptoms to a compression of the cord caused by a disease of the vertebrae.

The diagnosis is more difficult if the signs of an affection of the vertebræ be not evident. It must once for all be stated that vertebral caries does not invariably and necessarily result in a manifest Pott's boss, and that even the tenderness of the vertebræ to pressure is sometimes very slight in spondylitis. In such cases the examination of the vertebral column must be repeated more frequently, since even slight anomalies obtain a diagnostic value if constantly present; and the whole course of the disease is also to be considered. The most characteristic features of a compression of the cord are its beginning with symptoms of sensory irritation, the preponderance of symptoms of motor paralysis with comparatively little disturbance of sensibility, and finally the frequent asymmetry of the symptoms on the two sides, which may even recall the type of the so-called "unilateral lesion" of the spinal cord (*vide infra*). Sometimes the cause of the spinal symptoms is at first obscure, and later on in the disease a marked anomaly of the vertebral column develops.

If the diagnosis of an affection of the vertebræ be certain, the next question is as to the nature of it, especially whether we have to do with a spondylitis, or with a cancer of the vertebræ. Since spondylitis is by far the more frequent disease, we must always think of that first, especially in young people, and where we have the formation of a pronounced angular kyphosis. In cancer of the vertebræ the coarser changes in the form of the vertebral column are generally less marked. This develops usually in older people, after the age of forty, and is manifested by the great intensity of the initial symptoms of sensory irritation. The "*paraplegia dolorosa*," the paralysis of the lower extremities associated with severe pains, is the most characteristic symptom of cancer of the vertebræ. The discovery of a primary nodule of cancer, as in the breast, or, as we ourselves have seen, the appearance of a swelling of the inguinal glands, may serve to support the diagnosis. Finally, a certain stress is to be laid on the well-known general habit of patients with cancer, and on the peculiar cancerous cachexia.

The place of compression is, in the majority of cases, to be recognized by the evident localization of the disease of the vertebræ. In other respects the same rules hold for localization which we shall discuss more fully in the description of myelitis in the following chapter.

**Treatment.**—In regard to the special treatment of spondylitis, especially the orthopaedic treatment, we must refer to the text-books of surgery. In general, we have not thus far gained the impression that a particularly favorable influence can be exerted on the symptoms of spinal compression by contrivances for extension of the vertebral column. These are often injudicious where there is paraplegia, since they increase the pain and make it harder to guard against bedsores. We would not deny, however, that in many cases certain supports for the vertebral column, and contrivances for extension, may be used to advantage. Permanent rest in bed is, at any rate, always of the greatest importance. Local applications to the vertebral column are much used—dry cups, painting with iodine, and especially the hot iron. The use of the latter in spondylitis has even to-day warm advocates, and, in fact, deserves to be tried, the procedure with Paquelin's thermocautery being especially easy; we make some three or four eschars on each side of the diseased vertebræ.

Among other remedies we may mention stable galvanization at the point of pressure, and the electrical treatment of the paralyzed extremities; also the use of baths, especially salt baths, and, finally, the internal use of compounds of iodine—iodide of potassium and iodide of iron. In regard to the symptomatic treatment we will refer to the following chapter.

[In a few cases great benefit has been derived from trephining the vertebræ and removing the inflammatory products which have compressed the cord. In some

cases a patient who was completely paraplegic has regained considerable use of the legs. It is obvious that the operation should not be too long delayed after symptoms of pressure have once developed.—K.]

#### CHAPTER IV.

#### ACUTE AND CHRONIC MYELITIS.

(*Diffuse Myelitis. Transverse Myelitis.*)

**Preliminary Remarks.**—The pathological processes in the spinal cord known to us at the present time may be divided into two groups. In the first group we find this peculiarity, that the pathological changes are confined, with a remarkable constancy, to certain definite parts of the spinal cord, so that consequently the clinical symptoms of the disease may be quite exactly defined. To this group belongs the disease known as anterior poliomyelitis (πολιός, gray), which is localized almost exclusively in the anterior cornua of the gray matter of the spinal cord, and also a class of affections, such as tabes dorsalis, amyotrophic lateral sclerosis, etc., in which perfectly definite fasciculi in the cord are diseased. From the comparison of the anatomical lesions in these cases with our other knowledge as to the structure and functions of the spinal cord, it has been shown that the diseased portions occupy a distinct position, even in their anatomical and physiological relations. Hence we are justified in terming these affections of the cord systemic diseases. We can not at present give a correct explanation of the remarkable fact that such isolated diseases may occur in parts of the cord which have perfectly definite functions, in "systems of fibers." We must imagine that the factors which cause the disease, in such cases, do not exert their influence upon the whole cord, but only upon the fibers and cells of a definite system; an idea which finds a fitting analogy in the action of many poisons, such as curare, strychnine, lead, etc.

Besides the systemic diseases there is a second group of affections of the cord in which there is not, by any means, such a limitation of the process to definite portions of the cord. In these cases the disease extends more or less widely over the cross-section or the length of the cord, and forms either one large focus, or several single smaller foci, separate from one another. To this group, to the unsystemic, diffuse diseases of the spinal cord, belong the hæmorrhages and traumatic lesions already described, and the new growths, the acute and chronic "inflammations" of the cord (diffuse myelitis), multiple sclerosis, etc.

Since in the diffuse diseases of the spinal cord all those portions may be affected whose isolated affections form the systemic diseases, of course all the clinical symptoms of the latter may also be found in the diffuse affections; for the individual symptoms of spinal disease, as such, never depend upon the form of the pathological process, but only upon its situation, and upon the irritation or interruption of conduction in certain nerve-tracts caused by it. The diagnosis of spinal diseases, therefore, is, in the first place, always a topical diagnosis. We seek to recognize, from the functional disturbances prominent in the different cases, the place in the cord in which the affection must be situated, which has as a consequence these disturbances. By comparing all the existing morbid symptoms, and by attending to the functions which are still normal, we can decide whether the affection is limited in a systemic fashion to a special physiological region, or whether it extends in a diffuse, irregular fashion over a greater portion of the cord. In the former case we usually have no difficulty in finding a connection

with the different well-known typical forms of disease; in the latter case we can at least decide the main point, as to the extent and seat of the disease, and then, from the whole course and the combination of the morbid symptoms, we can also draw our conclusions, as far as it is possible, as to the form of the affection.

After these general remarks we will pass on to the description of myelitis.

**Ætiology.**—Hardly anything certain is known as to the causes of diffuse myelitis, in the same way as little is known in regard to the ætiology of diseases of the spinal cord in general. We often see the disease develop in men previously healthy, without being able to discover any influence which may act as a cause of the disease. In those cases, too, where we may at least ascribe a possible ætiological significance to certain conditions, we are still completely in the dark as to the manner in which they act.

The factors which seem to be most frequently related to the development of myelitis are as follows: Exposure to cold, especially repeated wettings, and working in the open air under unfavorable conditions; bodily fatigue and overexertion, especially when combined with the factors first named, as in the hardships of war, etc. The ætiological significance of profound emotions and sexual excesses, which formerly were often mentioned in the ætiology of myelitis, is extremely doubtful as far as the development of anatomical changes in the cord is concerned.

The occasional appearance of spinal disease after certain acute infectious diseases, such as typhoid, small-pox, or puerperal affections, favors the possibility of infectious causes; but these cases are very rare in comparison with the great number of cases of primary myelitis, and their anatomy is also but little known. Syphilis probably has a greater importance, although our knowledge on this point is not so broad that we can give a definite description of "syphilis of the spinal cord"; but, at any rate, it is quite striking that in the history of patients with diffuse myelitis, especially in myelitis in the upper dorsal region, we quite often get, as it seems to us, an account of a former syphilitic infection. Of course, in any individual case, the actual connection between the two diseases can hardly ever be proven with certainty.

It is proven with regard to purulent spinal meningitis that inflammations of neighboring organs may invade the spinal cord. In most of the other cases which are usually cited in regard to this point, we have to do with confusions between lesions of the cord from mechanical pressure and actual myelitis, as we have explained in detail in the previous chapter on compression of the cord. Hence we consider it unjustifiable to speak of a "traumatic myelitis" except in very rare cases. If spinal symptoms develop after an injury, we usually have to do either with the type of symptoms described above under spinal concussion, or with genuine traumatic lesions of the vertebrae, or sometimes perhaps with traumatic hæmorrhages, etc., which always excite disturbances in the functions of the spinal cord by mechanical conditions alone. Finally, in regard to the theory of an "ascending neuritis"—that is, the supposed extension of an inflammation from the nerves to the cord—it is a hypothesis that is still very much in need of further confirmation.

**Pathological Anatomy.**—Macroscopic examination of the cord in its fresh condition shows no marked pathological changes except in a small number of cases. At the first glance, the spinal cord often seems almost completely normal, even if there have been severe spinal symptoms during life, and sometimes the opacities and adhesions of the pia, which often strike us at first, have no practical importance. If we test the consistency of the cord carefully by touching it, of course a change in it often strikes the practiced examiner, since the cord over a definite extent is either softer and more flexible, or, on the other hand, harder and firmer. If we

now make a number of cross-sections through the cord, we notice that the substance of the cord rises up more on section, that the outline of the gray matter is less distinct, and especially that the white matter is of a reddish-gray color, and that sometimes there is also a reddish, hyperæmic coloring of the gray matter. In some cases we can recognize small capillary hæmorrhages with the naked eye, but the macroscopic examination of the fresh cord is never sufficient for the precise determination of the extent and intensity of the disease.

The changes are much more plainly visible if we harden the cord in chromic acid, or Müller's fluid,\* for at least eight or ten weeks. All the normal parts of the white matter of the cord assume a dark-green color from the acid, which is really due to the staining of the medullary sheaths. The diseased portions, in which the medullary sheaths are mainly if not entirely absent, are thus often very sharply distinguished from the healthy, dark-green portions. Since similar differences in color between healthy and diseased tissue are also noticed in the gray matter, although less sharply defined, the cross-section of the cord, well hardened in chromic acid, usually gives quite a correct idea of the extent of the disease.

We obtain more precise disclosures, however, as to the form of the anatomical changes by microscopical examination. When made on the fresh, unhardened cord, it affords little information. The presence of numerous granular cells (*vide infra*) in fresh teased-out preparations is the only thing that is important, since they show with certainty the existence of a pathological change. If, however, we make fine cross-sections of the hardened cord, and stain them with carmine or some similar staining fluid, even the naked eye notices at first a marked difference between the diseased and the healthy tissue, since the former, which is almost always richer in connective tissue, has a much darker staining, and thus is distinguished from the brighter normal tissue. The microscopic examination now shows that in the diseased parts the normal nerve-tissue has been almost wholly or at least partly destroyed. Only occasionally do we see nerve-fibers of normal appearance remaining here and there. In other places the fibers that are still visible are smaller and atrophied, and the axis-cylinders have in part lost their medullary sheaths, or are swollen. The changes in the ganglion-cells are harder to follow, but in more advanced cases they also show marked signs of destruction; they are contracted, rounder, and have lost their processes. The increase of the connective tissue corresponds to the destruction of the nerve-substance. The meshes of the neuroglia extend and swell, so that the space formed by the destruction of the nerve-tissue is in great measure taken up by connective tissue. The older the process, the firmer and more fibrous is the connective tissue. The nuclei of the neuroglia increase in number, and we often find a very great increase in those peculiar, flat, connective-tissue cells with many processes, first described by Deiters, and named after him—the so-called "Deiters' spider-cells." The fatty granular cells are also easily recognized in hardened preparations, so long as they are not treated with alcohol. They lie in the interstices between the meshes of the neuroglia, and are especially numerous about the vessels. They are to be regarded either as white blood-corpuscles, or as endothelial cells from the sheaths of the vessels, which have taken up the fat from the disintegrated nerve-substance. If, therefore, the process be still fresh, or if it be still advancing, the fatty granular globules are to be met with in great numbers, while in old, sclerosed nodules, only a few of them, or scarcely any, are to be found. The changes in the vessels are usually very striking. They are often dilated and congested. Here and there

[\* The formula for Müller's fluid is as follows: Two and a half parts of potassic bichromate, one part of sodic sulphate, and one hundred parts of water.—TRANS.]

there may be hæmorrhages. The vascular walls are thickened, especially in old cases, and sometimes have become peculiarly homogeneous—"hyaline degeneration"; and a large accumulation of nuclei may be found about the vessels. The so-called corpora amylacea are sometimes present in great numbers, and sometimes they are only scanty. Their significance and their genesis are still unknown.

The extent of the whole process varies very much in different cases. We usually find one main focus of myelitis, which extends in a diffuse manner over the greatest part of the transverse section of the spinal cord, and may reach upward and downward for a space of five to ten centimetres or more. The dorsal portion of the cord is most frequently affected (dorsal myelitis), the upper half being usually most involved, but in some cases the lower half is chiefly affected. Nearly the whole of the dorsal cord is often the seat of a diffuse inflammatory affection, which, of course, differs in extent at different levels. In other cases the chief focus of disease is in the cervical cord (cervical myelitis), while it is most rare in the lumbar cord (lumbar myelitis). We often find small, distinct foci in the vicinity of the main focus. In all severe cases there develops later on a systemic ascending and descending secondary degeneration (*vide infra*).

We have intentionally avoided any division of the process into different stages, because, according to our present knowledge, this can be only artificial. As a general rule, the cases where the cord is soft and has more of a reddish-gray color, where the fatty granular cells are still abundant, and the meshes of the neuroglia are not yet fibrous, may be considered as belonging to the comparatively more acute and fresher stages; while in the older cases the cord has become firmer, "sclerosed," in the affected part, through the formation of a denser fibrillary connective tissue, and it has more of a gray appearance; but we can not draw a sharp distinction between acute and chronic myelitis in regard to their pathological anatomy. Genuine transverse myelitis always shows a chronic course, and many cases deserve the name of "acute myelitis" in their clinical aspect only in so far as the beginning of the morbid symptoms is acute and rapid. We may entirely disregard actual abscess of the cord, because it is so rare that it very seldom comes into question as an independent disease. It is still undecided whether there is a softening of the cord analogous to the foci of softening in the brain—that is, as a result of an obstruction of the vessels by a thrombus or embolus. At any rate, an actual softening of the cord is quite rare—that is, a change of the substance of the cord into a soft pulp, which contains nothing but the remains of the nerve-tissue and some fatty granular cells. We have seen ourselves only one such case, in the lower dorsal region, which lasted two years as a chronic transverse myelitis, and ended fatally.

**The Individual Symptoms of Myelitis.**—The course of transverse myelitis differs so much in the different cases that it is impossible to give a picture of the disease which will be generally applicable. According as one or another part of the cord is involved, the clinical symptoms will affect chiefly the sensibility or the motility, the trophic functions or the reflexes, and will be present in the upper or the lower extremities, or in both at once. The following description will, therefore, be devoted first to the single symptoms, and will give the inferences which, according to the present state of our knowledge, may be drawn from their presence as to the seat and the extent of the anatomical process.

1. **SYMPTOMS OF MOTOR PARALYSIS** are not only the chief symptoms, as a rule, in well-developed myelitis, but are often the first sign of the beginning of the disease. The patient feels at first only a slight weakness in one or both legs; he gets tired more easily in walking, and begins to "drag" his legs after him. The motor weakness gradually becomes greater and increases to complete paralysis. The

patient is then bed-ridden, and, finally, can not make the least active movement with his legs. The symptoms of paralysis in the arms are analogous.

Since the chief paths for the conduction of voluntary motion are situated, as we have seen, in the lateral columns of the spinal cord, and especially in the lateral pyramidal tract, we conclude, in every spinal disease where symptoms of paralysis are present, that there is an interruption of this tract—that is, an implication of the posterior portions of the lateral columns. Since in transverse myelitis the whole cross-section of the cord is more or less involved, the paralysis also extends to the two halves of the body: motor paraplegia is the characteristic form of paralysis for transverse myelitis. Paraplegia of the lower extremities may of course arise wherever the myelitis is situated, whether in the lumbar, dorsal, or cervical region; but the upper extremities necessarily remain entirely free in every dorsal or lumbar myelitis. The occurrence of paretic symptoms here, and the final development of a brachial paraplegia, point with certainty to an implication of the cervical region, to a cervical myelitis. If the symptoms of paralysis are not alike in the two corresponding extremities, but are more marked on one side than on the other, the anatomical affection must also be more intense on that side of the cord than on the opposite side.

2. SYMPTOMS OF MOTOR IRRITATION of various sorts are often seen, both at the beginning and during the whole course of myelitis. Single twitchings come on spontaneously in the limbs, which are at the same time paralyzed, or at least paretic, and these twitchings are short and rapid or slow and persistent. The thighs are drawn up on the abdomen, or there are severe spasms of the extensors. The interpretation of these symptoms is not always easy. It is often particularly hard to decide whether they are the result of a direct irritation of motor fibers in the cord, or whether they represent reflexes (*vide infra*). The value of the symptoms of motor irritation for the localization of the disease is accordingly slight, but, of course, in these cases we must chiefly consider the motor tracts in the lateral columns.

Ataxia and intention tremor are comparatively rare, but they are most frequent in the upper extremities. They are also seen in the stage of convalescence in acute cases.

3. DISTURBANCES OF SENSIBILITY.—The disturbances of sensibility usually appear to a marked degree only in the later stages of the disease. At the outset we usually notice merely mild symptoms of sensory irritation, such as formication, prickling, numbness, a woolly feeling, etc., while severe pain is hardly ever present in transverse myelitis, and hence it always points to some affection of the vertebrae or the meninges. Slight diminution of sensibility is often to be made out early on careful examination, but, in many cases, the sensibility remains for a long time wholly, or almost wholly, intact, either because the localization of the disease spares the sensory portions of the cord, or because the sensory paths of conduction are more resistant, or can act vicariously for one another to a higher degree. In the further course of the disease, however, there are almost always more marked disturbances of sensibility: at first a simple diminution in the sensitiveness of the skin, sometimes partial paralyses of sensation, analgesia, paralysis of the sense of pressure, and finally frequently a complete anæsthesia. On the other hand, we see in many cases a striking hyperæsthesia to painful stimuli, such as a pin-prick.

From the presence of marked disturbances of sensibility we can conclude with certainty that there is an affection of the posterior columns, and especially of the posterior cornua of the gray matter. With marked anæsthesia the latter are always involved. It is still very doubtful whether the statement made by Schiff, that the conduction of painful sensations is chiefly in the gray matter, and the

conduction of tactile sensations is chiefly in the white matter, holds in man. The pathological facts, as we have said before, also give no support at all to the theory that there are sensory fibers in the lateral columns in man.

The disturbance of sensibility gives important service in estimating the height at which the affection in the cord is situated. If we search on the trunk for the line where the cutaneous sensibility becomes normal, we may place the upper boundary of the myelitis, as far as it disturbs the sensibility, at approximately the same level. In myelitis in the lumbar region the disturbance of sensibility reaches to the umbilicus, or even a little higher; in myelitis in the lower dorsal region it reaches about to the lower end of the sternum; in myelitis in the upper dorsal region to the level of the axillæ; and in cervical myelitis the sensibility of the upper extremities is also impaired, but complete anæsthesia is very rare.

4. CUTANEOUS REFLEXES.—As is well known, the reflex arcs in the cord are found at about the same level as the centripetal sensory and the centrifugal motor fibers. They are also connected with fibers which come from above, and to which must be ascribed the property of reflex inhibition. If these fibers above the reflex are put into a state of irritation, the reflex is thereby impaired; but if the conduction be broken in these fibers, the reflex activity appears increased, the reflex comes on at a weaker irritation, and the contraction is more vigorous. If the reflex arc itself be broken at any point, the reflex must disappear.

The data from the examination of the patient may generally be harmonized with this scheme, although, of course, the reality probably shows more complicated conditions. In extensive lumbar myelitis, by which the reflex path in the lumbar cord is broken, the cutaneous reflexes in the lower extremities must be diminished or absent. In these cases the loss of sensibility runs about parallel to the diminution of the reflexes. In dorsal and cervical myelitis, however, the reflex arc in the lumbar cord remains unimpaired, but the conduction of sensory impressions to the brain may very well be interrupted. In these cases the cutaneous reflexes are retained, even when there is anæsthesia; or, if the reflex inhibitory influences be removed, they are decidedly increased. The cutaneous reflexes in the legs, however, may be diminished, even in disease above the lumbar cord, in which case we must imagine a loss of irritability in the fibers which take part in the reflex, or an irritation of the reflex inhibitory fibers. The cremaster reflex has its reflex arc about at the point of exit of the first lumbar nerves; diseases of the cord at this point must therefore, under some circumstances, cause a disappearance of the reflex. Of the abdominal reflexes the upper, epigastric, corresponds about to the level of the fourth to the seventh dorsal nerves, and the lower abdominal reflex proper to the lower portion of the dorsal cord.

5. TENDON REFLEXES.—The same rules generally hold in judging of the tendon reflexes as are to be considered in judging of the condition of the cutaneous reflexes. We know comparatively little of the course of the reflex arc of the patellar reflex in the lumbar cord. It lies about at the levels of exit of the second to the fourth lumbar nerves. We know, also, that the reflex fails as soon as the middle part of the posterior columns (see the chapter on *tabes dorsalis*) or the anterior cornua of the gray matter of the lumbar cord are much diseased. The Achilles' tendon reflex, or the ankle clonus, has its reflex arc at the level of the first sacral nerves. It is always absent in extensive disease of the posterior columns and of the gray matter in the corresponding portion of the lumbar cord, so that, besides the other symptoms, the absence of the tendon reflexes in the lower extremities is one of the most important points for the diagnosis of a myelitis of the lumbar cord. In almost all inflammations above the lumbar cord—that is, in dorsal and cervical myelitis—there is, however, a very decided increase of the

tendon reflexes, the result, as we must suppose, of the loss of the reflex inhibitory influences. We have a certain right to assume that the fibers which influence the condition of the tendon reflexes run chiefly in the lateral columns of the spinal cord, but that they are not identical with the fibers of the lateral pyramidal tracts which serve for voluntary motion (see the chapter on spastic spinal paralysis). We may therefore assert that, with a considerable increase of the tendon reflexes in the lower extremities, the seat of the myelitis must be above the lumbar cord—that is, in the cervical or dorsal cord—and that in these cases we have to suppose that the lateral columns are chiefly implicated. In cervical myelitis the tendon reflexes in the upper extremities are often considerably increased.

We have already said, on page 544 *et seq.*, what is necessary in regard to the different signs of the increased tendon reflexes, the exaggerated patellar reflex, ankle clonus, the periosteal reflexes, etc. The peculiar character which the paralysis of the legs assumes from a considerable increase of the tendon reflexes at the same time will be described more fully in the chapter on "spastic spinal paralysis" (*vide infra*).

6. DISTURBANCES IN THE BLADDER AND RECTUM.—Disturbances in micturition are one of the commonest symptoms of myelitis. The first manifestation is usually a difficulty in micturition; the patient has to strain and to wait longer before urinating. There may finally be a complete retention of urine from paralysis of the detrusor urinae. In the later stages of the disease, however, there is usually a paralysis of the sphincter vesicae, and consequently incontinence of urine. The disturbances of the bladder give no points for the localization of myelitis, since they may occur with disease at any level of the spinal cord; but we believe we are right in assuming that they always permit us to decide that the posterior columns of the cord are involved.

The clinical significance of disturbances of the bladder in myelitis, and in many other diseases of the cord, apart from the great distress and discomfort for the patient, lies in the fact that they very often—almost always in severe cases—give rise to the development of cystitis. In retention of urine the use of the catheter, by which inflammatory irritants are often brought into the bladder, in spite of all attempts at disinfection, leads to decomposition of the urine and to cystitis; but where there is also incontinence, the imperfect closure of the sphincter and the constant presence of stagnating and decomposing urine in the urethra are the causes of the entrance of these irritants into the bladder. If cystitis have developed, it may be followed under some circumstances by pyelitis and purulent pyelo-nephritis (*vide infra*), which conditions are often the immediate cause of death from the sequelae connected with them, such as fever, which is sometimes associated with chills, general weakness, and emaciation.

Defecation is also disturbed in many cases of myelitis. There is usually constipation at first, which may depend either upon weakness of the intestinal peristalsis, or upon paresis of the abdominal muscles. Sometimes the constipation reaches such a degree that the bowels move only at intervals of one or two weeks. In many severe cases there is finally incontinence of faeces, as a result of paralysis of the sphincter ani. We can give no details as to the localization of the nerve-tracts in the cord which take part in defecation.

We have yet to note that micturition and defecation are often aroused reflexly in an abnormal fashion where there is increased reflex irritability. On irritation of the skin over the thighs, the perineum, the gluteal region, etc., there is often an involuntary contraction of the bladder, associated with loss of urine.

In conclusion, we may mention, as an addendum, that the sexual functions are often considerably disturbed in many cases of myelitis, and finally may be wholly

lost. The tracts involved here lie probably chiefly in the upper lumbar cord, but their precise localization (posterior columns?) is still unknown.

7. TROPHIC DISTURBANCES.—The trophic condition of the paralyzed muscles affords extremely important points for diagnosis. In cervical and dorsal myelitis

the trophic centers in the lumbar cord for the muscles of the legs remain intact; the paralyzed muscles, therefore, retain essentially their normal volume, and especially their normal electrical excitability. Even in such cases the muscles are sometimes flabbier and of lesser girth than under normal conditions, but this depends partly on the decline in the general nutrition, and partly perhaps on the lack of movement, the "atrophy of inactivity." Only occasionally do we find more marked muscular atrophy, but it is of a simple character and not degenerative, and hence without reaction of degeneration; but if we find in myelitis a genuine degenerative atrophy, with reaction of degeneration in the muscles of the lower extremities, we can from this draw a definite conclusion that the anterior gray cornua or the fibers of the anterior roots in the lumbar cord are affected (see page 538). In an analogous fashion degenerative atrophy with reaction of degeneration in the muscles of the upper extremities points to an affection of the anterior gray matter in the cervical cord.

Trophic disturbances in the skin are also frequent, but they have no definite diagnostic significance. We often find the skin dry, hard, with a scaly epidermis, and the nails thickened and brittle. Exceptionally there are eruptions of herpes, urticaria, etc. Vaso-motor disturbances also occur. Sometimes the paralyzed extremities show a mottled, cyanotic reddening, and feel cold. Slight œdema is quite frequently present in the paralyzed parts. Disturbances of the sweat secretion are not infrequent. We find either that it is absent or that there is a great increase in it, so that the paralyzed parts are constantly moist. All these symptoms have no value at present for the special topical diagnosis.

The frequent occurrence of bedsores in the sacral region, over the glutæi, or more rarely on the feet or the inner side of the knees, is of great practical importance. Although trophic and vaso-motor influences may play a part in their origin, still their ultimate cause is always to be found in external conditions, pressure, uncleanness, etc. The more faulty the care of the patient is, the easier bedsores arise. With completely paralyzed and anæsthetic patients, with incontinence of urine and fæces, of course they sometimes can not be wholly and permanently avoided, even with the most careful management. The extent to which a bedsore may reach is sometimes absolutely frightful. A large part

FIG. 83.—A diagram designed to show the relations of the vertebrae to the spinal segments.

of the sacrum may be laid bare, after the overlying soft parts and the periosteum have become gangrenous and been thrown off.

8. DISTURBANCES IN THE REGION OF THE CEREBRAL NERVES are entirely absent in most cases of transverse myelitis. In rare cases of cervical myelitis the process may gradually extend upward and give rise to bulbar symptoms. We sometimes see changes in the pupils also in cervical myelitis, such as inequality and spinal myosis; and finally myelitis has been repeatedly found combined with an optic neuritis.

**Different Forms of Myelitis, Course of the Disease, and Diagnosis.**—The whole picture of transverse myelitis in its different forms may be constructed from the symptoms described in detail in the preceding paragraphs. We can usually determine without difficulty, at least approximately, the seat and extent of the disease. If we group the chief symptoms of the different forms of myelitis together, they are as follows:

*Cervical Myelitis.*—Paraplegia of the legs, combined with more or less extensive disturbances in the upper extremities, and eventually disturbances of sensibility over a like extent. At times atrophy of single muscular regions in the arms. Muscles of the legs not materially atrophied. Increased tendon reflexes and spastic symptoms in the legs and often in the arms. Cutaneous reflexes in the legs retained, and sometimes even increased. Disturbances of the bladder and rectum. Sometimes changes in the pupils.

*Dorsal Myelitis.*—Upper extremities free. Motor, and eventually sensory, paraplegia of the legs, without degenerative atrophy. Increased tendon reflexes, especially strong in myelitis in the upper dorsal cord; cutaneous reflexes retained, rarely increased. Disturbances of the bladder and rectum.

*Lumbar Myelitis.*—Upper extremities free. Motor, and eventually sensory paraplegia of the legs. Cutaneous and tendon reflexes in the legs diminished or absent. Under some circumstances degenerative muscular atrophy, with reaction of degeneration. Disturbances of the bladder and rectum.

[In view of the increasing importance of exact localization of lesions of the spinal cord with regard to surgical interference we have thought it best to add Starr's tables, as modified by Herter, showing the functions of the segments of the spinal cord at the level of the various nerve-roots, and Starr's recent diagrams which show the sensory distribution of the different lumbar and sacral roots (see

FIG. 84. — Areas of anesthesia in lesions at various levels of the spinal cord from sacral v. to lumbar ii. I, Sacral v. II, Sacral iv. III, Sacral iii. IV, Sacral i. V, Lumbar v. VI, Lumbar iii. VII, Lumbar ii.

Fig. 84). These, with the accompanying illustration (Fig. 83), showing the relation of the vertebræ to the nerve-roots, will serve as a guide to the exact localization of the lesion in cases which may require surgical interference, such as cases of meningeal hæmorrhage, fracture, caries, or new growths.—K.]

## LOCALIZATION OF THE FUNCTIONS OF THE SEGMENTS OF THE SPINAL CORD.

SEGMENT OF CORD.	NERVES.	MUSCLES.	SENSORY AREAS.	REFLEXES.
Second and third cervical.	Occipitalis major and minor. Auricularis magnus. Superficialis colli. Supra-clavicular.	Sterno-mastoid. Trapezius. Scales and neck muscles. <i>Diaphragm.</i>	Neck and back of head.	Hypochondrium (?).
Fourth cervical.	Supra-clavicular. Circumflex. Musculo-cutaneous. Musculo-spiral (radial).	<i>Diaphragm.</i> Supra- and infra-spinatus. Deltoid. Supinator longus. Rhomboidel.	Neck. Superior surface of shoulder. Outer surface of arm.	Cilio-spinal (fourth cervical to second dorsal).
Fifth cervical.	Supra-clavicular. Circumflex. External cutaneous. Internal cutaneous. Post. spinal branches.	Deltoid. Biceps and coracobrachialis. Supinator longus and brevis. Rhomboidel. Deep muscles of shoulder-blade. Pectoralis (clavicular part). Teres minor. Serratus magnus. Brachialis anticus.	Back of shoulder and arm. Outer side of arm and forearm.	Scapular (fifth cervical to first dorsal). Biceps jerk. Supinator jerk.
Sixth cervical.	External and internal cutaneous. Radial.	Biceps. Brachialis anticus. Pectoralis (clavicular part). Subscapular. Serratus magnus. Triceps. Extensors of wrist and fingers. Pronators.	Outer side and front of forearm. Back of hand (radial distribution).	Elbow jerk (triceps). Wrist jerk.
Seventh cervical.	External and internal cutaneous. Radial. Median. Post. spinal branches.	Triceps (long head). Extensors of wrist and fingers. Pronators. Flexors of wrist. Subscapular. Pectoralis (costal part). Serratus magnus. Latissimus dorsi. Teres major.	Radial and median distribution.	Palmar (seventh cervical to first dorsal).
Eighth cervical.	Internal cutaneous. Ulnar.	Triceps (long head). Flexors of wrist and fingers. Small muscles of hand.	Inner side of arm and forearm. Ulnar area of hand.	
First dorsal.	Internal cutaneous nerve of Wrisberg.	Extensors of thumb. Small muscles of hand. Thenar and hypothenar muscles.	Inner side of arm and forearm.	
Second dorsal.	Intercosto-humeral.		Inner side of arm near axilla.	
Second to twelfth dorsal.	Intercostals and dorsal posterior nerves.	Muscles of back and abdomen. Erectores spinæ.	Skin of back and upper gluteal region, and of breast and abdomen, in bands running downward and forward.	Epigastric (fourth to seventh dorsal). Abdominal (seventh to eleventh dorsal).
First lumbar.	Ilio-hypogastric. Ilio-inguinal.	Ilio-psoas. Sartorius. Rectus.	Skin over groin and front of scrotum.	Cremasteric (first to third lumbar).
Second lumbar.	Genito-crural. External cutaneous.	Ilio-psoas. Sartorius. Quadriceps femoris.	Outer surface of thigh.	
Third lumbar.	Anterior. Crural. Internal cutaneous. Long saphenous. Obturator.	Quadriceps femoris. Anterior part of biceps. Inner rotators of thigh. Adductors of thigh.	Anterior surface of thigh.	Knee jerk.

SEGMENT OF CORD.	NERVES.	MUSCLES.	SENSORY AREAS.	REFLEXES.
Fourth lumbar.	Internal cutaneous. Long saphenous. Obturator.	Adductors of thigh. Abductors of thigh. Flexors of knee. Tibialis anticus. Peroneus longus.	Inner side of thigh, leg, and foot.	Glutinal (fourth to fifth lumbar).
Fifth lumbar.	External popliteal. External saphenous. Musculo-cutaneous. Plantar.	Outward rotators of thigh. Flexors of knee. Flexors of ankle. Extensors of toes. Peronei.	Outer and back side of leg and foot. Sole of foot.	Ankle clonus.
First and second sacral.	Same as fifth lumbar.	Flexors and extensors of ankle. Long flexor of toes. Small foot muscles.	Same as fifth lumbar.	Plantar (fifth lumbar to second sacral).
Third, fourth, and fifth sacral.	Small sciatic. Pudic. Inferior hæmorrhoidal. Inferior pudendal.	Perineal. Muscles of bladder, rectum, and external genitals.	Back of thigh, anus, perineum, and genital organs.	Vesical and anal centers.
Fifth sacral and coccygeal.	Coccygeal.	Coccygeus.	Skin about anus and coccyx.	

The whole course of myelitis is almost always chronic. We consider it impossible, as we have said, to make a sharp distinction between acute and chronic myelitis. Many cases, of course, show quite a rapid beginning, so that severe spinal symptoms develop in a few weeks. Such cases may be termed acute myelitis, but their further course is almost always chronic. In only a few cases do the morbid symptoms come on suddenly, progress rapidly, and speedily prove fatal. In such cases the autopsy shows a true acute inflammation of the spinal cord which is often disseminated. Sometimes the severe initial symptoms may after a certain time subside. There then remains a more or less severe, quite pronounced stationary type of spinal disease. In such cases the acute myelitis has healed, but the resultant cicatrization (contraction) is the cause of the permanent symptoms.

True chronic myelitis begins very gradually from the start, and in some cases only after years results in complete paraplegia.

As a rule, the disease begins with motor symptoms, either in one leg or in both at about the same time. The paresis gradually increases more and more, spastic symptoms set in, and symptoms of sensory irritation, such as formication, and also disturbances of the bladder, etc. The sensibility is sometimes a little blunted quite early, but it is almost always retained for a longer time than the motility. Only in the last stages is complete anaesthesia common. The whole duration of the disease is seldom under a year, and it often lasts two or three years, or even longer. Remissions, apparent halts, and improvements are not infrequent, and the condition often becomes rapidly worse. Recoveries are not impossible, but they are rare, at any rate. We know of no case that recovered where the diagnosis could be made with certainty. The cases reported where a recovery is claimed are usually cases of pressure paralysis, multiple neuritis, poliomyelitis, etc. The fatal termination is the result of the general weakness which finally sets in; or it comes from cystitis or pyelo-nephritis, both of which are often combined with pyæmic conditions; or from extensive bedsores; or finally from some complications, such as tuberculosis or acute diseases.

The diagnosis of diffuse transverse myelitis is always made by considering the whole group of symptoms prominent in the individual case. The possibility of a compression of the cord must be excluded by a careful examination of the vertebral column, and by consideration of the course of the disease. We must also be sure that the existing symptoms do not correspond to a definite typical disease, or

a systemic disease, but that they can agree only with the assumption of an extensive diffuse disease at a certain point in the cord, to be made out accurately according to the symptoms. The further distinction, as to whether this diffuse disease is a myelitis, can of course hardly ever be made with absolute certainty, since diffuse new growths and the formation of cavities in the spinal cord must cause precisely the same symptoms. In these cases the decision can be made only by considering the whole course of the disease, and by the physician's individual acuteness in diagnosis. It is also still impossible at present to formulate with certainty the differential diagnosis between diffuse myelitis and certain combined fascicular or systemic diseases of the spinal cord (*vide infra*).

**Treatment.**—Although our therapeutic endeavors may rarely hope for a permanent and complete success, still in many cases the treatment can relieve the suffering and delay the end.

We can try to meet the causal indication in cases where the history or the examination shows syphilis. Even if the connection between this and myelitis can not be assumed with certainty, which is usually the case, still we must always try inunction thoroughly, using half a drachm to a drachm (grm. 2-5) of mercurial ointment a day. We give twenty to thirty grains (grm. 1.5-2) of iodide of potassium daily at the same time. We sometimes see decided improvement from this; but in some cases, of course, the result is uncertain, or the treatment seems to exert even an unfavorable influence upon the disease. In the latter case we must stop it at once.

Of the other methods of treatment the chief are electricity, baths, and cold-water cures. We alternate with these. New attempts at cure raise the patient's courage and hope afresh.

Electricity may give improvement in many cases, but of course it causes recovery only exceptionally, at most. In severe and hopeless cases, however, it is at least the best means of consoling the patient. The constant current has the greatest therapeutic value. We use large electrodes placed on the vertebral column, and pass not too strong a stabile or slowly labile current through the cord for about four or five minutes, chiefly through the region where we suppose the seat of the disease to be. We usually take the ascending current, and alternate with the two poles on the diseased part. We should avoid changes and great variations in the current. We associate with this peripheral galvanization, and often faradization of the muscles and nerves of the paralyzed extremities. Single symptoms sometimes deserve special attention—faradization of the skin in anaesthesia, galvanization of the bladder in vesical weakness, etc. The sittings should take place daily or every other day. If we would be successful, the treatment must be kept up persistently for months.

The treatment of myelitis by baths, if prudently used, may also be of evident service. Even simple tub-baths, such as can be had in almost every household, do good service under some circumstances. The chief rules are never to make the baths too warm—about 85° or 90° at most (24°-26° R.)—to limit them at first to ten or fifteen minutes, and to give them at first not oftener than three or four times a week. If the baths are well borne, they can be employed daily. We should be most cautious in incipient and still advancing cases. The best action of the simple warm bath is seen in chronic myelitis with predominant spastic symptoms. In these cases the duration of the baths may be increased to an hour or more. Sometimes the baths work still better than baths of simple water when certain substances are added, especially salt baths, which are made by the addition of five or ten pounds of common salt (Stassfurt salt), or four to six pounds of brine salt, or one to three quarts of brine to the water. By bringing carbonic acid into the water by a perforated tube in the floor of the tub we can easily make "artificial

Rehme baths," which were formerly often used with good success in the clinique in Leipsic.

If we can send patients in easy circumstances to a health resort, the carbonic-acid thermal salt springs at Rehme and Nauheim are most suitable for this purpose, and also sometimes mud-baths such as Marienbad and Elster, and the thermal baths of Ragatz, Teplitz, Wildbad, Gastein, or Wiesbaden.

A methodical cold-water treatment sometimes gives quite good results; but in these cases we should wholly avoid all the more heroic treatment such as douches, violent rubbing, and very cold baths, and employ only short, cool, full or half baths, or mild cold sponging. Hydrotherapeutics are usually combined with electricity.

We can expect but little success from internal treatment, but it can not be dispensed with in practice. Ergotine, strychnine (also given subcutaneously), iodide of potassium, and nitrate of silver are most to be recommended.

The general hygienic and symptomatic treatment is very important. If the first symptoms of a beginning spinal disease show themselves, we should urgently advise the patient to take the best possible physical care of himself, and recommend mental rest. The diet should be strengthening but easily digestible. Large amounts of spirits, much smoking, much tea and coffee, etc., are to be avoided. If the patient becomes bedridden, we must first employ the utmost care to get a good bed in order to guard against bedsores. In severe cases, especially where there are disturbances of sensibility, a water-cushion is most desirable. The patient's position must also be frequently changed, and the sacral region must often be washed and rubbed. Every incipient bed sore must be very carefully treated by Peruvian-balsam ointment (1 to 30) or iodoform, in order to prevent its spreading. When the bed sore is very extensive the continuous bath is the best remedy.

If there is retention of urine and the patient has to be catheterized, the most extreme care must be employed in cleaning and disinfecting the catheter, or else cystitis will develop in a few days. If it does, it is best in severe cases to wash out the bladder regularly with acetate of lead (1 to 1,000) and like remedies. In milder cases we may try chlorate of potassium internally, fifty to seventy-five grains a day (grm. 3-5), astringents, or balsams. If there is complete incontinence it is advisable to introduce a permanent catheter (*sonde à demeure*) into the bladder—that is, a Nélaton's catheter, which lies in the bladder and is fastened to the thighs by strips of plaster. The urine runs away through a rubber tube, and we avoid the constant wetting of the skin and linen.

Constipation must be met according to the general rules. We should be as sparing as possible with cathartics at first, and try to make an appropriate diet and enemata suffice. If there is severe pain, subcutaneous injections of morphine are unavoidable, but we always delay this as long as possible, although finally we let the dose of morphine be unlimited in hopeless cases.

## CHAPTER V.

### MULTIPLE SCLEROSIS OF THE BRAIN AND SPINAL CORD.

(*Disseminated Nodular Sclerosis. Sclérose en plaques.*)

**Ætiology and Pathology.**—Multiple sclerosis of the central nervous system is a special chronic form of disease, whose anatomical basis consists in the development of numerous disseminated "sclerotic nodules" (*vide infra*) in the brain and

cord. We know practically nothing as to its aetiology, for the significance of exposure to cold, overexertion, and mental emotions, sometimes given as causes of the disease, is wholly doubtful. It is also still undecided whether syphilis plays any part in the aetiology of multiple sclerosis. A hereditary predisposition seems to be prominent in some cases. [Marie lays stress upon acute infectious disease as a possible cause.—K.] The affection occurs chiefly in youth, somewhere between

the ages of eighteen and thirty-five, but we have ourselves seen one case, which came to an autopsy, in a man of sixty. The disease also occurs in children. No material distinction has been made out as to sex.

In regard to the development of the different sclerotic nodules, nothing definite has been established at present as to their genesis. Various reasons lead us to favor the theory that the disease depends upon anomalies in the vessels, but the proof of this can not yet be given. The nodules are in part easy to recognize with the naked eye, from their gray color, and we can also feel an increased resistance. They are scattered over the whole central nervous system. Their favorite seats in the brain are the centrum ovale, the walls of the lateral ventricles, and the corpus callosum; the nodules are also quite abundant in the pons, less frequent in the medulla, and very abundant and variously distributed in the cord (see Figs. 85 and 86), and chiefly in its white substance. Examined microscopically, the nodules consist of an abundant, reticulated, fibrillary connective tissue, which is traversed only by comparatively few nerve-fibers that are preserved. In the vessels we notice first an increase in nuclei, and later usually a thickening of the walls. Fatty granular cells are always present in fresh cases. Charcot first made the statement, since confirmed by other observers, that the axis-

FIG. 85.—Example of disease of the cord in multiple sclerosis. The dark portions are the parts diseased.

FIG. 86.—Distribution of the sclerotic nodules on the surface of the pons. (From LEUBE.)

cylinders are preserved in the nodules for a remarkably long time, even after the destruction of the medullary sheaths. Perhaps this is connected with the fact that secondary degeneration in the cord is strikingly absent.

**Clinical History.**—From the variations which the number and the localization of the nodules show, it may be understood from the outset that a type of the dis-

ease which represents all cases can not exist; but a comparison of a number of cases taken together always shows so characteristic a group of symptoms that the diagnosis can often be made with quite great certainty. We will first describe this typical form of disease, for the knowledge of which we must thank Charcot chiefly, and to that we will add some remarks upon the cases which differ from this type ("*formes frustes*"), which are by no means very rare.

The symptom of the typical cases of nodular sclerosis which we must first mention is tremor. This has been the reason why multiple sclerosis has formerly been repeatedly confounded with paralysis agitans, although the tremor in the two diseases shows entirely different peculiarities. In distinction from the constant rhythmical oscillations of the limbs in paralysis agitans (*vide infra*), the tremor in multiple sclerosis comes on only with intended movements—"intention tremor"—and usually does not show a perfectly regular rhythmical character, but is unequal and jerking, although the intended direction of the motion is, on the whole, always retained. The tremor is most marked in the upper extremities, as shown when the patient tries to take hold of a certain object, to bring a glass of water to his mouth, to bring the tips of the forefingers together, etc.; but the tremor also occurs in the head, in the trunk, and in the lower extremities. When the patient is perfectly quiet the tremor ceases entirely. Only a few exceptions to this rule have been known. If the patient be mentally excited the tremor usually becomes more marked. We know nothing as to its peculiar cause. We are ourselves most disposed to assume that it is due to an abnormal cross-conduction of irritation from one fiber to neighboring fibers. The possibility of such an abnormal cross-conduction seems to us to be due to the loss of medullary sheaths in the sclerotic nodules, with persistence of the axis-cylinders (*vide supra*). At any rate, the anatomical fact of the persistence of the axis-cylinders in the sclerotic nodules seems to have some relation to the clinical symptom that, as a rule, in multiple sclerosis we do not see real paralyses but other motor disturbances, especially the pronounced intention tremor.

Two other symptoms which often occur in nodular sclerosis are to a certain degree analogous to the tremor—a peculiar disturbance of speech, and nystagmus. The disturbance of speech depends upon disturbances in the motor innervation of the organs of speech, the tongue and larynx, and may probably be referred to the presence of sclerotic nodules in the pons and medulla. The speech is slow, "scanning," obscure, and finally sometimes almost incomprehensible. The equality in the pitch is often very striking. We often notice tremulous movements in the tongue and the lips on speaking. Nystagmus shows itself in the form of slight and usually lateral twitchings of the eyeballs on fixation, or on intended ocular movements.

Other motor disturbances are usually present besides the symptoms thus far described.

In many cases the crude strength of the muscles is for a long time completely normal, but in other cases there is a marked paresis, which sometimes increases to complete paralysis. The "spastic symptoms," however, are far more characteristic and more frequent (see the chapter on "spastic spinal paralysis"). These depend, in great part at least, upon the very considerable increase in the tendon reflexes, which is almost always present. In the upper extremities the spastic symptoms are less prominent, but even here we almost always find very vigorous tendon and periosteal reflexes on striking the lower ends of the bones of the forearm or the tendon of the biceps or triceps. In the lower extremities we see not only marked patellar reflex and a very intense and persistent ankle clonus (formerly given the unsuitable name of "spinal epilepsy"), but very often a pronounced tonic rigidity of the two legs. Passive motion is difficult, and the gait is completely

spastic. If there is at the same time a marked paresis in the legs, the gait, although stiff, is also dragging—a paretic-spastic gait. The disturbances of sensibility are usually remarkably subordinate in multiple sclerosis. Only rarely do we find a blunting of sensation, and quite exceptionally marked anæsthesia. The cutaneous reflexes usually remain completely normal. Of the disturbances of the organs of the special senses we have still to mention that optic atrophy has often been seen, associated with considerable disturbance of vision, such as amblyopia or achromatopsia, or even with complete blindness. Optic neuritis with a subsequent atrophy also occurs, especially in the temporal halves of the papillæ, according to Gnauck. Finally, we sometimes see anomalies in the innervation of the ocular muscles, and diplopia caused by these anomalies.

In one class of cases there are certain cerebral symptoms which may be important with regard to diagnosis. In the course of the disease there often appears a certain mental weakness, an imbecility, which sometimes increases to marked dementia. Conditions of melancholy or exaltation are much rarer. We must also mention the occurrence of apoplectiform attacks. After slight prodromal symptoms, such as headache and vertigo, loss of consciousness and hemiplegia come on quite suddenly. With this the face is usually red, the pulse is frequent, and the temperature may rise to  $104^{\circ}$  or  $106^{\circ}$  ( $40^{\circ}$ – $41^{\circ}$  C.). After a day or two the consciousness gradually returns, and the hemiplegia soon disappears. Epileptiform attacks are much rarer. We saw these repeatedly in a typical case; they were mainly unilateral, and were followed by a hemiplegia which soon passed away. The precise cause of these attacks is still wholly unknown. Vertigo or giddiness is a frequent cerebral symptom, which may develop even in the earlier stages of the disease, and often comes on paroxysmally.

Symptoms on the part of the bladder, the rectum, or the genital organs, are usually entirely absent in the typical cases, or they appear only toward the close of the disease. Trophic disturbances, such as muscular atrophy, are also rare.

In regard to the general course of typical cases, the disease develops very slowly and gradually. Motor symptoms, tremor, paresis, and disturbances in gait, usually appear in the lower extremities first. The patient often complains at the same time of occasional headache and vertigo. The speech gradually becomes more indistinct, the intelligence weaker, and the other symptoms of the disease described above develop. The affection almost always lasts for years and years. Variations, cessations, and remissions are common. We often see the condition rapidly grow worse, especially after the above-mentioned apoplectiform attacks. The last stage is characterized by the gradually increasing disturbance of the general nutrition, and, finally, by paralysis and bedsores. Death ensues from intercurrent diseases, from the increasing weakness, or sometimes in an apoplectiform attack.

**ANOMALOUS CASES.**—Besides the typical form of multiple sclerosis described, there are often, as we have said, cases that vary from the type. We will mention briefly the following possibilities:

1. The disease may be very latent. We saw one case in which, for a long time, the only symptom was a complaint of slight headache and vertigo. Finally, there was a transitory apoplectiform attack, several months later an epileptiform attack, and a few days after that death took place. The autopsy showed a completely developed multiple sclerosis.

2. Sometimes the disease appears under the exact type of a chronic myelitis. The cerebral nodules cause no symptoms, they are present, perhaps, only in small numbers, and the spinal nodules cause a gradually increasing paraplegia of the legs, with vesical disturbance, loss of sensibility, etc. We have notes of two cases of multiple sclerosis, with autopsies, in which, during life, the diagnosis of a simple transverse myelitis had been made.

3. Cases have been repeatedly known where multiple sclerosis has appeared under almost the exact type of a spastic spinal paralysis (*vide infra*). In these cases many nodules were situated in the lateral columns of the cord. If the spastic symptoms be combined with muscular atrophy (nodules in the anterior gray cornua), the disease may even simulate the type of an amyotrophic lateral sclerosis, with at times co-existing bulbar symptoms (*vide infra*). If multiple sclerosis be localized to an unusual extent in the pons and medulla, the symptoms of a chronic bulbar paralysis may be prominent.

4. Symptoms like those of tabes dorsalis, pain and ataxia, are less frequently of chief prominence. Combinations of multiple sclerosis and gray degeneration of the posterior columns have, however, also been observed.

5. It sometimes happens that multiple sclerosis is the reason for a slowly developing hemiplegia, which may then be falsely regarded as cerebral, while the autopsy shows several nodules in the corresponding side of the cord and pons.

6. In many cases the mental disturbance, dementia, is so prominent that there is the pronounced picture of paralytic dementia (general paralysis), with disturbances of speech, etc.

7. Finally, we must mention here that Westphal has of late described some very chronic cases which have closely resembled multiple sclerosis in their type, although the autopsy usually showed no discoverable anatomical lesion of the nervous system at all. In these cases the symptoms consisted chiefly of muscular paresis, tremor on voluntary motion, parietic-spastic gait, disturbance of speech, difficulty in moving the eyes, rigid expression of the face, and of the presence of the so-called paradoxical contraction in the muscles of the legs (see page 546). A hereditary predisposition to nervous disease was probably of significance in their ætiology. Westphal proposes to call such cases provisionally "pseudo-sclerosis."

The **diagnosis** of multiple sclerosis in atypical cases is sometimes quite impossible, or at best it can be made with a fair amount of probability only when some, at least, of the characteristic symptoms of the disease are present besides the anomalous symptoms. The circumstance, indeed, that the anomalous cases will not properly fit the molds of any other form of disease, should make us think of the possibility of a multiple sclerosis; for in these anomalous cases, of course, there may be all possible combinations of symptoms.

The diagnosis is usually not difficult in the typical cases. The intention tremor, the spastic symptoms, the disturbance of speech, the nystagmus, the gradual manifestation of mental weakness, and eventually the apoplectiform attacks, are the most valuable signs in diagnosis. The distinction from paralysis agitans (*vide infra*) is almost always easy, if we remember that in this latter disease, in distinction from all others, the tremor is chiefly during rest, and the oscillations are much more equal. The diagnosis of "pseudo-sclerosis" can scarcely be made with certainty at present.

The **prognosis** of multiple sclerosis is utterly unfavorable. A case of recovery has never yet been seen with certainty. The disease may, of course, last for a very long time, as was said above.

The **treatment** adopts the same remedies that have been mentioned in the description of chronic myelitis. The galvanic current, tepid baths and sponging, and perhaps the internal use of nitrate of silver, may give the best promise of a temporary benefit.

## CHAPTER VI.

## TABES DORSALIS.

(*Locomotor Ataxia. Gray Degeneration of the Posterior Columns. Anterior Spinal Sclerosis.*)

WE give at present the old name of tabes dorsalis, "consumption of the spinal cord," to a perfectly definite chronic disease of the central nervous system, whose chief anatomical basis is regarded as a typical degeneration of the posterior columns of the spinal cord. The disease has not been accurately known for a very long time. The first description, which, of course, is defective in many respects, is found in a work of W. Horn in 1827. We must thank especially the investigations of Romberg in Germany, in 1851, and of Duchenne in France, in 1858, for a more comprehensive knowledge of the disease, and for a precise distinction between it and the other chronic diseases of the spinal cord.

**Ætiology.**—But little that is definite was known until lately as to the cause of tabes dorsalis. Hereditary conditions play a very slight part in genuine cases, and even a general "neuropathic taint" can only rarely be made out in ataxic patients. Much weight in regard to ætiology was formerly laid upon previous exposure to cold. It can not be denied that sometimes the first symptoms of the disease follow some pronounced exposure to wet or cold, but much more frequently nothing of the sort can be made out. The case is similar with regard to physical and mental overexertion, which were formerly made answerable for the origin of tabes. It is an utterly ungrounded assertion that sexual excesses may be the cause of tabes. Some observers report that tabes may develop as a result of acute diseases or of injuries, such as a broken leg, etc. In these rare cases, too, it is hard to confirm the connection. The earlier teaching that tabes develops after "suppression of the foot-sweat" is manifestly due to a confusion of cause and effect. The absence of foot-sweat is not the cause, but a symptom, of incipient tabes.

The only ætiological fact which in our opinion is beyond any doubt is the relation of tabes to a previous syphilitic infection. This relation of the two diseases to each other was first confirmed in France by Fournier and in Germany by Erb, and in spite of the vigorous contradiction which the views of these observers at first met with on many sides, this theory of tabes is constantly acquiring more and more disciples.

In the first place, the connection between tabes and syphilis can be confirmed by statistics. Erb was able to find a history of syphilis, with secondary symptoms, in about 62 per cent. of his patients; and Fournier, in 103 cases, found syphilitic antecedents as many as 94 times. Our own observations agree exactly with Erb's data, since 61 per cent. of our patients stated definitely that they had formerly suffered from syphilis. If we also reckon the cases where the patients admit a former sore but no secondary symptoms, the percentage becomes much greater—90 per cent. In general it is worthy of note that, as a rule, in most cases of tabes the previous syphilis has not had a great intensity. Only quite infrequently do we find tertiary syphilitic symptoms as well as tabes; we have seen, for example, severe ulcers of the skin, gummous periostitis, etc. The time between the infection and the beginning of the first symptoms of tabes varies very much; it may be from two to twenty years.

The connection between tabes and syphilis becomes especially striking and convincing when we consider certain peculiar cases. Thus we sometimes see tabes in perfectly irreproachable women; here we can almost always detect previous syphilis in the husband which has been transmitted to the wife. We have ourselves seen tabes arise in this way in both persons. We may also find tabes

in very young or very old persons, and then we can discover that syphilis was acquired at a very early or a very advanced age. Some cases of tabes observed in children were in all probability to be referred to hereditary syphilis.

Although we thus recognize the great probability of the connection between tabes and syphilis, we can not, on the other hand, conceal the fact that the perception of the precise nature of this connection causes no slight difficulty at present. The anatomical changes in tabes (*vide infra*) do not correspond at all to the other well-known anatomical products of constitutional syphilis, gummatous new growths; and thus they require an entirely separate classification. We are most disposed to assume that a chemical poison is formed by the action of the syphilitic infection, which has a special deleterious action on the affected system of fibers, these fibers being usually centripetal. Tabes accordingly stands in the same relation to syphilis as a "post-syphilitic disease," as diphtheritic paralysis and ataxia do to previous pharyngeal diphtheria. Whether the same disturbance of nutrition as in ordinary tabes can not also be provoked by other agents such as ergotine, can at present neither be affirmed nor denied. At least provisionally it can not be questioned that there are also cases of tabes where we can not discover a former syphilitic infection. We might state here, in opposition to statements that several authors have made, that the theory that syphilis excites merely an increased predisposition to the disease seems to us to mean absolutely nothing.

Finally, we must mention here the interesting fact discovered by Tuczek, that in chronic ergot poisoning—"ergotism"—symptoms may develop which are precisely analogous to tabes, and which depend upon a corresponding affection of the posterior columns of the cord that can be made out anatomically.

Tabes dorsalis is chiefly a disease of middle life. Most of the cases begin at the age of thirty-five or forty-five. The disease is decidedly more frequent in the male sex than in the female; but it is not especially rare in women, and here we can usually make out, with remarkable frequency, a previous syphilitic infection.

**Pathological Anatomy.**—If we examine the spinal cord of a patient who has died in the advanced stage of tabes, the smallness and thinness of the cord usually strike us first. The pia mater is thickened and opaque, especially on the posterior surface. We often see the posterior columns appearing through the pia as a gray band extending the whole length of the spinal cord. On cross-section we notice that the smallness of the cord is due chiefly to the atrophy of the posterior columns, which is often very considerable. These have wholly lost their normal backward prominence, and seem flat and sunken. From their pronounced gray color they are very plainly distinguished on cross-section from the rest of the white matter of the cord. The posterior cornua of the gray matter, and the posterior nerve-roots, show exceptionally a considerable atrophy, and appear very small and thin and also of a gray color.

Microscopic examination gives more exact information as to the extent and form of the degeneration. This shows that all portions of the posterior columns are not affected in like manner. The degeneration is always most intense in the lumbar cord; here it affects chiefly the middle and posterior portions of the posterior columns, while the most anterior portion remains intact in all cases (see Fig. 87). In the dorsal cord the posterior columns are almost completely degenerated. There are usually small normal areas still preserved in the posterior external and the most anterior portions. In the cervical cord (see Fig. 88) the so-called columns of Goll are chiefly affected, together with the prolongation of the fibers from the root-zones of the lumbar cord, and also the "lateral root-areas"—that is, those portions in the columns of Burdach where fibers enter directly from the posterior nerve-roots, and from which fibers may be traced farther into the gray matter of the posterior cornua; but the so-called posterior

external areas, and also two little antero-lateral areas, remain entirely, or at least for a long time, free from the disease. Figures 89 and 90 show how the first

FIG. 87.—Transverse section through the lumbar region in locomotor ataxia. The diseased portions of the posterior columns are shaded.

beginnings of the disease are localized in the posterior columns. These were drawn from preparations from a case examined by us in the very first stage of the disease. A system of very fine fibers, entering through the posterior roots, is also frequently affected, even very early. They branch outward immediately after

the entrance of the roots, and here occupy a small but very sharply defined territory at the point of the posterior cornua, between the posterior and lateral columns (Lissauer).

We must state, with reference to the participation of the gray matter in the disease, that the posterior cornua, as we have already said, are also found considerably affected, which is explained mainly by the atrophy of the posterior root-fibers which enter them directly. It also can not appear strange that the medullated fibers found in Clarke's columns seem very much reduced in number, since they are also direct processes of the posterior root-fibers. The cells of the columns of Clarke remain normal.

On the other hand, the peripheral processes of the posterior root-fibers are not wholly spared. At any rate, in advanced tabes we can also make out in the larger peripheral nerve trunks, such as the sciatic, and probably still more in the finer branches of the sensory nerves, a number of degenerated fibers, at least of centripetal fibers (Dérérine, Oppenheim and Siemerling, and others). At present we can make no definite statement as to which part of the conducting tract the degeneration here begins in, or how far primary and secondary atrophies are to be separated; but it now seems most probable that the peripheral degenerations in tabes occupy an independent position, since, besides the changes in the peripheral sensory nerves, pronounced degenerative conditions sometimes occur in the trunks of certain cranial nerves, notably in the optic and oculomotor nerves, and more rarely in the vagus, acoustic, etc.

It is most remarkable that the changes described are found in almost precisely the same manner in all cases, that the same portions of the spinal cord are always chiefly affected, while certain other portions constantly remain free; that the disease is very exactly limited, and is precisely symmetrical in the two halves of the cord. This condition is explained only by the assumption that in tabes certain systems of fibers are always affected—that is, fibers which belong together in their anatomical and physiological aspect. Since fibers of different functions are manifestly diseased, as the symptoms of tabes show, we must regard the trouble not as a simple affection but as a combined systemic disease, the more so as we often find certain cerebral nerves, as above stated, affected at the same time (*vide infra*).

The form of the disease consists of a primary degenerative atrophy of the nerve-fibers, and a corresponding secondary increase of the connective tissue. The gray color of the posterior columns is due to the loss of the medullary sheaths. Since the destruction of the nerve-fibers advances but very slowly, we never find more than a few fatty granular cells (see page 617). In old cases we find numerous corpora amylacea, whose origin and significance are still unknown. The thickening of the pia mater is a secondary and insignificant phenomenon.

We will state below the little that we know as to the precise relations between the anatomical lesions and the clinical symptoms of tabes, and we will also mention some other rarer anatomical changes in the disease.

**Clinical History.**—A disease which has as its basis so definite and strictly limited an anatomical change as is the case with tabes dorsalis would also be expected to give a very characteristic clinical picture. This supposition is entirely correct, and there are few diseases which can be diagnosed, even in their earliest stages, with as much certainty as tabes. This fact is explained only by regarding tabes as a systemic disease, in which certain systems of fibers are always affected, while others are as constantly spared by the disease. The difference between individual cases of tabes lies, therefore, less in the symptoms themselves than in their intensity, their duration, and the order of their occurrence. In this regard, however, the differences in the clinical pictures are extremely varied, so that, even with a comparatively great personal experience, we often see new combinations of symptoms and also peculiarities in their course.

For the majority of cases we may sketch the following general description of the disease, in which it is better to divide the whole course into several stages; but, of course, this division can have only a schematic value.

Tabes dorsalis begins, as a rule, with a stage of initial symptoms, which develop very gradually and insidiously, and which may be of a very varying duration. The most characteristic symptoms of this stage are those of sensory irritation, most frequently in the form of the so-called lightning-like, "lancinating" pains in the lower extremities. They are sometimes very severe, but at other times only of slight intensity, and are comparatively little noticed by the patient, who regards them as "rheumatism." Many patients have a feeling of numbness and tingling in the tips of the fingers, especially of the ring and little fingers, and there is often a pronounced girdle sensation in the trunk. In some cases, too, neuralgic and migraine-like pains in the head may appear in the early stages.

Besides these symptoms of sensory irritation, which may often be for years the only symptoms of which the patient complains, two objective symptoms appear very early, which are of the greatest importance in the diagnosis of incipient tabes: the disappearance of the patellar reflex, first discovered by Westphal, and the reflex immobility of the pupils (Argyll Robertson). The absence of the patellar reflex is the most constant of all the known symptoms of tabes, and it is found so early that we can hardly ever decide with exactness upon the time of its occur-

rence. The reflex immobility of the pupil—that is, the failure of the pupil to contract to light, while the changes on accommodation may be perfectly retained—is, indeed, not so constant as the failure of the patellar reflex, but still it is quite frequent. If all three symptoms—lancinating pains, absence of patellar reflex, and immobility of the pupils—are present at the same time, the diagnosis of tabes is absolutely certain, even if all other symptoms are wanting, because this peculiar combination of three such apparently heterogeneous symptoms is seen in this disease alone.

Among the rarer initial symptoms we shall also learn to recognize diplopia, caused by paralysis of certain ocular muscles, loss of vision, from optic atrophy, and certain disturbances of cutaneous sensibility, such as analgesia. Sometimes disturbances in micturition appear quite early, while in other cases, however, gastric crises (*vide infra*) are the first symptom which the patient notices.

After this first stage of the disease has lasted for a very varying period, from a few months to two or five or even twenty years, the second stage begins; this we usually term the ataxic stage of tabes.

The beginning of this stage is recognized by the appearance of disturbances of gait. The gait becomes more difficult and more uncertain, and there are certain peculiarities which we will describe more fully later. Careful examination shows that the disturbance in gait is due not to a paresis of the muscles but to a disturbance of co-ordination, ataxia of the lower extremities. This symptom usually increases very slowly, until it reaches a degree where the patient can walk only with effort, and finally can not walk at all. There is often later, but almost always not for years, ataxia of the upper extremities.

Besides the persisting symptoms of the first stage, there are often now more marked disturbances of sensibility, as well as ataxia. The patient has a feeling as if he were walking on wool, felt, or similar substances. If he closes his eyes there is great swaying of the whole body—"Romberg's symptom." Physical examination of the sensibility often shows a marked loss of tactile sense, of sensibility to pain, or other disturbances (*vide infra*). A loss of muscular sense is especially frequent. The disturbances of micturition, such as incontinence, gradually become more marked, and very often cystitis gradually develops. This stage may also last for years. Sometimes the disease seems to stand still, frequently even manifest improvement is seen, but then the condition becomes worse again.

The third stage, the terminal stage of the disease, develops if the patient has not previously succumbed to an intercurrent disease. The symptoms are the same as in most of the other chronic diseases of the spinal cord. The patient gradually becomes more and more wretched and helpless, and finally is confined almost wholly to his bed. The ataxia is very marked, and sometimes even paresis develops, which may increase to an actual paralysis of the legs. In these cases, which are by no means frequent, we are right in calling the third stage of tabes the "paralytic stage." A severe pyelo-cystitis usually develops, bedsores appear, and death finally frees the patient from his lamentable condition.

We must now complete this briefly sketched picture of the disease by a more careful description of the single symptoms.

1. DISTURBANCES OF MOTILITY IN THE EXTREMITIES.—The typical motor symptom of developed tabes dorsalis is the disturbance of co-ordination, the ataxia (see page 542). This is almost always seen in the lower extremities first. If we have the patient describe a circle in the air with his foot, while lying on his back we notice the irregularity, the "excursion" of the movement. It is still better to tell the patient to touch the knee of one leg with the heel of the other foot. We see then that the leg moved is often carried beyond the point designated several times before it reaches it. The ataxia is often noticeable, even in throwing one

leg over the other, as the leg raised makes much too great and too "throwing" a movement.

The alteration of the gait is very characteristic—the ataxic gait, from which we can often perceive the patient's disease at the first glance. If the patient sits down and tries to get up again to walk, there is difficulty in rising. He separates his legs to find a firm point of support, he takes a stick to help himself if he can, and he often gets the proper balance to keep himself erect only after several attempts. The gait itself is straddling, and the legs are raised abnormally high and set down with a stamp. If we have the patient turn rapidly or make a proper military "about face," the uncertainty of movement is still more marked. These methods of testing are therefore especially suitable for ascertaining the first beginnings of ataxia. Most patients always walk with a stick and control the movements of their legs by keeping their eyes fixed on the floor as they walk. This control is particularly necessary when the sensibility of the legs, especially the muscular sensibility, is diminished at the same time.

The disturbances of sensibility are also the sole reason for Romberg's symptom mentioned above—namely, the swaying with the eyes shut, especially when the patient puts his feet together. This phenomenon has often been classed with ataxia, but it depends merely upon the defective control of the muscular movements, which are necessary to preserve the equilibrium, as a result of the impaired sensibility of the skin of the soles of the feet and that of the muscles themselves. If this control be supplied by the eyes, the swaying is insignificant, but it at once becomes more marked if the control by the eyes is lost. From a like reason it is much harder for most ataxics to walk in the dark than by daylight.

If the ataxia be very marked, the patient can finally keep on his legs no longer. Walking is wholly impossible. The ataxia can then be made out very plainly from the different movements of the legs in bed. The throwing movement, the excess of innervation, is almost always most prominent.

If ataxia of the upper extremities occur in the course of the disease, it is easily recognized if the patient tries to take hold of some definite object, such as his ears, or if he brings the tips of his two forefingers together from a certain distance, or if he does fine work with his hands, such as writing or sewing. The movements are irregular and uncertain, and the excursions are marked. If there be at the same time any sensory disturbance in the arms, the anomaly in their movements is still greater with the eyes shut.

There has been much written and much dispute as to the cause of the ataxia in tabes dorsalis, although at present we have not attained perfect clearness and unity. There are three principal theories, or, more properly, groups of theories, which have been advanced up to the present time to explain the ataxia. According to the first theory (Jaccoud, Cyon, Benedikt), ataxia depends upon a disturbance in the reflex activity of the spinal cord. According to the second theory (Leyden and others), ataxia is the result of the sensory disturbance in tabes, "sensory ataxia"; and finally, according to a third theory (Friedreich, Erb), in ataxia we have a lesion of definite "co-ordinatory fibers," which run centrifugally, and preside over the co-ordination of motion. The exact place where these fibers run is not definitely asserted. If Charcot places these fibers in the external portions of the posterior columns, in the "cuneate fasciculi," it does not agree with the above theory, because centrifugal fibers probably do not pass through this part at all.

It would be an impossible task for us to try here to estimate these theories exactly and critically. The main reason why it is at present impossible to give an incontrovertible explanation of the occurrence of ataxia lies in the fact that we are not yet in a condition to know and to analyze exactly the process of normal

co-ordination of motion; for manifestly every theory as to the causes of ataxia must begin with the processes involved in the co-ordination of normal movements. If we try to get a clear idea of this, the most essential point seems to us to be that co-ordination of motion is not a congenital function, but a power of our organs of motion learned by practice. The movements of little children who are learning to walk are ataxic, and even in later life it often happens that we have to learn how to perform certain complicated and difficult movements. We can get no other idea of this learning how to co-ordinate than that it takes place by the aid of the constant action of controlling and correcting impressions coming from the periphery—that is, centripetal—but we must bear in mind that these actions are mainly unconscious. The surer we become in the execution of the movements, the more the regulatory influence of the centripetal irritations falls into the background, without ever wholly disappearing. In these cases we must not consider, by any means, merely the irritations which are brought to the central organs from the skin of the parts moved; but we should consider, just as much or even more, those irritations which are due to the varying tension and position of the deeper parts, the muscles, the fasciæ, the ligaments, and the articular surfaces. Even the special organs of sense, particularly the eye, under some circumstances, assist materially in regulating motion.

According to this, a disturbance of co-ordination must take place when the regulating influences themselves either are absent or have lost their activity—that is, when the possibility of a successful transmission of these influences to the motor apparatus is absent. We do not know exactly which of these two conditions is realized in tabes. Perhaps both are concerned. Several circumstances may be cited to favor the theory of a loss of centripetal irritations in tabes: the disturbances of sensibility that can often be made out, the absence of the tendon reflexes, the undoubtedly diminished muscular tonus, etc. All these symptoms are certainly not in themselves the causes of ataxia, but still they are noteworthy facts, because they generally point to the actual loss of centripetal irritations. A second theory has perhaps still more support. According to this, the transmission of the regulatory centripetal irritations to the motor apparatus is disturbed in tabes. It harmonizes completely with the fact that the degree of ataxia in tabes does not run at all parallel to the disturbance of conscious sensibility. There are doubtless cases where there is a good deal of ataxia, while the sensibility—that is, the conscious perception of sensory impressions—is practically undisturbed. On the other hand, there are several cases recorded in literature in which, in spite of marked anaesthesia, there was no ataxia. In these cases the regulatory influence of the irritations from the anaesthetic parts was certainly absent, but it could be replaced by the control of the organs of the other senses, especially the eye; for as long as the completely anaesthetic patient has his eyes open he can walk well, but as soon as he shuts his eyes he can no longer stand a moment, and falls at once. In these cases, then, a regulation of motion by the eyes is still possible; there is no special ataxia. In genuine ataxia, motion remains unco-ordinated in spite of the control sought from the sensations of sight; which can be explained by the fact that the influences coming from the eyes, which regulate motion, are no longer of value, because their transmission to the motor apparatus has become impossible. Nevertheless, the eye has a certain unmistakable influence on the movements of ataxies. As soon as the patient shuts his eyes all the movements become much more uncertain and lack any control, so that the patient's judgment as to the degree of his movements, when there is at the same time cutaneous and muscular anaesthesia, is entirely lost.

We may suppose that the point where the transmission of centripetal impressions to the motor apparatus for the purpose of co-ordination of motion takes place

is only in the gray matter, and that it takes place only by the interposition of the ganglion cells. We must thus assume that ataxia, so far as it depends upon any disturbance of transmission, is due anatomically to a lesion of the gray matter (posterior cornua *†*); although, of course, we do not exclude the idea that the loss of centripetal, unconscious irritations, independently of a lesion of the centripetal fibers running in the posterior roots into the cord itself, may have an influence upon the occurrence of ataxia.

These brief glances at the conditions to be considered in the question as to the origin of ataxia may suffice to give the reader a preliminary survey of the most important points, and an incitement to further reflection upon this interesting subject.

Ataxia is the chief motor disturbance in tabes. The crude strength of the muscles may be perfectly normal, and it is chiefly a service of Duchenne's to have made clear for the first time the principal distinction between ataxia and paralysis. He showed that ataxics, who can no longer walk a step alone, can nevertheless exert the greatest strength with their legs. We have ourselves treated a teacher of gymnastics who, in spite of the most marked ataxia of the arms, had still so much strength in them that he could support himself in bed on his arms and keep his whole body, with his legs extended, in the air.

It sometimes happens, however, that even the crude strength disappears in tabes, and that the muscles become parietic. We have stated above that even a complete paraplegia may finally develop in the course of the disease. In these cases we find, on anatomical examination, that the process is no longer confined to the posterior columns, but that there is also a systemic degeneration of the lateral pyramidal motor tracts in the lumbar cord. The rare paralyses of certain motor nerves have another significance. They have usually been noted at the beginning of the disease, and affect the radial, peroneal, accessory, etc. They are probably due to changes in the affected peripheral nerves, but as a rule they are transitory, and, in our opinion, are to be put in the same category with tabetic oculomotor paralyses (*vide infra*).

We may add, finally, that slight symptoms of motor irritation, slight twitches in the muscles, especially in the fingers, are not uncommon, but they are noticed only when the attention is especially directed to them. It is not certainly known how they arise; in our opinion, they are of reflex origin.

The condition of the muscles on passive motion is very characteristic. We notice in most cases a very striking flaccidity of the limbs, so that there is hardly any muscular resistance to be felt. We have to do, as it seems, with a diminution of muscular tonus, whose cause is not yet quite clear; but since there are many reasons for believing that the normal muscular tonus is of reflex origin, we are led to think of a connection between the absence of muscular tonus and the other reflex disturbances in tabes, such as the absence of the tendon reflexes.

The electrical excitability of the nerves and muscles, as we may also note here, remain perfectly normal in uncomplicated tabes.

2. DISTURBANCES OF THE CUTANEOUS AND MUSCULAR SENSIBILITY.—As we have already said, tabes begins, in the great majority of cases, with symptoms of sensory irritation, which usually persist in the later course of the disease also. Besides the simple paræsthesia—the feeling of tingling and numbness in the legs, and sometimes, too, a similar feeling which appears quite early in the upper extremities (especially often, as we have said, in the ulnar region)—the tabetic pains are remarkably characteristic of the disease.

The intensity of the pains differs very much in different cases; but we see a complete absence of them extremely rarely. The patient's attention is often first called to his slight and infrequent pains by direct questioning; but in some cases

the severe pains are a constant distress to him. The pains most characteristic of tabes are the lightning-like, "lancinating" pains, which shoot like neuralgic pains for some distance along the course of the nerves. They often come on in very severe paroxysms, and are absent at other times. There are also boring, stabbing pains, which are fixed at one point and have their seat especially in the vicinity of the joints; and finally "constricting pains," which are felt most frequently in the back and loins. The well-known "girdle feeling" of tabetics—that is, the sensation of a band tightly encircling the trunk, or a tight, "drawn-together" pressure on the lateral portions of the trunk—belongs to the latter form of symptoms of sensory irritation. The girdle feeling is manifestly due to irritative processes in the region of the lower dorsal or upper lumbar nerves. Since it is comparatively frequent, and often appears quite early, it also has a certain diagnostic significance.

The tabetic pains also begin in the legs, corresponding to the almost constant beginning of the symptoms of the disease in the lower extremities; but later on quite analogous pains sometimes appear in the arms, and in very advanced cases we have also observed pains in the region of the occipital nerves and of the trigeminus. On the other hand, neuralgic pains in the face, especially in the region of the frontal nerve, or in the occiput, or even migraine-like attacks, also occur, even in the initial stage of tabes, as we have ourselves observed. In some cases the lancinating pains in tabes may be accompanied by the appearance of an eruption of herpes—a condition which at any rate is extremely rare.

Usually much later than the pains appears also a diminution of sensibility which can be made out objectively. As a rule, it may be stated that in most, but not in all, cases of tabes the sensibility does not remain normal; although more marked anæsthesia never appears until the more advanced stages of the disease.

The form of the disturbances of sensibility varies extremely, and no disease furnishes so many opportunities for the study of interesting details in the region of anomalies of sensation as tabes dorsalis. Our knowledge of the occurrence of partial paralyses of sensation especially is very largely based on the examination of tabetic patients. The tactile sense suffers in most cases of tabes, but we can usually make out only a certain blunting of it. Only when the disease is far advanced does the patient cease to feel a light touch on the skin. The sense of pain is also often abnormal. We sometimes see a pronounced analgesia, but in other cases there is a very decided sensibility to pain, in spite of a defective tactile sensibility. It is a very frequent symptom that, at a pin-prick, the patient has at first only a slight and not a painful sensation, and that a few seconds later, especially if the prick persist, he suddenly winces and says he feels a decided pain. With it there is usually a reflex contraction in the affected leg. We generally speak of this symptom as a "delayed conduction of painful sensations" or "delayed reflex", but it seems to us that the symptom has not yet been analyzed carefully enough, and especially that it has not been properly separated from the after-sensations, which are also very common in tabes. It often happens that after a single prick, tabetic patients report at varying intervals five or six or more painful after-sensations.\*

If the first sensation is not painful in these cases, it may happen that the patient may first say "Now" at a prick, and soon after "Ow," when he first feels the pain (the "double sensation" of Naunyn, Remak, and others). Fischer has termed a peculiar disturbance of sensibility occurring in tabes, *polyæsthesia*; the

\* If, while the patient's eyes are shut, we prick the leg and the arm or neck as nearly as possible at the same time, the prick on the leg would necessarily be felt much later than that on the arm, if there is a delayed conduction of sensory impressions from the leg; but we have never as yet been able to make out this condition with certainty.

patient asserts, when examined with an æsthesiometer, that he feels several (four or five) points, although he was touched with but one.

Disturbances of the sense of pressure, and still more that of temperature, are also quite frequently found, especially as partial paralyses of sensation, when the sensibility is otherwise well preserved. We should note particularly the occurrence of partial anæsthesia of the sensibility to heat or cold. On the other hand, the special sensations of temperature may sometimes be pretty well defined, while in other respects there is quite a high degree of anæsthesia.

The considerable anomalies of the muscular sense, which are often to be made out in more advanced cases, have a special interest (see page 509). If the patient shuts his eyes, he is often entirely unaware of the situation and position of his limbs. He makes a false report as to the direction and extent of passive motions.\* If the muscular sense in the arms be disturbed, and we put the arms into any unusual position, the patient has considerable trouble in bringing the hands together with his eyes shut. He gropes about in the air with his arms until he accidentally touches one arm with the other hand, and then he feels down this to the hand. The action of ataxia and muscular anæsthesia are accordingly combined in these cases, but we can not possibly consider the former as a result of the latter; for there are doubtless cases of ataxia—we have ourselves carefully examined such with regard to this question—in which the perception of motion and position is perfectly normal in spite of the existence of ataxia. The disturbance of movements willed, by the loss of muscular sense, is noticed only when the eyes are shut. With the eyes open the control by the sense of sight supplies the lack of muscular sensibility. Pitres has lately described peculiar attacks of muscular rigidity, and attacks of a decided feeling of fatigue in the muscles, apparently coming on spontaneously in incipient tabes (*"crises de courbature musculaire"*).

Only in rare and far-advanced cases is there finally a complete anæsthesia of the lower, and exceptionally of the upper extremities. We then see also at times disturbances of sensibility in the region of the trigeminus, in the skin of the face. These disturbances are probably connected with a degeneration of the sensory ascending root of the trigeminus, which degeneration has already been observed several times at the autopsy (Westphal).

It is very hard to judge as to the dependence of all these sensory disturbances mentioned upon the anatomical changes of tabes. In many cases both the initial pains, and in part the anæsthesias, especially if they have their chief seat in a single nerve territory (ulnar, etc.), are to be referred to disease of the sensory peripheral nerves. The severer pains, however, are perhaps due chiefly to morbid processes in the posterior roots, while with a high degree of anæsthesia we are usually right in assuming that there is a pronounced atrophy in the posterior cornua.

3. DISTURBANCES OF THE REFLEXES.—The cutaneous reflexes show no constant changes in tabes. They are usually approximately normal, but sometimes they are diminished, especially if there be at the same time a marked disturbance of sensibility.

The absence of the tendon reflexes, especially of the patellar reflex, is, however, an almost constant sign of tabes, and is a sign of the highest diagnostic value. As we have already said, the disappearance of this reflex is one of the earliest symptoms of the disease, and is therefore of the greatest significance in the diagnosis of initial tabes. There are certainly cases of tabes in which the patellar reflex may persist for a long time, in spite of the development of many other morbid symptoms. These, however, are only very rare exceptions, which do not disprove the

\* We can describe different letters and figures in the air with the patient's extremities, and try whether they can be correctly recognized with the eyes shut.

rule, and do not at all contradict our general views as to tabes. In individual cases the affected fibers, which serve to set free the reflex, may be spared for a long time, just as any other characteristic symptom of the disease may under some circumstances occasionally be absent. Concerning the precise anatomical cause of the disappearance of the patellar reflex, it can be due only to a degeneration in the centripetal portion of the affected reflex arc—that is, only in the fibers which belong to the territory of the posterior roots. It is in accordance with this that disease of the middle portion of the posterior columns in the lumbar cord (that is, the root-zones, see Fig. 89) always seems to be accompanied by a failure of the patellar reflex. The direct mechanical irritability of the muscles, especially of the quadriceps, is almost always retained in tabes.\*

4. DISTURBANCES IN THE EYE AND THE OTHER ORGANS OF SPECIAL SENSE.—The authority for regarding tabes as a combined systemic disease arises from the frequency with which certain cerebral symptoms, as well as the spinal, are found in it.

The symptoms in the eyes deserve the first attention. We find disturbances in the pupils, of course not in all cases, but still in the great majority of them. The pupils are often very much contracted—"spinal myosis"—and show no trace of contraction to light, although the well-known changes in the pupils are very manifest upon any variation of the accommodation—dilatation of the pupils with approximately parallel axes of vision on looking at distant objects, and contraction of the pupils with the most marked convergence of the eyeballs on fixing a near object. We give this phenomenon, whose precise anatomical cause is not yet known, the name of reflex immobility of the pupils with retained mobility on accommodation (Argyll Robertson pupils). It is not at all necessary, however, that there should also be a myosis, for we not very infrequently find the pupils quite dilated or unequal, although we find there is reflex immobility. As we have already said, the immobility of the pupils is often a very early symptom, so that it also has a diagnostic importance. In other cases we find inequality of the pupils and, as a rare symptom, a striking change in the size of the pupils, so that first one and then the other pupil is the larger.

The paralyses of the ocular muscles in tabes are also very interesting. They are usually unilateral, but sometimes bilateral, and often appear even at the beginning of the disease, so that diplopia may be the first subjective symptom of which the patient complains. In every sudden oculomotor or abducens paralysis, coming on without any other cause, we must think of the possibility of an incipient tabes. It is remarkable that these paralyses in many cases disappear permanently and entirely after some time; but sometimes they remain, as we have repeatedly seen, especially in a case with bilateral abducens and unilateral oculomotor paralysis, and also in a case with almost complete bilateral oculomotor paralysis. In the autopsies on such cases we find the trunks of the affected nerves and their nuclei markedly atrophic. It seems to us very probable, however, that the temporary ocular paralyses in tabetic patients depend upon changes in the peripheral nerves of the ocular muscles.

The third complication in the eyes in tabes is optic atrophy. It occurs in about ten or fifteen per cent. of all cases, and is usually an initial symptom, at a time when the absence of the tendon reflexes, which may usually also be

\*[From autopsies on cases of combined sclerosis, where the symptoms very closely resembled those of tabes, but where the patellar reflex persisted until near the close of life, Westphal thinks that the patellar reflex disappears only when a special region in the posterior columns is involved in the disease. This region lies at the junction of the dorsal and lumbar cords, between the posterior cornu and a line running parallel with the posterior fissure, and starting from the angle seen in the posterior cornu at the site of the substantia gelatinosa.—TRANS.]

noticed, is the only thing, except this, to render the diagnosis of the disease possible. The patient complains of diminution of vision, and the power to distinguish colors, especially green, disappears quite early. On objective examination, we find, besides this anomaly in the color sense, usually a limitation of the field of vision, and the beginning gray degeneration of the optic nerve can easily be made out on ophthalmoscopic examination. The affection sometimes makes little halts and slight apparent improvements, but it usually ends with complete blindness. The optic atrophy more rarely first appears in the later stages of the disease, when all the other symptoms are already fully developed.

Auditory disturbances are much rarer than those of sight, but they also occur. The cause, in at least a part of the cases, is an atrophy of the acoustic nerve. Symptoms are also frequently seen which resemble those of Ménière's disease—tinnitus, vertigo, and deafness.

Changes in the senses of taste and smell have been observed only in a few cases.

5. DISTURBANCES IN THE BLADDER, THE RECTUM, AND THE SEXUAL ORGANS.—Difficulty in emptying the bladder is an almost constant symptom in the later stages of tabes. It sometimes, indeed, appears very early. The patient feels the desire to urinate more frequently, there is often a slight involuntary micturition, and at other times there is retention of urine, sometimes coming on quite suddenly; in advanced stages there is frequently complete incontinence. A cystitis very often develops as a result of all these disturbances, which may be the starting-point of severe cysto-pyelitis and pyelo-nephritis, and thus be the cause of death.

Persistent constipation is also a very frequent symptom of tabes, the reason for which is perhaps to be sought in the defective reflex excitation of intestinal peristalsis. The constipation may in many cases give rise to great distress to the patient, since it sometimes provokes very painful sensations in the loins and abdomen. The coccydynia, which sometimes occurs in tabes, has already been mentioned (see page 528). Incontinence of feces occurs quite rarely in the last stages of the disease.

A diminution in the sexual functions is found almost constantly in advanced cases. The loss in power is also often one of the initial symptoms.

6. SYMPTOMS IN THE INTERNAL ORGANS.—We see, not very infrequently, in tabes certain symptoms in the internal organs which are in part very characteristic, and which, at any rate, are based upon disturbances of innervation. The most important and the most frequent are the so-called "gastric crises." These almost always come on suddenly and paroxysmally, and consist of an extremely severe cardialgic pain, which is accompanied by violent vomiting. The patient also feels very wretched, and there is often at the same time palpitation, acceleration of the pulse, vertigo, etc. The attacks last about two or three days. In many patients they are repeated every few months. As we have said, the gastric crises may appear very early. We ourselves know cases where, in consequence of severe gastric crises, a severe gastric affection has been falsely diagnosed, in the beginning of the disease. Attacks of diarrhoea, "intestinal crises," usually not associated with pain, have also been repeatedly observed.

We term attacks of severe dyspnoea "laryngeal crises." These probably depend upon a (reflex ?) spasm of the glottis, and may attain a very alarming degree. They are also associated with a severe spasmodic nervous cough. Paralysis of the laryngeal muscles (crico-arytenoids) has also been observed. We may assume changes in the vagus-accessory nucleus, or in the vagus or recurrent itself (Oppenheim), as the anatomical cause of all these symptoms.

In a few cases "renal crises" ("*crises nephritiques*") have also been described. They consist of severe attacks of pain, like renal colic. French authors also

describe "urethral crises" and "*crises clitoridiennes*," the paroxysmal appearance of voluptuous feelings with a vaginal secretion in women, in the beginning of the disease.

We may mention, finally, that we sometimes see in tabetic patients a constant and very great frequency of the pulse, 100 to 120 a minute. We also frequently see the combination of tabes with aortic insufficiency which has been mentioned by some authors. The precise connection between the two affections is probably dependent upon previous syphilis.

7. TROPHIC DISTURBANCES.—In many cases of tabes trophic disturbances are entirely absent. We have already spoken of the occasional appearance of an eruption of herpes, with severe lancinating pains. In some cases a marked exfoliation of the epidermis has been seen, and also a falling out of the hair and nails. Sometimes there are small hæmorrhages, apparently spontaneous, into the skin or into the visible mucous membranes, especially into the conjunctiva, as we have seen in several cases.

The peculiar joint affections which occur in tabes, and were first accurately described by Charcot as "*arthropathies tabétiques*," have a greater interest. (See Fig. 91.) The affection is situated most frequently in the knee- and hip-joints,

FIG. 91.—Tabetic arthropathy of the right knee and left ankle. Personal observation.

more rarely in the ankle- and shoulder-joints. It is usually bilateral, even if it be more marked on one side than on the other. We sometimes find abundant serous effusions, so that the knee-joint in particular may swell up in monstrous fashion; but we find especially a high degree of arthritis deformans, with marked atrophy of the ends of the bones, and with the formation of many osteophytes. Spontaneous dislocations and fractures also occur. An affection of the anterior gray cornua, which Charcot suspected to be a cause of the articular affection, could not be made out in a case examined by us anatomically. We do not believe that the theory of an exclusive "nervous-trophic disturbance" can explain the origin of the tabetic joint affections. Perhaps we have to do with syphilitic joint affections, and perhaps with those of some other more fortuitous (traumatic ?) origin, which are rather a complication than a symptom of tabes. We believe, however, that the unusual intensity and the peculiar form of the

anatomical lesion are indeed directly connected with tabes, and are due chiefly to the anæsthesia of the articular surfaces. We saw a case, a short time ago, where an affection of the knee-joint developed in a comparatively very early stage of tabes, which up to that time had not been diagnosticated at all. As the patient felt no pain at all in his knee, he nevertheless hunted most vigorously through a whole autumn, until finally an extremely severe swelling of the knee-joint and an actual dislocation of the leg ensued.

The muscles preserve their normal state of nutrition, except as they take part in a general emaciation. Charcot described a case of a combination of tabes with genuine progressive muscular atrophy, in which the autopsy showed a degeneration of the anterior gray cornua in the spinal cord besides the atrophy of the posterior columns. The first report upon a unilateral atrophy of the tongue, which

sometimes develops quite early in tabes, is due to the same observer. Nothing definite is known at present as to the origin of this peculiar complication.

In conclusion, it is worthy of note that cases of "*mal perforant du pied*" (ulcerations on the heels or between the toes) have been repeatedly observed in tabes.

**8. CEREBRAL SYMPTOMS.**—Besides the frequent important disturbances on the part of certain cerebral nerves, such as the optic and oculomotor, which have already been mentioned, we must mention here the relation between tabes and progressive general paralysis (*q. v.*). On the one hand, the symptoms of tabes are often present in the course of general paralysis, so that the autopsy shows a typical degeneration of the posterior columns (Westphal); and, on the other hand, it also happens that the whole process begins with a tabes, which may exist alone for years without any mental symptoms, and then only at the close do the symptoms of paralytic dementia, delusions of grandeur, dementia, etc., appear.

The complication of tabes with hemiplegia repeatedly occurs. The latter depends upon a cerebral hæmorrhage or an embolic or thrombotic softening, so that it is doubtful whether the two affections have a real connection or are merely a chance combination. It seems to us worthy of note that in two such cases we saw scarcely any contracture develop in the paralyzed limbs.

**Course and Prognosis.**—Although most of the characteristic symptoms of tabes develop in almost all cases, still the order and the intensity of their onset vary greatly. We have already briefly described the general type of the disease which most frequently comes under observation, and many other peculiarities in its course have been mentioned from time to time.

We have stated that the initial period is usually characterized, apart from the symptoms that can be made out only objectively, such as absence of the patellar reflex and reflex immobility of the pupils, by the lancinating pains; that these may differ very much in intensity; and that the duration of this first stage may vary between a few months and ten or twenty years. The optic atrophy, the ocular paralyses, gastric crises, vesical disturbances, etc., were mentioned as rarer initial symptoms. The passage from the first stage to the second—the stage of ataxia—is sometimes very gradual, but in some cases very rapid and sudden. We have repeatedly seen such changes, with a sudden change for the worse in the condition. If the previous symptoms were slight, the patient dates his disease from this point, and says that he was quite suddenly broken down by some cause, and that since then he has not been able to walk at all, or else only with difficulty. In such cases there is often slow improvement following the sudden change for the worse in the condition, which, of course, is not permanent.

No rules of general value can be given as to the further advance of the disease, the invasion of the arms by the ataxia, or the occurrence of the rarer symptoms, such as the joint affections, etc. Almost every individual case affords its idiosyncrasies, since one group of symptoms is often especially prominent, while another is entirely absent or developed only to a slight degree. On the whole, however, we can almost always make out a gradual, even if a very slow, advance in the disease. New symptoms appear, the old ones increase, the general condition becomes worse, until finally the last stage of the disease comes on.

Recovery from tabes occurs only very rarely, if at all. The treatment of the affection may indeed cause improvement, delay the course of the disease, and alleviate single symptoms, but the prognosis is always to be regarded as unfavorable, although many patients, especially under favorable external conditions, may lead a tolerable existence for years.

**Diagnosis.**—There is scarcely any other disease of the spinal cord whose diagnosis can in most cases be made with so great certainty and such comparative

ease. Since tabes is a combined systemic disease, it affords a definite combination of symptoms such as can occur under no other conditions. The diagnosis, therefore, is to be made not from any one single symptom, but only from the combination of all and from the whole course of the disease.

The diagnosis of initial tabes is especially important. In every case of obstinate "rheumatic" pains, or similar pains in the lower extremities, we should think of the possibility of tabes, and examine the tendon reflexes and the pupils. The combination of characteristic pains, absence of the patellar reflex on the two sides, and reflex immobility of the pupils, usually makes the diagnosis almost perfectly certain; two of these symptoms, especially if the reflex immobility of the pupils be one, make it at least very probable. Ocular paralyses, temporary ptosis, or temporary diplopia, may be very important for the diagnosis. With these symptoms, too, we should never forget to think of the possibility of tabes, and to look for the other characteristic symptoms. Finally, we may recall the fact here that the disease may begin with an optic atrophy, and that early gastric crises may simulate a gastric affection, early disturbance in micturition a vesical trouble, or swelling of the joints a joint disease, until careful examination of the other symptoms explains the true nature of the disease.

In the fully developed ataxic stage of tabes the diagnosis is almost always easy, and often can be made at the first glance. The history, the characteristic ataxic gait, the swaying with the eyes shut, the absence of the reflexes, etc., make the diagnosis certain. The diagnosis may be more difficult if we happen to see the patient for the first time in the final stage, when actual paralysis has set in, when a complicating hemiplegia has arisen, etc. In such cases we must lay stress on the development of the disease and find out what characteristic tabetic symptoms—pupillary symptoms, absence of patellar reflex, remains of ataxia, or pains—can now be discovered. With proper attention and knowledge of the case, the diagnosis can even then almost always be made correctly.

Vertebral affections are to be mentioned first of the diseases which may be confused with tabes. These also cause, under some circumstances, lancinating pains and an absence of the patellar reflex, as a result of compression of the spinal roots; but in these cases the later course of the disease is entirely different, apart from the changes in the vertebral column and the absence of other characteristic symptoms of tabes. The same holds true of certain deep-seated tumors in the neighborhood of the spinal cord. We have already said that in rare cases a multiple sclerosis may offer symptoms similar to those of tabes. In these cases the chief stress in regard to diagnosis is to be laid on the *ensemble* of symptoms and their development. It is of greater practical importance that certain toxic nervous diseases may have a great similarity to tabes. Chronic alcoholic neuritis has already been spoken of in this connection (see page 583). In these cases, however, the reflex immobility of the pupils and the disturbances of the bladder are usually absent, while atrophic paralysis may develop later, which never happens in tabes. The aetiological factors are also, of course, to be taken into account.

Finally, it may be mentioned here that we have twice seen a group of nervous symptoms in workmen who have worked many years in tobacco factories, which resembled tabes in so many points that we might term it "nicotine tabes." The morbid symptoms, which resemble tabes, consist of painful sensations, absence of the patellar reflex, contracted pupils with reflex immobility, and uncertainty of gait; but the whole type of the disease is distinguished from tabes by a peculiar tremor, by a marked increase of the cutaneous reflexes, especially in the lower extremities, etc.

**Treatment.**—The tedious course of tabes demands that the physician have at hand a choice of remedies and methods of treatment which he can vary according

to the predominating circumstances, either to obtain a certain amount of improvement by a new way of attacking the disease, or at least constantly to kindle the patient's hope and courage anew.

If syphilis be a possible aetiological factor, we regard it as entirely justifiable to prescribe first an antisyphilitic treatment: inunction of fifty to seventy-five grains (grm. 3-5) of mercurial ointment a day, with iodide of potassium internally. In very many cases this, of course, does no brilliant service—at times the disease has even been noticed to grow worse under inunction—but sometimes we see distinct improvement. The earlier the treatment is begun, the more is to be expected of it. At any rate, we should try whether we can not check the further advance of the disease by a methodical and continuous antisyphilitic treatment. When symptoms implying loss of function (*Ausfallsymptome*) have already appeared, we can not, of course, cause them to disappear, for iodine and mercury can not restore fibers in the posterior columns that have already been destroyed.

If the antisyphilitic treatment be not indicated, or have been unsuccessful, electricity and balneo-therapeutics or hydro-therapeutics deserve the most confidence.

The electrical treatment consists chiefly of the passage of the ascending constant current through the spinal cord. The currents must not be too strong, and the sittings should take place daily, or every other day. Erb recommends placing the medium-sized cathode in the vicinity of the sympathetic, and the large anode close to the spinous processes on the other side of the vertebral column, moving it at intervals from above downward. This procedure lasts about four or five minutes for each side. We also obtain good results symptomatically when there are severe pains, vesical weakness, etc., by peripheral galvanization. If we find painful points on the vertebral column, as is rarely the case, they should be especially treated with the stable anode. Lately, the treatment recommended by Rumpf with the faradic brush has been used several times with good results. This consists in brushing the skin and the extremities with a strong current for five or ten minutes. Every form of electrical treatment, in order to obtain results, must be kept up for months.

Hydro-therapeutics, used rationally, have often resulted in considerable improvement in tabes, although they may cause much mischief. Hot baths, especially vapor-baths, are often followed by a rapid change for the worse—a fact which, unfortunately, we can often observe where vapor-baths have been prescribed for patients at the beginning of their disease "for rheumatism." Continuous wet packs and severe rubbings are also often accompanied by unfavorable results. Tepid half or full baths, however, of 75° to 86° at most (20°-24° R.), associated with gentle rubbing of the skin, often do good service. Wet compresses, laid about the abdomen or the legs at night, often have a favorable influence on the pains. In general, it is a good plan to send well-to-do patients in summer to a water-cure establishment which is conducted by an experienced director and well managed, but the necessary procedures may also be undertaken at home.

Of the baths whose use is recommended in tabes, Oeynhausen-Rehme has the greatest reputation, and the best results to show. Many tabetics, of course, come back from Rehme just as they went; but, in advising a bath, Rehme is always the first to be considered. We may refer to what was said on page 626 as to the establishment of artificial Rehme baths. The baths in Nauheim have a very singular composition. The indifferent thermal baths, Teplitz, Wildbad, and Ragatz, formerly much in favor, have at present lost their reputation in tabes. Mud baths and iron baths—Pyrmont, Driburg, Cudowa, Elster, Franzensbad—may sometimes act favorably.

Besides the methods of treatment so far mentioned, there are still a number of internal remedies, the use of which seems sometimes to be of advantage. The chief ones to be mentioned are nitrate of silver, first recommended by Wunderlich, one-sixth-of-a-grain pills (grm. 0.01), at first three, gradually increasing to six a day, before meals; and ergotine,\* one-grain pills (grm. 0.05), three to six a day; we may also try iodide of potassium, phosphorus, arsenic [chloride of aluminium, two to four grains (grm. 0.1-0.25), thrice daily], etc. All these remedies, especially the two first named, may be used for a long time, and, with interruptions, even for years.

Finally, we must mention here nerve-stretching, usually stretching of the sciatics, which for a short time was practiced on many tabetic patients as a result of a somewhat too sanguine recommendation on the part of Langenbuch. Since, however, experience has taught us that nerve-stretching, in spite of some apparent successes, scarcely ever exerts a permanent favorable action, and is also not wholly without danger, the operation has been almost entirely given up in tabes. It may still be tried in those cases where we have unusually severe attacks of pain in the region of definite nerves.

[Of late years Charcot has advocated suspension in the treatment of tabes. The patient is suspended in a Sayre apparatus from one to three minutes daily or every other day. It is not without danger, and it should not be employed if any spastic symptoms be present. It has not met with the success at first claimed for it, but in a few cases it seems to relieve the pain and the ataxic gait.—K.]

Symptomatically, the same remedies are to be considered as were mentioned in the treatment of chronic myelitis. We try to alleviate the pains by narcotic embrocations and bandaging the legs. Of internal remedies, sodic salicylate and antipyrine sometimes undoubtedly alleviate and shorten the pains. In bad cases morphine is indispensable. We try to remove the constipation by prescriptions as to diet, or by mild cathartics, such as the bitter waters, tamarinds, and rhubarb, and by enemata. Morphine is the best remedy in the gastric and laryngeal crises. Cystitis and bedsores must be treated according to the rules in general use.

In regard to the patient's general manner of life, we must warn him against any physical or mental overexertion, prescribe a prudent but strengthening diet, and enjoin good air, a country residence in summer, or perhaps the Alps or sea air. The earlier we get the patient under treatment, the more persevering and careful should we be in our treatment, because then we can still hope for success. In old and far-advanced cases we must confine ourselves to a purely symptomatic treatment.

## APPENDIX.

### HEREDITARY ATAXIA. FRIEDREICH'S FORM OF TABES.

A peculiar and rare disease, which has a certain similarity to tabes, was first described by Friedreich under the name of "hereditary ataxia." The affection almost always occurs in several children of the same family, and develops in youth, somewhere between twelve and eighteen years of age. The female members of the family are decidedly more often affected than the male. A stage of initial pains is usually absent. The disease begins with a pronounced ataxia of the legs, which usually very soon passes to the arms. The tendon reflexes disap-

\* There is only an apparent contradiction in the fact that, in spite of the occurrence of an "ergotine tabes" (*vide supra*), ergotine is also used as a remedy against tabes. It may very well be that the same remedy, which in large doses causes certain systems of fibers to atrophy, may in smaller doses have some favorable (irritating) action on the same system of fibers; but we must always be cautious in the use of ergotine.

pear in most cases, but the sensibility of the skin and muscles remains perfectly intact, a fact which may properly be regarded as evidence for the independence of ataxic disturbances from anomalies of sensibility. The vesical functions also remain completely normal for a long time. Disturbances of vision have not been observed up to the present time, but in the further course of the disease a peculiar disturbance of speech arises, which is probably due to a disturbance of co-ordination in the muscular movements of the lips and tongue necessary in speaking. Friedreich has also sought to interpret the nystagmus which appears by the hypothesis of an "ataxic nystagmus." The disease lasts for a very long time, for many years, and finally leads to complete paralysis, contractures, and atrophy of the paralyzed muscles.

The anatomical examination of the spinal cord has so far shown in all cases a combined fascicular disease of the posterior and lateral columns. In the case reported by Kahler and Pick this disease could be demonstrated as a combined systemic disease. It affected the lateral pyramidal tracts, the lateral cerebellar tracts, the fundamental bundle of the posterior columns, and the columns of Goll. F. Schultze has lately taken the same views in regard to the anatomical lesion.

The disease is incurable; at least all the attempts at treatment up to the present time have been unsuccessful.

#### ATAXIC PARAPLEGIA.

(*Combined Postero-lateral Sclerosis.*)

[This name has been given by Gowers to a chronic degenerative disease of the spinal cord which involves both the posterior and lateral columns. It differs from Friedreich's ataxia in that it is not a family disease, and that it usually attacks persons in middle life, men being affected more frequently than women. Unlike true tabes, syphilis is only rarely a factor in the ætiology. The various alleged causes of chronic myelitis have been supposed to have an influence in producing this affection, especially exposure to cold, trauma, and sexual excess. In Italy, pellagra has been known to produce it. Chronic lead poisoning may be of influence.

As has been said, the pyramidal tracts and the postero-median columns are chiefly affected, but the degeneration is not limited absolutely to these systems of fibers.

The symptoms, as may be inferred from the distribution of the sclerosis, are a combination of those of spastic paraplegia and true tabes. There is weakness of the legs combined with ataxia. Rigidity is a late symptom. Pain is occasionally present, but it is much less marked than in true tabes. Sensory disturbances are rarely met with. The knee-jerk is usually exaggerated, and there may be ankle clonus. If, however, Westphal's tract be involved (*vide supra*), the knee-jerk is lost. The bladder and rectum may become affected later. Eye symptoms are not common. The affection may be associated with general paralysis (*q. v.*).

The affection is slowly progressive. The diagnosis is based on the co-existence of ataxia and paraplegia, and the absence of sensory and ocular symptoms. Transition forms more closely resembling chronic myelitis may also occur. The treatment is that of chronic myelitis.—K.]

## CHAPTER VII.

## AMYOTROPHIC LATERAL SCLEROSIS.

AMYOTROPHIC lateral sclerosis is a disease perfectly sharply defined both in its clinical and its pathological aspects, and in the majority of cases it may be diagnosed with great certainty, even during the patient's life. For the first accurate knowledge of it we must thank Charcot, who published in 1869, in company with Joffroy, his first observations upon such cases, and who in 1874 was able to give quite a complete description of the disease; but an exact knowledge of amyotrophic lateral sclerosis was first made possible by Flechsig's investigations upon the course of the paths of conduction in the spinal cord. According to these, it may be stated with perfect certainty that the affection is to be regarded as a systemic degeneration of the pyramidal tract throughout its whole extent, or at least in certain portions of it, combined with atrophy of certain nerve-nuclei in the medulla oblongata. It is still entirely unknown to us what causes bring on the disease of these nerve-fibers and the cells belonging to them. In individual cases we can not usually make out any definite aetiological factor at all. Severe physical exertion is sometimes claimed to be a cause for the disease. It occurs chiefly in persons in youth and middle life, between twenty-five and forty-five. The male sex seems to be decidedly more prone to the disease than the female.

**Pathological Anatomy.**—In the typical cases of amyotrophic lateral sclerosis, which come to autopsy in the last stage of the disease (initial cases have not yet been examined anatomically), we find in the spinal cord a degeneration or "sclerosis" of both pyramidal tracts, and a considerable atrophy of the corresponding large ganglion-cells in the anterior gray cornua, especially in the external portion. The degeneration of the pyramidal tract is to be made out either in the two lateral columns alone, or, if there be an anterior pyramidal tract also, in one or both anterior columns (see page 535 and Figs. 66 and 67). It occupies mainly the same area on cross-section of the cord as the region of the pyramidal tract; the boundaries of which tract have been determined by the distribution of secondary descending degeneration (*vide infra*), and by the results of the history of development. Beginning in the lowest part of the lumbar cord, it may be traced upward to the pyramids of the medulla, and sometimes, but not always, still farther through the pons and the crura to the internal capsule. In some cases examined recently by Charcot and Marie the degeneration extended even to the central convolutions, whose large motor ganglion-cells also showed a pronounced atrophy. Toward the lateral cerebellar tract the disease of the pyramidal tract in the cord is very sharply defined, but in the anterior portions of the lateral columns other bundles of fibers are often affected. The whole extent of the disease in the lateral columns is therefore usually greater in amyotrophic lateral sclerosis than in secondary descending degeneration. Of the greatest clinical importance, however, is the already-mentioned co-existing disease of the motor ganglion-cells in the anterior cornua of the spinal cord and the disease of certain nerve-nuclei in the medulla oblongata, especially the hypoglossus nucleus, the vagus-accessory nucleus, etc. From these cells, which are inserted into the motor tract, the degeneration passes on toward the periphery, in the affected nerve-trunks (hypoglossus, etc.), or in the anterior roots belonging to them. It is difficult to make out atrophied fibers in the peripheral nerves, and up to the present time they have not always been looked for with sufficient care, but it can scarcely be doubted that the affected motor fibers, which are processes of the atrophied ganglion-cells, are likewise to be found in a condition of degeneration. Finally, the muscles show a considerable atrophy, as is plainly manifest even during the life-time of the

patient. Their volume is much diminished; many muscles (for details *vide infra*) finally almost wholly disappear, so that in their place there is little left but connective tissue and fat. In the other muscles we find, besides a number of normal fibers still preserved, many very small fibers, and also some which have lost their transverse striation and show a granular or fatty degeneration. The nuclei of the sarcolemma are usually increased, and the interstitial fat tissue is often, but not always, abundantly developed.

We accordingly see that the anatomical basis of amyotrophic lateral sclerosis is a more or less completely isolated disease of the great motor cortico-muscular conducting tract from the center to the periphery. The process is to be regarded as a simple degenerative atrophy. Fiber after fiber becomes diseased and atrophies. We do not know where the process begins, whether at one definite spot, whence it extends upward and downward, or whether the fibers throughout their whole extent, with the corresponding ganglion-cells and muscular fibers, are attacked at the same time. Perhaps different possibilities are to be regarded in these cases, which may explain the many variations in the clinical course. At any rate, the different portions of the system may become diseased in a varying order, and the further extension of the disease may vary in its rapidity. The spinal and the bulbar diseases are perfectly analogous to each other and are co-ordinated. Both affect portions of the same system; one belongs to the muscles of the extremities, the other to the muscles of the face, tongue, etc. The nerve-nuclei in the medulla are to be regarded as precisely analogous to the anterior gray cornua. The destruction of the nerve-fibers is always the primary process, the increase of the interstitial connective tissue and the slight changes in the vessels are a secondary, accidental process.

Besides the typical cases of amyotrophic lateral sclerosis, there are also, quite rarely, combined and transitional forms. Besides the degeneration of the pyramidal tract, an affection of the posterior columns and a degeneration of the lateral cerebellar tract have also occasionally been found.

**Clinical History.**—In all typical cases the clinical symptoms give a perfectly characteristic type of disease, limited strictly to the motor sphere, corresponding to the perfectly systemic anatomical lesions just described.

The first signs of the disease almost always begin in the arm. The patient notices a difficulty in working, and becomes easily tired. The weakness of the arm gradually increases, and finally, usually some months later, involves the other arm. A wasting of certain muscles, which gradually increases and becomes more extensive, is now often noticed by the patient. About six months or a year later, symptoms appear in the lower extremities. The gait becomes stiff and uncertain, the patient gets tired more easily, and quite a marked tremor of the legs often comes on, apparently spontaneously.

If we now examine the patient carefully, the type of the disease is usually perfectly plain. We notice, first in the upper extremities, a very pronounced and more or less extensive muscular atrophy. This is usually most marked where it begins—namely, at the thenar and hypothenar eminences. The interossei are also plainly atrophied, and the muscles on the extensor side of the forearms. The flexors of the hand and the fingers remain intact longer. In the upper arm the triceps and the deltoid are usually the most atrophied, and later, and to a less degree, the biceps and the muscles of the shoulder. We find a functional disturbance of the muscles—a paresis—corresponding to the degree of atrophy. The functional capacity depends upon how much muscle is left, and only with a complete disappearance of the muscle is there a complete loss of the corresponding motion, but a marked paresis can sometimes be noticed in muscles which are not yet much atrophied. The electrical excitability in the

muscular fibers still preserved is normal. The strength of contraction of the muscle irritated by the faradic current is therefore proportional to the amount of muscular substance still present. In the much-atrophied muscles the effects of irritation are finally very slight, and then we can always make out a distinct reaction of degeneration in the degenerated muscular fibers that are still left, especially in the ball of the thumb. We can scarcely ever make out with certainty a loss of excitability in the nerve-trunk, probably because here a greater number of normal fibers are always preserved.

The examination of the tendon reflexes is very important. They are invariably much increased, even from the early stages of the disease. We obtain vigorous reflex contractions from a gentle blow on the tendons of the biceps and the triceps, and on the lower ends of the bones of the forearm. These are of diagnostic importance, because they never occur in this way in ordinary "progressive muscular atrophy"—that is, that disease in which the degeneration extends merely from the muscles to the motor ganglion-cells in the anterior cornua, while the lateral motor-tracts remain free (*vide infra*). In the later stages of the disease marked contractures in the arms and hands sometimes, but not always, develop. The sensibility of the skin and deeper parts, however, remains absolutely normal.

The first morbid symptoms usually develop in the lower extremities some months later than in the arms. The pure spastic symptoms are here remarkably prominent, while the muscular atrophy is late in its development, and is but slight. The legs become stiff, and oppose considerable muscular resistance to attempts at passive motion, but the crude strength of the muscles is decidedly below the normal. There is an obvious paresis, although there is, as it seems, hardly ever a complete paralysis of the legs; and the disturbance of motion, at any rate, is considerably increased by the spastic symptoms (see a later chapter). These symptoms depend mainly upon the great increase of the tendon reflexes. The patellar reflex is very vigorous, and we often find a marked and persistent ankle clonus. The patient can still walk quite a distance, but the gait is, of course, difficult and laborious. The patient walks with short, slow, dragging steps—the spastic-paretic gait. The sensibility also remains absolutely normal in the legs. The cutaneous reflexes show no striking changes. Disturbances in micturition are also entirely absent. The bowels may be somewhat costive, but are otherwise normal.

After the condition has lasted for some time (a year or two) in this form—muscular atrophy and increased tendon reflexes in the upper extremities and spastic paresis in the lower—and has slowly grown worse, bulbar symptoms come on in the third and last stage of the disease. The speech gradually becomes more indistinct, and there is difficulty in swallowing. If we examine closely we find the lips atrophied, so that puckering the mouth, whistling, etc., are difficult. We also notice a decided atrophy of the tongue. Its surface is uneven, and we notice more or less marked fibrillary twitchings of single muscular bundles. The sensibility is also normal here. We sometimes find a vigorous masseter reflex (jaw-jerk) on striking the lower jaw, analogous to the increased tendon reflexes in the extremities. If the patient have trouble in taking food, from difficulty in swallowing, the state of the general nutrition soon becomes worse. Respiratory disturbances are usually the final immediate cause of death, if an intercurrent disease, such as inhalation pneumonia, etc., does not previously put an end to the patient's melancholy condition.

The picture of amyotrophic lateral sclerosis just sketched accords very well with the pathological lesions. As the degeneration affects the main motor tract exclusively, the clinical symptoms are also limited entirely to the domain of

motility. The associated affection of the anterior gray cornua explains the occurrence of muscular atrophy, while the degeneration of the lateral columns must be made answerable for the paresis, independent of the atrophy, and for the spastic symptoms. The increase of the tendon reflexes, whose reflex arc passes through the anterior cornua, forces us to suppose that the disease in the lateral columns precedes the degeneration in the anterior cornua, as this increase is seen especially in the lower extremities; for manifestly there can be no longer any reflex in muscular fibers whose special ganglion-cells are already atrophied. The increased reflexes are seen only in muscles which are composed, at least in part, of normal fibers. The bulbar symptoms are dependent upon the degeneration of the nerve-nuclei in the medulla.

The **diagnosis** of the disease is usually easily made. Its typical course, the muscular atrophy with co-existing increased tendon reflexes, the complete absence of sensory or vesical disturbances, and the final appearance of bulbar symptoms, are chiefly to be considered in diagnosis. Confusion may arise from the fact that tumors or myelitis may for a long time have a similar localization, as in the gray matter of the cervical cord, and therefore provoke analogous symptoms; but in such cases the later course is almost always different, and thus a subsequent diagnosis can be made correctly.

The **prognosis** of anyotrophic lateral sclerosis must be regarded as absolutely unfavorable. The disease advances slowly but unceasingly, and usually leads to death in a few years. Only in a few cases, occurring in early youth (Seeligmüller), does the disease seem to come to a standstill.

We can therefore expect but slight results from **treatment**. At most we can perhaps check the advance of the disease by an electrical treatment, kept up with very great patience and perseverance.

## CHAPTER VIII.

### PROGRESSIVE (SPINAL) MUSCULAR ATROPHY.

**Preliminary Remarks and Pathological Anatomy.**—Few diseases of the spinal cord have undergone such different conceptions and significations in the course of time as progressive muscular atrophy. The reason for this lies chiefly in the fact that its main symptom, the progressive atrophy of the voluntary muscles, may be found in many totally distinct diseases, and hence has given rise to constant confusion and mistakes. If, at the present time, we read the older and even a part of the newer literature on this subject, we find everywhere a mixture of different cases, not at all of the same disease, and only the latest accurate clinical and anatomical methods of investigation have enabled us to bring at least some order out of this chaos.

Except for a few earlier observations, Duchenne and Aran, in 1849 and 1850, gave the first good description of progressive muscular atrophy. The French observers, therefore, at present speak of the disease, in distinction from other similar affections, as "*atrophie musculaire progressive, type Duchenne-Aran.*" A short time after, in 1855, Cruveilhier, on the ground of a positive lesion on autopsy, first pronounced the opinion that a disease of the gray matter in the spinal cord was to be regarded as the special anatomical cause of the disease. Since then a tedious dispute has been carried on, and even in part kept up to the present time, as to whether, in fact, the disease has its seat in the spinal cord, or rather in the muscles themselves—a dispute which was neces- results

for a long time; the more because the actual pathological basis was very scanty, and because the data of examinations completely contradicted one another, owing to the confusion between different forms of morbid processes which did not belong together at all. The spinal nature of the disease was proven especially by the investigations of Lockhart Clarke, and Chareot, while in Germany Friedreich in particular has of late asserted its myopathic origin.

In our opinion there can no longer be any doubt\* of the fact that there is a perfectly clearly defined disease, whose chief clinical symptom consists of a very slow but constantly progressing atrophy of the muscles, following a certain type, while anatomical examination shows a degenerative atrophy, not only of the affected muscles, but also of the corresponding peripheral nerve-fibers, anterior root-fibers, and motor ganglion-cells in the anterior cornua of the spinal cord. We are therefore right in separating this disease, as a "spinal form of progressive muscular atrophy," from those cases where there is also the development of an independent progressive atrophy of the muscles, but where the affection always remains to the last confined to the muscles, and never invades the motor nerves and the spinal cord. These last-named cases form the pure muscular atrophies, which correspond to the types of the "hereditary or juvenile muscular atrophy or pseudo-hypertrophy" (see the appendix to this chapter). The spinal form of progressive muscular atrophy, with which we have to do here, is undoubtedly nearly allied to "amyotrophic lateral sclerosis," described in the previous chapter; but although in the latter the whole pyramidal motor tract may be degenerated, and the lateral pyramidal tracts in the cord are in particular always affected, in "progressive muscular atrophy" the degeneration, as we have said, is confined to that portion of the motor conducting tract which extends from the ganglion-cells of the anterior cornua to the muscular fibers themselves. The further central prolongation of this tract, however—that is, the lateral pyramidal tract—remains perfectly normal. It is very improbable that this difference in the extent of the anatomical localization is the principal distinction between the two diseases named. In their ætiological relations the two diseases, and also progressive bulbar paralysis (*vide infra*), are identical. The clinical distinctions due to the different anatomical localization are, however, of sufficiently marked prominence to justify, at least provisionally, a special description of progressive muscular atrophy and of amyotrophic lateral sclerosis. [In the great majority of cases which have come to autopsy, changes have been found in the lateral columns, so that an anatomical distinction between the three affections can hardly be maintained. Hence Schultze suggests the name of motor tabes as a general term for the three.—K.]

The precise anatomical lesion in progressive (spinal) muscular atrophy is as follows:

In the spinal cord, most marked usually in the cervical cord, we find the anterior gray cornua very small; the ganglion-cells have wholly or largely disappeared, and those remaining are atrophied; and the neuroglia is changed to a fine fibrous tissue, sometimes studded with spider-cells; but the lateral columns, especially the pyramidal tracts—that is, the portion of the motor conducting tract central to the ganglion-cells of the anterior cornua—are perfectly normal. The anterior roots and the affected motor fibers in the peripheral nerves are also atrophied, although in the nerve-trunks the discovery of degenerated fibers mixed

\* To the cases already published we can add a recent observation of our own, on a case of progressive muscular atrophy, involving the upper extremities chiefly, with almost complete atrophy of the ganglion-cells in the anterior cornua, although it was not followed by a corresponding co-existing degeneration of the lateral pyramidal tracts.

with many other normal fibers is not perfectly easy. In the muscles the atrophy is, of course, still more noticeable on a post-mortem examination than on examination during life. The muscles most affected are reduced to small, pale, and flabby bundles, in which fat and connective tissue outweigh the proper muscular tissue. On histological examination, we find in many fibers a simple atrophy—that is, a very considerable diminution, but with the transverse striation still retained; but in many other fibers we run across the signs of a degenerative atrophy—fatty and waxy degeneration of the muscular fibers, a splitting longitudinally or transversely, etc. The interstitial connective tissue is always increased, the muscular nuclei are increased in number, and we often find quite a deposit of fat between the fibers which are still preserved.

So far the actual lesion. In comprehending it, the only difficulties arise from the questions as to the mode of development, and as to the reciprocal dependence of the different disturbances. Is the atrophy of the anterior cornua to be regarded as primary, and the atrophy of the nerves and muscles as a secondary descending degeneration; or does the process begin in the muscles, and extend upward from them to the spinal cord; or, finally, do we have to do with an approximately simultaneous degeneration of the whole motor portion affected? These are questions to which at present no definite answer can be given. Many reasons seem to us to favor the belief that the degenerative process begins in the last terminal branches of the motor nerves, and from these ascends gradually to the spinal cord. This, however, is not yet proven, and possibly the starting-point of the disease and its further extent may differ in different cases.

**Ætiology and Clinical History.**—Progressive muscular atrophy is an extremely slow and chronic disease from the beginning. We often can not find any ætiological factors which seem to favor its development, but in a good many cases the first symptoms follow an immoderate muscular exertion. Thus we see the first signs of muscular weakness coming on, for example, after continued thrashing, hard washing, and similar severe physical toil. A hereditary predisposition is reported as common by most observers, but it is at present certain that most cases of this "hereditary muscular atrophy" belong, not to the spinal, but to the myopathic form (*vide infra*). It also seems to us to be very probable that of most of the other ætiological factors reported their number is to be explained, for the most part, only by erroneously reckoning other forms of atrophic processes with genuine progressive muscular atrophy. We refer especially to the alleged origin of this disease from injuries, from acute diseases, such as typhoid and diphtheria, or from syphilis.

The disease begins, by far the most frequently, in the upper extremities, and especially, as it seems, in the right arm, but sometimes in the left, or in both arms at once. As a rule, it begins with an atrophy of the short muscles of the thumb and of the hypothenar eminence, which is accompanied by a corresponding disturbance of function. Any other symptoms, especially disturbances of sensibility, paræsthesia, or pain, are usually entirely absent. The atrophy usually affects the abductor pollicis brevis first, and then the opponens and the adductor. We notice very early the characteristic sinking in and flattening of the ball of the thumb, and the abnormal position of the thumb, which is persistently approximated to the second metacarpal bone—the "ape hand." At the same time, or a little earlier or later, the interossei begin to atrophy, which is recognized by the sinking in of the interosseous spaces and the increasing incomplete extension of the terminal phalanges of the fingers. The atrophy of the lumbricales causes a visible flattening of the hollow of the hand. If the disturbance in the function of the interossei have reached a certain degree, the same claw-like position of the fingers appears, as we have already learned to recognize in ulnar paralysis (see

Fig. 78), due to the contracture of the antagonist of the interossei, the extensor communis digitorum.

In the further progress of the disease the atrophy extends either to the muscles of the forearm, or, what is not at all rare, it jumps over these and attacks the muscles of the shoulder, usually the deltoid first. In the forearm it is usually the muscles on the extensor side which are first attacked, the abductor and extensor longus pollicis, and only later the supinators, flexors, etc. In the upper arm the deltoid almost always atrophies first, and then the biceps, while the triceps may remain intact for a comparatively long time. Sooner or later the muscles of the trunk are often added to the list, the trapezius first usually, then the pectorals, the rhomboidei, and the latissimus dorsi. The disturbance of function caused by the atrophy of all these muscles is readily apparent from what was said in the chapter on the different forms of paralysis. In advanced cases the arms hang down laxly by the two sides of the trunk. Only with the greatest difficulty, if at all, can the patient do anything with them, either dress or undress; but he sometimes learns to help himself, at least in some degree, by throwing movements, by bending his body to meet anything, by using his mouth in taking hold of things, etc. Quite rarely the atrophy finally attacks the muscles of the neck. The severest respiratory disturbances may be excited by an implication of the diaphragm and the other muscles of respiration.

The time which elapses before the gradual appearance of the more marked disturbances of function is almost always very long. Years may elapse before the atrophy extends from the little muscles of the hand to the other muscles of the arm. In the muscles of the legs the first signs of atrophy almost always develop very late if at all. The arms are often perfectly useless when the patient can still walk for hours. Of course there are some exceptions to this rule. In the arms themselves, too, the process does not always develop in the way described above. Thus we not very rarely see the affection begin in the scapular muscles or the deltoid, and from this point the atrophy involves the muscles of the hand or of the upper arm. The muscles of the trunk, the pectorals, and the muscles of the back, are much more rarely the starting-point of the disease, and in only a very few cases have we been able to make out that the disease began in the legs. It is worthy of note that in such abnormal cases the muscles first affected were sometimes, but not always, subjected to extraordinary demands in carrying loads, etc.

Besides the atrophy, and the loss of function that runs parallel to it, we must mention some other changes in the muscles. The fibrillary muscular twitchings are often very striking. A constant tremor and wave of the muscle may be provoked by them. In some cases they are weak and only rarely noticed. They usually become vigorous if one irritates the muscle mechanically by a blow. The electrical excitability of the diseased muscles varies, inasmuch as it depends entirely upon the number of normal fibers still preserved in the muscle. Since the atrophy affects only one fiber after another, the faradic and galvanic excitability decrease gradually, and are lost completely only when the greatest part of the muscle is destroyed. On careful testing, we can then, however, almost always make out a decided reaction of degeneration in single muscles that are much diseased, especially in the form of the so-called partial reaction of degeneration: the excitability of the nerves is retained, but the contractions in the muscles themselves seem very slow, and the anodic closure contractions (AnSZ) predominate (see page 552).

In many cases there is an increase of the fatty tissue at the same time with the atrophy of the muscular substance, which often makes it very hard to judge of the atrophy; but the loss of function in the muscles, the diminished electrical

excitability, and the peculiar soft feeling which atrophied muscles have when covered with fat, reveal the true condition of things. Other trophic disturbances in the skin are usually entirely absent, but they are sometimes seen. In a few cases a spontaneous pemphigoid formation of bullæ has been observed, especially in the hands. The skin sometimes becomes thick and fissured, and the nails become brittle, grooved, and greatly curved. The coldness and cyanosis of the skin sometimes seen are due perhaps to vaso-motor disturbances, but at any rate we must also consider the disturbance of circulation which is due to the lack of muscular movements.

The examination of the tendon reflexes is of great diagnostic importance. While they are invariably decidedly increased in the upper extremities in amyotrophic lateral sclerosis, they are entirely absent in genuine progressive muscular atrophy, a condition which is easily explained by the atrophy of the motor ganglion-cells belonging to the reflex arc, or by the atrophy of the centrifugal motor fibers. Since no degeneration of the lateral pyramidal tract precedes this atrophy, it goes without saying that the preceding increase of the tendon reflexes, characteristic of amyotrophic lateral sclerosis, is also absent. In the lower extremities the patellar reflex is retained as long as the disease spares the legs, but it is not increased. If the atrophy involve the legs, the patellar reflex is usually lost.

In distinction from all these manifest disturbances in the motor region, the sensibility of the skin and deeper parts remains perfectly preserved. There are also never any morbid symptoms on the part of the bladder or rectum.

In many cases the affection finally invades the muscular region innervated from the medulla; the symptoms of "progressive bulbar paralysis" (*vide infra*) are added to those of progressive muscular atrophy. This combination of spinal and bulbar disease appears, as we have previously shown, as a rule, in amyotrophic lateral sclerosis, and even after the disease has lasted a comparatively short time. In genuine progressive muscular atrophy the bulbar symptoms usually develop, if at all, only after the disease has gone on for years. Then the speech begins to become indistinct, from the atrophy of the tongue, swallowing is difficult, and the patient finally succumbs to increasing inanition or to respiratory disturbances. In their principal characteristics the muscular atrophy of the extremities and the bulbar symptoms are precisely analogous phenomena, inasmuch as the nerve nuclei in the medulla have precisely the same significance for the muscles of the tongue, the pharynx, and the face, as the anterior gray cornua of the cord have for the muscles of the trunk and the extremities. In many cases, however, bulbar symptoms do not develop at all, since the patients die before then of some intercurrent disease.

**Diagnosis.**—The diagnosis of progressive muscular atrophy can easily be made if we confine ourselves strictly to the definition of the disease, and do not confuse it with other affections in which the muscular atrophy is only a symptom which under some circumstances may have an entirely different origin: muscular atrophies in extensive diffuse myelitis, in tumors, and in the formation of cavities in the cord, in multiple neuritis, as a result of articular affections (see the chapters on acute and chronic inflammations of the joints), etc. We should consider especially the typical course of the affection in most cases of genuine progressive muscular atrophy, its beginning in the upper extremities, the small muscles of the hand, or more rarely the muscles of the shoulder and upper arm, its slow advance, the peculiar "individualization" of the atrophy—that is, the affection of some muscles while other neighboring muscles remain completely normal; and, finally, the absence of all disturbances of sensibility or of the sphincters. Progressive muscular atrophy is doubtless nearly allied to amyotrophic lateral sclerosis, but the latter is distinguished by its more rapid course, and especially by the increase of

the tendon reflexes due to the affection of the lateral columns, and the corresponding appearance of spastic symptoms in the legs. The differential diagnosis between the spinal and the myopathic, juvenile muscular atrophy, will be described in the appendix to this chapter.

The **prognosis** of progressive muscular atrophy is to be regarded as absolutely unfavorable. The disease appears comparatively benign only in its frequently very slow advance, since it may last for ten or fifteen years, or even longer. As we have already said, the fatal termination at last appears from some intercurrent disease, or as a result of the final appearance of dangerous bulbar symptoms, paralysis of deglutition and respiration.

The results of **treatment** are accordingly very slight. An electrical treatment, continued for months and years with very great persistence, can alone produce a little improvement or check the advance of the atrophy somewhat. Temporary improvement may also sometimes be attained by a methodical massage of the muscles and a rationally conducted gymnastic treatment. In other respects, the treatment must be symptomatic. [Gowers claims that daily subcutaneous injections of strychnine, gr.  $\frac{1}{100}$  to  $\frac{1}{40}$  (grm. 0.0005-0.002) often arrests the disease.—K.]

## APPENDIX.

### THE PRIMARY MYOPATHIC FORMS OF MUSCULAR ATROPHY.

(*Hereditary or Juvenile Forms of Muscular Atrophy. Pseudo-hypertrophy of the Muscles. Pseudo-hypertrophic Muscular Paralysis.*)

Besides the spinal form of progressive muscular atrophy, just described, there are also morbid conditions of the muscles, which develop exclusively in the muscles themselves, independently of any discoverable affection of the spinal or peripheral motor nerve-tracts, and which also lead to a very considerable atrophy and a corresponding disturbance of function in them. Besides this anatomical distinction, which is still more sharply pronounced in the special form of the disease of the muscles (*vide infra*), an essential clinical distinction between the spinal and the myopathic forms of muscular atrophy is shown by the fact that, with few exceptions, the myopathic form appears in youth, and often even in childhood, and that it very often attacks several members of the same family. We may therefore imagine that a congenital defective predisposition of the muscular system is the chief cause of myopathic muscular atrophy.

The form of this class of muscular diseases longest known is the so-called pseudo-hypertrophy of the muscles, a disease in which the actual atrophy of the muscular fibers is in part so concealed by an increase of the interstitial fatty tissue that the atrophied muscles show even an increase of volume. Griesinger in 1864 gave the first accurate description of this condition in Germany, while Duchenne first called attention to the disease in France, and in 1868 was able to give a very complete description of the clinical aspect of the disease. M. Eulenburg and Cohnheim, by the first careful anatomical examination of the nervous system, had already before this (in 1866) made out that its condition was perfectly normal.

Of late, however, we have reached the opinion that juvenile myopathic muscular atrophy need not always appear wholly in the form of lipomatous pseudo-hypertrophy, but that it may develop partly, if not exclusively, as simple muscular atrophy with a considerable loss of volume in the muscles. Erb in particular has lately described a number of cases, which have led him to establish a second special form of juvenile muscular atrophy. In fact, we can not deny that we can establish different "types" of myopathic muscular atrophy on the ground of cer-

tain peculiarities; but it is shown by increasing experience, as Erb himself has already stated, that the individual types do not differ in principle, but that they may run into one another in various ways. In what follows, the separate description of the chief types known at present is to be regarded as separate only in a clinical sense. We hold firmly, however, to the general distinction between these types and the spinal form of muscular atrophy. The constant confusion of these two forms of disease has been the main cause of the errors that obtained until a short time ago in regard to all the questions with reference to this subject. It is still advisable at present, however, especially from didactic reasons, to describe the myopathic forms directly after the spinal forms.

1. PSEUDO-HYPERTROPHY OF THE MUSCLES (*Lipomatosis luxurians muscularis progressiva* of Heller; *Atrophia musculorum lipomatosa* of Seidel).—Pseudo-hypertrophy develops almost invariably in childhood, somewhere between the ages of five and eight years. It very often depends upon a pronounced heredi-

FIG. 92.—Positions of a child with hereditary (pseudo-hypertrophic) muscular atrophy, on rising to an erect attitude. (From GOWERS.)

tary predisposition, since several children of the family are affected by the disease in the greater part of the cases. More rarely we can make out the same disease in the patient's antecedents. The male sex is decidedly more disposed to the disease than the female. Sometimes, but not always, we also find in the affected families some disposition to a nervous taint, such as hysteria, epilepsy, feeble-mindedness, anomalies of the skull, etc.

The disease begins gradually and almost always without a special exciting cause. The parents notice that the child, who had been previously perfectly well and strong, becomes insecure on his legs, so that he can no longer jump or go up-stairs as well as he used to do. This points to the first characteristic peculiarity wherein pseudo-hypertrophy differs from progressive muscular atrophy. It begins, with rare exceptions, in the muscles of the trunk, especially in the muscles of the back and loins, and in the muscles of the lower extremities, especially in those of the thigh. While the arms and hands are still perfectly normal, walking constantly grows more and more difficult, and the gait very soon assumes so characteristic a type that from this alone the diagnosis can often be made at the first glance. The gait becomes waddling, the belly appears very prominent, the vertebral column is arched forward in the lumbar region in marked lordosis, and the

whole upper part of the body is balanced on the legs. The legs are raised slowly and with difficulty, and the toes usually droop from paresis of the dorsal extensors. The child's movements, when he tries to raise himself from the floor or pick up any object, are very characteristic, and are alike in almost all cases. Since it is impossible to raise the trunk, the child usually gets on all fours first, and then gradually straightens himself up by leaning his arms on his knees (see Fig. 92). Later on disturbances of motion appear in the upper extremities also, and in general they are very similar to those to be described more fully in the next type.

FIG. 93.—Pseudo-hypertrophy of the muscles.  
(FROM DUCHENNE.)

If we examine the patient more closely we shall usually find at the first glance an extraordinary increase in the volume of single muscles (see Fig. 93). The calves are disproportionately thick, and sometimes the thighs also; the arms are affected later, especially the deltoids, the triceps, etc. This increase of volume is caused by an abnormal interstitial development of fat, "pseudo-hypertrophy." Hence the muscles do not feel firm, but soft and spongy. It is by no means rare, however, that, besides the pseudo-hypertrophy in some muscles, a genuine atrophy develops in others, with a pronounced loss of substance and without any co-existing development of fat. This is seen especially in the upper extremities. Finally, there seems to be in addition even a genuine muscular hypertrophy. In several cases we have seen a marked increase in volume in the muscles of the calves, which were capable of quite an extraordinary display of strength. In such cases, however, there is, probably, in our opinion, a sort of compensatory hypertrophy, since the muscles that are still able to work are exerted immoderately.

Fibrillary twitchings of the muscles can only very rarely be plainly noticed, which is probably connected with the form of atrophy (*vide infra*). Electrical examination shows a diminution of excitability corresponding to the atrophy and to the increased deposit of fat, but never reaction of degeneration. This is a fact of great importance because it agrees with the anatomical condition of the diseased muscles, and is in remarkable contrast to the occurrence of reaction of degeneration in spinal muscular atrophy. The sensibility remains perfectly normal, and also micturition and defecation; the patellar reflex was absent in some of the cases examined by us. It is noticeable that the skin, especially in the legs, very often shows a peculiar bluish marbled coloring. Bulbar symptoms probably never occur. The intelligence in most cases is perfectly normal, but it sometimes happens that children with hereditary muscular atrophy at the same time show manifest signs of mental or even of moral weakness.

The disease advances very slowly but without remissions. Finally the patient can not walk at all; he is confined to the bed, and becomes more and more helpless. Death usually ensues from some intercurrent disease, but sometimes from insufficiency of the respiratory muscles.

The anatomical lesions in all cases of genuine pseudo-hypertrophy, whether hereditary or arising in childhood, which have thus far been carefully examined (Charcot, F. Schultze, Berger, and others), have been completely negative with regard to the nervous system. Except for accidental and insignificant complications, the spinal cord, and especially its anterior gray matter, have been perfectly

normal. In the muscles microscopic examination shows a very considerable increase of the interstitial connective tissue, and especially of the fatty tissue between the single fibers of the muscle. This may sometimes be seen, even during the patient's life, by harpooning or excising little pieces of muscle. The fibers themselves have not undergone fatty degeneration, and they show but very little degenerative atrophy, but everywhere their transverse striation is manifest. Some of them are perfectly normal in volume, others decidedly smaller, and some are even actually hypertrophied (compensatory hypertrophy?). We see, then, that the anatomical lesions of the muscular disease are essentially different from the purely degenerative changes in the muscles in spinal muscular atrophy.

2. ERB'S FORM OF JUVENILE OR HEREDITARY MUSCULAR ATROPHY.—This form also begins almost always in youth, before the age of twenty, but, as a rule, somewhat later than the form associated with pseudo-hypertrophy. It is occasionally or even very often hereditary or generic (that is, occurring in families), and the female members of the family are often attacked by this form, while pseudo-hypertrophy is seen especially in boys. The disease is also, like pseudo-hypertrophy, sometimes seen to begin in the back and legs, but quite frequently the shoulders and upper extremities are first attacked. There is also a remarkable regularity in the choice of the muscles attacked. According to Erb, the following muscles are almost constantly diseased in the trunk and the upper extremities: the pectoralis major and minor, the trapezius, the latissimus dorsi, the serratus magnus, the rhomboidei, the sacro-lumbalis and longissimus dorsi, and later the triceps. The following, however, almost always remain normal: the sterno-mastoid, the levator anguli scapulae, the coraco-brachialis, the teres major and minor, the deltoid, the supra-spinatus and infra-spinatus, and, in distinction from what was especially stated in regard to spinal muscular atrophy, the small muscles of the hand. The muscles of the forearm, too, except the supinator longus, remain intact for a long time, if not entirely. In the lower extremities the atrophy attacks chiefly the glutei, the quadriceps, the peronei, and the tibialis anticus, while the sartorius and the muscles of the calf are usually spared for a long time. Fibrillary twitchings in the affected muscles are generally absent, and there is never any reaction of degeneration.

The disturbances of function due to this condition are self-evident, so that a full description of them may be omitted. The arms usually suffer first, as we have said. The marked projection of the scapulæ, from the paralysis of the serratus, is especially characteristic. The gait soon becomes waddling, as in pseudo-hypertrophy, and, finally, walking is utterly impossible. The whole course of the disease is always very chronic. Erb describes cases in which the disease has existed from twenty-three to thirty-eight years. Bulbar symptoms are as rare as in muscular pseudo hypertrophy. It is of significance that the diaphragm may atrophy, and the consequent respiratory disturbance may be the cause of death.

If we have an opportunity to examine the diseased muscles anatomically, we find that the interstitial development of fat is entirely absent. The connective tissue is somewhat increased, and its nuclei are more numerous than in healthy muscles. In the beginning of the disease some of the muscular fibers are hypertrophied, but simply atrophied fibers predominate. The number of muscular nuclei is considerably increased. We often see vacuoles in the individual fibers. The more the muscular substance wastes the more abundant becomes the connective tissue.

3. THE INFANTILE, USUALLY GENERIC FORM OF MYOPATHIC MUSCULAR ATROPHY WITH IMPLICATION OF THE FACIAL MUSCLES.—(Duchenne and Déjérine; see Fig. 94.)—Duchenne had already here is a form of muscular atrophy which begins in his statements were almost forgotten until, a few y ine called atten-

tion anew to this subject, and demonstrated, contrary to previous belief, that implication of the facial muscles is by no means an unusual symptom. Indeed, the

FIG. 94.—Juvenile myopathic muscular atrophy in a ten-year-old child, with marked implication of the facial muscles. Inability to close the eyes or move the lips. Atrophy of the pectorals, etc. (From the Erlangen Medical Clinique.)

disease very often begins in the facial muscles; the eyes can no longer be completely closed, and the movements of the mouth in whistling, laughing, and talking become impaired. From the sinking in of the cheeks, the drooping of the under lip, etc., there develops a very characteristic type of countenance ("*facies myopathique*"), by which the practiced eye can recognize the affection at once. As the disease advances the muscles of the shoulder and upper arm are usually first affected, sometimes the muscles of the back, the thigh, etc. The muscles of mastication, the internal ocular muscles, and the muscles of the forearm and hand almost always remain normal. A slight permanent contraction of the biceps is often present and is characteristic. The selection of muscles usually affected is almost precisely the same as in the previously described juvenile muscular atrophy. Fibrillary contractions and reaction of degeneration

are almost always absent. We therefore believe that the two forms are not sharply to be separated, but that they are closely allied to each other. The implication of the facial muscles was in former times probably often overlooked. In order to detect it it is the best plan to have the patient close his eyes when the head is bent backward; we can then readily detect the fissure left between the eyelids (insufficiency of the orbicularis oculi). Sometimes the defective development and functions of the facial muscles seem to be a congenital condition, which may remain as such, or to which sooner or later an actual progressive muscular atrophy is added. We have ourselves recently made the especially interesting observation that sometimes we find in the relatives (brothers or sisters) of patients with pronounced myopathic muscular atrophy, signs of a congenital weakness of development of the facial muscles, such as incomplete closure of the lids, inability to whistle, etc., without any disease which progresses further.

That all three of the forms just described of juvenile atrophy and pseudo-hypertrophy are, at bottom, probably identical diseases, follows not only from all the other similarities mentioned, but also from the fact that sometimes one of the children affected in the family displays rather the type of pseudo-hypertrophy, another the type of simple juvenile atrophy. We also find various transitions between the different forms. Thus, for example, pseudo-hypertrophy in the legs

may be associated with simple atrophy of the arms. The affection may also begin in the arms, while later the facial muscles are also affected. We do not know what causes produce the great increase of fat-tissue in a part of the cases. Even in the cases without the interstitial development of fat the atrophy of the muscles is essentially simple, not degenerative, and the motor nerves and spinal cord remain normal, at least according to all present experience. Erb groups the two forms together, under the name of "*dystrophia muscularis progressiva*."

The differential diagnosis between the myopathic and the spinal muscular atrophies is not difficult, if we pay attention to the juvenile or generic character of the former, and also to its characteristic localization, affecting the extensors of the spine and leaving free the small muscles of the hand, etc., and to the absence of fibrillary twitchings and of reaction of degeneration in the muscles.

The treatment can scarcely ever be expected to give permanent results, but sometimes, even in juvenile muscular atrophies, some considerable improvement has been obtained by a very persistent electrical treatment and massage of the muscles.

[Charcot and Marie, and, independently of them, Tooth, have described a form of progressive atrophy, the "peroneal type," which begins in the peroneal muscles, or perhaps in the intrinsic muscles of the foot. It occurs usually in families, and begins in the second half of childhood, seldom after the age of twenty. Males are most frequently affected. There is some fibrillary twitching of the affected muscles, and reaction of degeneration may occur. The muscular atrophy may lead to club-foot. Vasomotor and sensory disturbances have been noted. It is rather apt to follow acute diseases, especially measles. The pathology is still obscure, but many writers are disposed to think it due to a peculiar form of chronic peripheral neuritis. Hence it is sometimes spoken of as progressive neuritic atrophy.—K.]

## CHAPTER IX.

### THE SO-CALLED SPASTIC SPINAL PARALYSIS.

(*Primary Lateral Sclerosis. Spasmodic Tabes Dorsalis.*)

In the year 1875 Erb, and soon after Charcot, called attention to a clinical form of spinal paralysis by no means rare, which is characterized "by a gradually increasing paresis and paralysis, usually advancing slowly from below upward, with muscular tension, reflex contractions and contractures, with a marked increase of the tendon reflexes, with complete absence of sensory and trophic disturbances, of vesical and sexual weakness, and of any cerebral disturbance." Both observers agreed in assuming a "primary symmetrical sclerosis of the lateral columns" as the anatomical cause of this condition.

The numerous observations published in the following years have shown that the type of disease just briefly described is, in fact, often to be met with, and may easily be distinguished from the other forms of spinal paralysis. The hypothesis as to its anatomical basis has not yet been confirmed, however, since, in all the cases that have come to autopsy so far, other anatomical changes were found instead of the primary lateral sclerosis supposed to be the only lesion; but it can not be denied that, besides other lesions, of course, a disease of the lateral columns has been repeatedly made out in such cases; and that this was certainly not without significance for the occurrence of the gr

estion. It is

also not at all impossible that there may be an isolated systemic disease of the lateral columns, especially of the pyramidal tracts, without any disease of the gray matter or of other portions of the cord at the same time, which disease is closely connected with amyotrophic lateral sclerosis in particular, and is a further link in the chain of primary diseases of the motor conducting tract; but, as we have said, a definite case of isolated disease of the spinal pyramidal tracts, without invasion of the anterior gray cornua, has not yet been known.

In what follows we will first describe the clinical peculiarities of spastic spinal paralysis, and then add the enumeration of its anatomical causes, as far as they are known at present. Hence we mean by "spastic spinal paralysis" only a group of symptoms which is so often observed that, from practical reasons, it is advisable to give it a short and unprejudiced name.

**Type of Spastic Spinal Paralysis.**—Two symptoms predominate in the picture of spastic spinal paralysis: motor paresis, and the increase of the tendon reflexes—the patellar reflex, and the ankle clonus. The former—we are speaking at present only of the spastic paralysis of the legs, which is by far the most frequent and the most clearly marked—is found in various degrees, from a simple weakness of movement to a complete and more or less extensive paralysis. It is the second symptom, however, which gives to the disturbance of motion its characteristic feature of spastic paralysis. If the increase of the tendon reflexes be very considerable, the reflex contractions come on even upon the stretching and pulling of the tendons, which is excited by the weight of the limbs or by any active or passive movements. The reflex muscular tension opposes any attempt at motion. The muscles feel rigid and firm, and the legs are often found in almost permanent contracture and extended, with the feet in plantar flexion. If we try to flex the leg passively at the knee, or if we try to extend the foot dorsally, we find it almost impossible to do so. The more rapidly and suddenly we try to produce the motion, the more marked is the muscular resistance, which can scarcely be overcome. If, however, we go to work very slowly and cautiously, and avoid any sudden tension of the tendons, we can almost always flex the leg without special trouble. If we put the patient on the edge of the bed, the legs do not hang down laxly, but they usually fall at once into a vigorous extensor tetanus, since the weight of the leg puts the quadriceps into contraction by the tension on the ligamentum patellæ. A convulsive, reflex tremor of the whole leg often comes on at once, similar to ankle clonus. If we examine the patient while in the bath we find the spasms decidedly less, because in the water the influence of the weight of the limb is absent.

Active motion, as is easily explained, must also be impaired from the inhibitory action of the reflex spasms. The degree of disturbance of motion is thus increased, and the paresis often seems greater than is really the case. The influence of the muscular tension is especially manifest in the gait of the patient. As long as walking is still possible, we notice very plainly that it is rendered difficult, not only by the muscular paresis, but also by the stiffness of the legs. The patient walks with short and difficult steps, the legs are scarcely flexed at the knee, and the feet are scarcely raised at all. The feet "stick to the floor" and are slowly slid forward, and there is a marked tendency to walk on the toes from the contraction in the muscles of the calves. The weight of the body alone presses the feet downward. We term this very characteristic form of gait the spastic-paretic gait.

The increase in the tendon reflexes may also exist without the presence of any special motor paresis of the muscles at the same time. Since, however, in this case, the motion is not a little influenced by the constant spasms, a disturbance of motility may be counterfeited, which might be called "spastic pseudo-paralysis."

or, more properly, pseudo-paresis. In these cases the muscular strength is almost normal, and the patient can walk for quite a long time. Nevertheless, all his movements are stiff and difficult, and the gait shows all the peculiarities of the pure spastic gait. The steps are not very short and they follow one another quite rapidly, but the legs remain perfectly stiff and are scarcely raised from the ground, and the patient walks almost entirely on his toes. In the house the patient walks with a noisy shuffle, and in soft sand we can see the furrows drawn by the feet as they slide along the ground.

Although we are doubtless justified in referring the spastic condition mainly to the increase in the tendon reflexes, we must also add that sometimes symptoms of direct motor irritation may occur—single rapid or slow contractions, for which we can not make out a reflex origin. In some muscles there seems sometimes to be a state of constant tonic irritation; thus we often see the great toes in a permanent state of marked dorsal extension. If the patient bend his knee, a marked dorsal extension of the foot is added as an associated movement. Although the symptoms mentioned are the characteristic positive features of "spastic spinal paralysis," yet, in the original sense of the word, the affection is also characterized by the fact that certain other spinal symptoms, especially disturbances of sensibility, disturbances in micturition and defecation, ataxia, muscular atrophy, and other trophic symptoms, are entirely absent. Only when such was the case have Erb and Charcot claimed that a special anatomical cause must lie at the bottom of the peculiar group of symptoms. In fact, the cases in which we happen to see the type of genuine spastic spinal paralysis without any other symptoms are not very rare. It develops slowly and gradually, without known cause, and usually in patients in youth and middle life. One leg is first affected and then the other. The muscles of the trunk and of the arms are sometimes added to the list later on, and in the arms we find a paresis with a decided increase of the tendon reflexes and without any disturbance of sensibility or any muscular atrophy. This type of disease, however, only very rarely remains in its purity—at least, according to present experience. Sooner or later other symptoms are mixed with it, and in those cases, which so far have come to autopsy, the anatomical lesions are by no means always of the same sort.

**Pathological Lesions.**—As we have already said, Erb and Charcot originally advanced the hypothesis that the anatomical basis of spastic spinal paralysis is to be found in a sclerosis of the lateral columns. This opinion is well-founded, inasmuch as the picture of the symptoms of spastic spinal paralysis manifestly recalls amyotrophic lateral sclerosis in many of its relations. In both diseases we find symptoms limited exclusively to the motor sphere, and an increase of the tendon reflexes. The only distinction is in the muscular atrophy, whose anatomical cause is undoubtedly to be found in the atrophy of the anterior gray cornua. If we imagine the pyramidal tract exclusively affected, without co-existing disease of the gray matter, the result must be the picture of "spastic spinal paralysis." This line of reasoning, the justification of which must to-day be acknowledged, has, however, not yet been entirely confirmed by facts; but we have learned to recognize a chain of circumstances under which, at least at times, the symptoms of spastic spinal paralysis may arise.

We must first mention that cerebral changes, especially chronic hydrocephalus, may sometimes simulate the type of spastic spinal paralysis. Except for some anomalies in the skull, special cerebral symptoms may be entirely absent, while the motility of the legs (and arms) is diminished, and the tendon reflexes are so decidedly increased that the symptoms of spastic paralysis may result. R. Schulz and we ourselves have made such observations.

The following changes are also to be consi

1. Transverse myelitis in the upper dorsal or the cervical cord. This sometimes shows a remarkable symmetry in its distribution for some time, and a predominant localization in the lateral columns, while the posterior columns remain comparatively free. Hence, as we can easily understand, the result is a paralysis of the legs with greatly increased tendon reflexes, but with normal sensibility. Tumors of the cervical cord may more rarely cause similar appearances.

2. *Compression of the Spinal Cord.*—A gentle compression of the cord in the cervical or dorsal region is followed, as we have seen, by paresis and increase of the reflexes, but not by sensory disturbance. We can understand that, if no manifest cause of compression can be made out, a primary affection of the cord may simulate the symptoms of spastic spinal paralysis.

3. Multiple sclerosis may also frequently show such a localization of its nodules as to be followed by paresis and spastic symptoms without sensory disturbances. The case diagnosed by Charcot himself as "*spasmodic tabes dorsalis*" turned out on autopsy to be multiple sclerosis.

4. In a case observed by us, with almost the entire and pure type of symptoms of spastic spinal paralysis, the autopsy showed a hydromyelus with co-existing degeneration of the lateral columns.

5. Spastic paralysis has been sometimes observed to come on after acute diseases, but the reports of autopsies in such cases are at present wanting.

6. Finally, we will here briefly mention the combined systemic disease of the pyramidal tract, the lateral cerebellar tract, and the columns of Goll, in adults, described by us. In these cases we find a gradually increasing paralysis of the legs, and later of the arms, with increased tendon reflexes, spastic symptoms, and sensibility almost perfectly normal. Later on, however, vesical disturbances arise, which are probably to be referred to the disease of the columns of Goll. The occurrence of true ataxia in the legs, with weakness and increased tendon reflexes, seems to be not unusual; but lancinating pains, marked disturbances of sensibility, and pupillary changes are always absent, so that the morbid picture is always very materially different from that of *tabes dorsalis*. Further observations must give us more definite knowledge as to the frequency and the possibility of diagnosis of this apparently especially limited form of spinal disease. Minkowsky has also recently reported a case in which anatomical examination showed nothing but primary degeneration of the pyramidal and cerebellar tracts in the two lateral columns as the cause of a spastic spinal paralysis. In this and in some similar cases, which come very close to Erb's and Charcot's theoretical postulate, syphilis was perhaps to be regarded as the special cause of the disease.

**Diagnosis.**—The symptomatic diagnosis of spastic spinal paralysis is easy to make, with attention to the description given above. We must always, however, be very cautious at present in our anatomical diagnosis. Only the further course of the disease can give us data whereby we can first consider the morbid conditions mentioned above.

**Prognosis.**—The prognosis of most cases which show the symptoms of spastic spinal paralysis is just as unfavorable as most of the other diseases of the spinal cord, but we must always bear in mind that many of these cases run a very slow course. The disease seems to stand perfectly still for a long time, the symptoms are less severe than in other spinal diseases, there are no pain and no incontinence, and sometimes we have seen manifest improvement and even a few recoveries, but such cases at present lack definite anatomical proof.

**Treatment.**—The treatment of spastic spinal paralysis in general agrees with that of chronic myelitis (*vide supra*). Galvanic treatment usually gives comparatively the best results. We must also mention especially that prolonged warm

baths often act well against the spastic symptoms. They may last for half an hour to an hour and a half, and should be of a temperature of 90°, or at most 95° (26°-28° R.). The legs are more flexible and more movable after them. Among internal remedies we may try nitrate of silver and ergotine. If there be a suspicion of syphilis, for which we should always look carefully, it is an absolute necessity to employ inunction, and to prescribe iodide of potassium internally.

## CHAPTER X.

### ACUTE AND CHRONIC POLIOMYELITIS.

#### 1. SPINAL PARALYSIS OF CHILDREN.

(*Acute Poliomyelitis in Children.*)

**Ætiology and Pathological Anatomy.**—In children there is quite frequently a definite and well-characterized form of paralysis, for the first accurate knowledge of which we must thank Jac. von Heine in 1840. Although Heine later, in 1860, expressed the opinion that a disease of the spinal cord formed the basis of the paralysis, the first actual confirmation of this opinion was furnished later by Prévost and Vulpian, Charcot and Joffroy, and others, so that at present we are justified in exchanging the old term "essential paralysis of children" for the name of "spinal paralysis of children."

As the name indicates, the affection occurs chiefly, if not exclusively (*vide infra*), in children, and is most frequent in the earlier years, somewhere between one and four. An exciting cause, such as taking cold, has hardly ever been made out. The children are almost always perfectly healthy\* previously, and come of healthy families without any neuropathic predisposition. The whole course of the disease makes the hypothesis very probable that we have to do with an acute infectious disease—with an infectious process, which first causes a general infection of the body, and then is localized chiefly in a circumscribed portion of the spinal cord. It also, perhaps, bears some relation to the nature of the disease as just signified that most of the cases occur in warm weather. With regard to this, it is worth mentioning that a short time ago we observed that in a little village within a few days three children fell ill with acute poliomyelitis.

With reference to its anatomy, the disease may be defined as an acute inflammation, which affects chiefly a definite extent of the anterior gray matter of the

FIG. 95.—Section through the cervical enlargement in anterior poliomyelitis: the left anterior column is very much contracted and is without ganglion-cells. (From CHARCOT and JOFFROY.)

\* The paralyzes arising after acute diseases—such as measles, scarlet fever, smallpox, etc.—are perhaps partly of spinal origin, but they can not be identified with the idiopathic spinal paralysis of children.

spinal cord, usually attacking only the anterior gray cornu of one side; yet it does not always limit itself strictly to this, but it may involve the white matter in the vicinity somewhat, although, of course, to a lesser extent than the gray matter. Although fresh cases have so far been examined in very scanty numbers, still we can sometimes make out clearly the remains of inflammation in the older centers of disease. The ordinary lesion in old cases, which is most frequently found, consists of a considerable atrophy of one anterior cornu, which is changed to a dense sclerosed tissue, often pierced by dilated and thickened vessels, and which contains scarcely a single normal ganglion-cell. If the paralysis affect one arm, the corresponding anterior cornu in the cervical enlargement is atrophied (see Fig. 95); if the leg be paralyzed, the process is seated in the lumbar enlargement. In bilateral paralysis we must think of an affection of both anterior cornua at the corresponding level of the cord.

This inflammation of the anterior cornu, the poliomyelitis, is to be regarded as the primary center of disease. From this point, as in every severe lesion of the motor ganglion-cells there situated, there develops a secondary degeneration, which, extending to the periphery, affects the corresponding anterior roots, and later their appropriate motor nerves and the muscles supplied by them. In the paralyzed muscles and nerves we accordingly find a marked pure degenerative atrophy, such as we have learned to recognize in severe peripheral paralyses.

Although at present the spinal origin of the atrophic paralysis of children is regarded as sufficiently certain, we would not deny that some authors, especially Leyden, have assumed a peripheral origin for some cases—that is, a primary neuritis, without a material implication of the spinal cord. In fact, it does not seem impossible that the same morbid aetiological factor, which we have supposed to be infectious, may exceptionally be localized chiefly in a peripheral motor nerve. In the chapter on cerebral paralysis of children, which is by no means very rare, we shall see that a manifestly closely allied acute process in children—one, perhaps, even aetiological identical—may also develop in the motor regions of the cortex cerebri.

**Clinical History.**—The disease almost always begins suddenly. A child who was previously perfectly well and lively is all at once attacked with severe fever, often reaching  $105^{\circ}$  or  $106^{\circ}$  ( $40^{\circ}$ – $41^{\circ}$  C.), which is associated with quite severe general symptoms even from the beginning. The child complains of headache, and sometimes of pain in the loins and in the limbs, and is decidedly stupid and somnolent. Very often still more marked cerebral symptoms develop: complete loss of consciousness, single twitchings in the face or the extremities, or general convulsions. The eclamptic attacks, turning of the eyes, and clonic contractions in the face and the extremities, often appear even at the beginning of the disease. The whole of the initial symptoms, whose intensity varies very much in the different cases, sometimes last only a very short time—a day or two—although they often continue for a week or two. Indeed, we even know cases in which, as the mothers have assured us, the children are said to have “lain in spasms,” almost uninterruptedly, even for four or five weeks before the beginning of the paralysis—that is, before it became noticeable. On the other hand, however, it may happen that the initial symptoms, especially the severe cerebral symptoms, are entirely absent or only intimated.

After the initial period of the disease just described has passed away, the parents usually notice that the child is attacked by a more or less extensive paralysis. If its development can be followed more closely, we always find that it spreads rapidly, often in single spurts which rapidly follow one another, so that it usually reaches quite a great extent in a short time. Either both legs, or the legs and one arm, or all the extremities, and even the muscles of the trunk, are

affected; but the paralysis scarcely ever remains permanently as extensively distributed as at first; it is reduced much more rapidly, and soon draws back to a definite muscular region, which remains permanently paralyzed. In some cases the paralysis may even entirely disappear, but as a rule a complete paralysis is left in one extremity, or at least in a portion of it; most frequently in one leg, especially in the peroneal muscles; somewhat more rarely in the arm, chiefly in the deltoid; sometimes in both legs; or, very rarely in spinal paralysis, in one arm and leg on the same side or on opposite sides. Meantime the child's general health has been completely restored. He is well and vigorous, has an excellent appetite, never shows any permanent cerebral disturbance—only the painless, flaccid paralysis, the inability to use the affected extremity, is left behind. In the following weeks and months a further, slower advance in the improvement in the power of motion often becomes noticeable, but, as a rule, a permanent and more or less complete paralysis of certain muscles remains.

In regard to the more intimate peculiarities of this remaining paralysis, it may invariably be characterized as a flaccid atrophic paralysis. A marked atrophy of the paralyzed muscles shows itself a few weeks after the beginning of the paralysis. This atrophy gradually advances further and may finally attain the highest degree. The atrophy is often, but not always, partly concealed by a more abundant development of fat tissue. The changes in the electrical excitability of the paralyzed nerves and muscles come on still more rapidly than the visible atrophy. Since we have to do with a pure degenerative atrophy of nerve and muscle, as follows from the anatomical basis of the disease, a pronounced reaction of degeneration must necessarily develop in the affected parts. Duchenne found that usually the faradic excitability of the nerves and muscles is completely lost after a week or two. On galvanic examination, we can at first detect an increase of excitability in the muscles with a predominance of slow anodic closure contractions (AnSZ), while later, after two or three months, the galvanic excitability also sinks very considerably; but the muscular contractions preserve their qualitative peculiarities characteristic of reaction of degeneration (see page 551). Very often the whole affected extremity remains backward in its growth, so that later the bones may show a shortening of several centimetres. The parallel between the muscular atrophy and the stunted growth is not, however, present in all cases, as Volkmann, in particular, has stated.

Passive motion of the paralyzed extremity is at first, and even later, perfectly free, except for the contractures that finally set in (*vide infra*). Many joints are so flaccid that we can actually make flapping movements with the paralyzed limbs and give them the most extraordinary positions. The tendon reflexes are invariably completely absent in the paralyzed extremities, and so almost always are the cutaneous reflexes—a condition which may sometimes be of diagnostic significance. The skin often shows certain trophic disturbances; it feels cool and has a cyanotic appearance. Its sensibility, however, is completely retained in all cases. Micturition is sometimes a little disturbed at the beginning of the disease, but in most cases this disturbance completely disappears later.

After the paralysis has existed for a long time, certain secondary contractures almost always develop in the paralyzed parts, which are in part of a very characteristic type. In the legs especially the "paralytic club-foot" (*talipes varo-equinus*) is a condition long known. It is due to the fact that, from the paralysis of the peronei muscles and of the tibialis anticus, the point of the foot constantly droops, and that a contracture is gradually developed in the intrinsic muscles of the calf, whose points of insertion are permanently fixed. In paralysis of the muscles of the calf there arises, on the one hand, a moderate degree of calcaneus from the contracture of the antag-

and in the vertebral column, in paralyses of the spinal muscles, the most manifold and sometimes very considerable contractures and deformities may also arise, the chief cause of which is always to be referred to the contracture of unparalyzed antagonists and to external mechanical conditions, such as weight and pressure.

In conclusion, if we simply compare the type of disease sketched with its anatomical cause, the general agreement of the two may at once be seen. The affection of the anterior gray cornu must have as a result a paralysis with a subsequent atrophy and reaction of degeneration, in which the reflexes must be lost by the destruction of the reflex arc, but the sensibility must remain perfectly normal from the persistence of the sensory conduction (the posterior columns and the posterior gray cornua), and the vesical functions must also remain normal. The subsequent paralysis is the result of the destruction which the morbid process, in itself completely ended, has caused in the spinal cord.

**Diagnosis.**—The diagnosis of the spinal paralysis of children is almost always easy to make and certain if we hold strictly to the definition and peculiarities of the disease, and do not reckon as spinal paralysis every paralysis appearing in a child. We should consider chiefly the acute beginning, the subsequent flaccid paralysis with atrophy and reaction of degeneration, with the loss of the reflexes, but with retained sensibility. If we observe these features, we are sufficiently protected against confusion with cerebral diseases and other diseases such as spondylitis, hereditary muscular atrophy, or spastic spinal paralysis.

**Prognosis.**—It is not impossible, but it is not yet proven, that many of the cases where children die speedily with convulsions are to be regarded as the initial stage of acute poliomyelitis. If, however, the first stage of the disease be past, the prognosis as regards life is entirely favorable, since the rest of the child's physical development is no further affected in any way. The prognosis as regards the complete restoration of the disturbance of function is, however, much more unfavorable. What has not recovered in the first weeks or months usually remains paralyzed for the whole life. Nevertheless, this experience should not restrain us from persevering in treatment, at least in the first years, since sometimes a very noticeable improvement in the functions of the paralyzed parts can thus be procured.

**Treatment.**—If we have an opportunity, even during the initial stage of the disease (when, of course, the diagnosis can not usually be made with certainty), to attack the disease by our treatment, we may prescribe cold compresses or an ice-bag to the head, and eventually, where there is high fever or great stupor, a tepid bath with cool affusions. We are but rarely led to try local bloodletting by leeches behind the ears or on the temples, where there are signs of marked cerebral hyperemia. Internally we usually prescribe a mild "intestinal derivative," such as half a grain or a grain (grm. 0.03-0.05) of powdered calomel every two or three hours, infusion of senna, etc.

After paralysis appears, we can expect the most success from electrical treatment, kept up consecutively for months, and, with interruptions, for years. We put a large, broad electrode on the vertebral column at the spot which corresponds to the place of the lesion in the spinal cord—on the cervical vertebrae in paralysis of the arm, and the lower dorsal in paralysis of the leg—while the other electrode serves for peripheral application to the paralyzed nerves and muscles. In this way we apply a moderately strong constant current, reversing it occasionally, for two or three minutes, partly stable and partly by passing the cathode, or eventually the anode, slowly over the paralyzed muscles and nerves. We may also employ occasional interruptions and changes of the current. Duchenne has also found persistent treatment by the faradic current of advantage. The sittings should take place three or four times a week, and later even oftener, if possible.

Besides electrical treatment, methodical gymnastic exercises of the muscles, that can still be moved somewhat actively, may be of distinct advantage. Regular and persistent massage of the muscles is also to be recommended in the later stages. In practice we can not avoid prescribing certain embrocations, such as spirits of camphor, spirits of mustard, or spirits of formic acid. Passive motion is very important to guard against contractures, and to improve the already existing deformities. In regard to the further details of orthopaedic treatment, which is of great importance, we must refer to the appropriate special works on surgery and orthopaedics.

The use of baths, of brine or ferruginous waters, is to be recommended, although, of course, they must not be overvalued. They may be given at home. If circumstances permit sending the child to a bath during the summer months, we should chiefly consider the brine baths at Reichenhall, Kreuznach, Kösen, and Colberg; the acid salines at Rehme, Nauheim, and Soden; and eventually, with weak and anæmic children, the use of the iron baths at Driburg, Pyrmont, or Schwalbach. Good results are sometimes obtained at the indifferent thermal baths at Teplitz, Wildbad, Ragatz, or Gastein, but these must be used only with caution. We also obtain good results, especially with older children, at the cold-water cures.

Very little is to be expected from the use of internal remedies. Iodide of potassium and strychnine are recommended, the latter in the form of subcutaneous injections,  $\frac{1}{16}$  to  $\frac{1}{8}$  grain (grm. 0.001-0.003) daily.

In old cases, where there is no longer any hope of further improvement of the paralysis worth mentioning, the treatment may be limited to keeping up and strengthening the patient's general condition as much as possible by proper food and good air.

## 2. ACUTE POLIOMYELITIS OF ADULTS.

(*Acute Atrophic Spinal Paralysis of Adults.*)

Although it had been believed for a long time that the form of acute atrophic spinal paralysis, just described, occurred only in children, later observations, by Moritz Meyer, Duchenne, Erb, F. Schultze, F. Müller, and others, have established the fact that precisely analogous cases of disease may also develop, although decidedly less frequently, in adults, especially in young persons under thirty. There is no longer any doubt of this fact, especially if we consider an undoubted anatomical lesion found by F. Schultze. We have, however, already stated that for a long time we have regarded the diagnosis of acute, and, as we shall soon see, of chronic poliomyelitis also, as too readily made, and that certainly very many of the cases diagnosticated and published as poliomyelitis are to be classed as primary neuritis (see page 582). Since we know that primary degenerative processes may develop acutely and subacutely in the motor nerves, and that these also lead to an atrophic paralysis, a greater part of the teaching on poliomyelitis needs new and careful revision in order to exclude what does not belong to it.

The type of acute poliomyelitis of adults, so far as it has been established by definite observations, which at present are not numerous, is, of course, not materially different from the type of the spinal paralysis of children.

We often can not make out any ætiological conditions; sometimes exposure to cold, overexertion, etc., seem to favor the development of the disease. Cases are seen more frequently in the male sex than in the female.

The disease likewise begins with quite severe initial symptoms, fever, headache, somnolence, delirium, and vomiting, which may last from a few days to a week or two. The violent spontaneous pains which are very often reported as occurring in the loins, the back, and the extremities, usually belong probably to those

cases in which a primary neuritis, but not a poliomyelitis, is the chief anatomical lesion. After the end of this stage the paralysis appears. This develops with varying distribution, usually in single spurts, but always rather rapidly. The paralyzed muscles are perfectly flaccid, the cutaneous and tendon reflexes are wholly absent, and very soon a pronounced atrophy and reaction of degeneration appear, while the sensibility and the vesical and sexual functions remain normal.

The distribution of the paralysis shows certain peculiarities, which must be briefly described here, since they can be studied much better in adults than in children. The paralysis may be very extensive, it may affect all four extremities, or it may occur in the form of paraplegia, or even of monoplegia. In the extremities we very often find certain groups of muscles paralyzed, to which E. Remak first called attention. Since the muscles that are paralyzed at the same time are not supplied by the same peripheral nerves, but usually are connected in their functions, we may suppose that the corresponding ganglion-cells in the anterior cornua of the spinal cord also lie together, without regard to the distribution of their peripheral processes in the different motor nerves. Thus, for example, it is worthy of note that, in paralysis of the crural region, the sartorius often remains entirely free; that in the leg the tibialis anticus, on the one hand, and the peronei and the extensor digitorum on the other, may be separately diseased; that in the forearm the supinator longus, supplied by the radial nerve, remains free, while all the other muscles on the extensor side of the forearm are paralyzed ("forearm type" of E. Remak); and that, on the other hand, the supinator may be paralyzed alone or together with the biceps, brachialis anticus, and deltoid ("upper-arm type" of E. Remak). This latter form of paralysis is said to correspond to a lesion in the cord at the level of the fourth and fifth cervical roots, the forearm type to a lesion at the level of the eighth cervical and first dorsal roots. According to Kahler and Pick, the center for the muscles of the calf lies at the level of the fourth and fifth dorsal roots. Ferrier and Yeo, in their experiments on monkeys, by irritation of the anterior motor spinal roots have obtained results which, for the most part, agree very well with the observations on men (*vide supra*, page 624).

In regard to diagnosis in the future, especial attention must be paid to the distinction between poliomyelitis and neuritis. The greatest stress is to be laid on the initial pains and any other slight disturbances of sensibility. In other respects, the course of the two diseases is so similar that we can indeed imagine that they are closely allied in their ætiological relations, and exhibit merely different forms of localization of the same (probably infectious) morbid agency. Some observations also seem to favor the theory that transitional forms may occur with a co-existing primary lesion of the cord and of the peripheral nerves.

The prognosis is not wholly unfavorable, as sometimes a complete recovery has been observed, although only after months. Of course, it is not certain whether these cases were not multiple neuritis. On the other hand, however, the same permanent paralyses as in spinal paralysis of children may be left, with atrophy and contractures.

The treatment follows precisely the same rules that we have mentioned in the spinal paralysis of children. The internal or subcutaneous use of ergotine may be added on the recommendation of some physicians. F. Müller recommends a solution of two and a half drachms of ergotine (grm. 10) with a third of a grain of sulphate of atropine (grm. 0.02) in five drachms of water (grm. 20), of which he injects seven to fifteen minims twice a day.

## 3. SUBACUTE AND CHRONIC POLIOMYELITIS.

(*Subacute and Chronic Atrophic Spinal Paralysis. Paralyse générale spinale antérieure subaiguë* [Duchenne]).

While the anatomical basis of acute poliomyelitis in adults is still lacking in proof, our anatomical knowledge of the occurrence of a subacute and chronic poliomyelitis, in the sense of the term given it by various authors, is still completely defective. Confusions with multiple neuritis are also undoubtedly very common here, and the diagnosis is not incontestable in all the cases published under the name of "subacute poliomyelitis." Therefore we will limit ourselves to reproducing here briefly the picture of the disease at present described under the above name, while we especially repeat that a certain and accurate confirmation of its anatomical basis must be left to the future.

In the cases classed under this heading a paralysis, first of the two legs and somewhat later usually of the two arms, develops in a comparatively short time—in the course of some days, or weeks at most. It usually has no special cause or any severe initial symptoms. The patient complains at first of weakness in the legs; he can no longer walk, and is confined to the bed. A short time later the same disturbances appear in the arms, and lead to a more or less complete paralysis. The patient often feels some slight paræsthesia in the affected parts, but in general the sensibility remains perfectly normal. The paralyzed muscles are often quite sensitive to pressure (neuritic symptoms?). Soon after the paralysis an equally extensive atrophy develops, and a distinct loss of electrical excitability, running parallel to it; which passes over into a partial or, in all severe cases, a complete reaction of degeneration. The cutaneous and tendon reflexes are very much diminished and often entirely lost. The bladder and rectum, however, remain intact, and bedsores never develop. We sometimes notice a striking diminution of the sweat secretion. In rare cases the muscles of the neck, the lips, the tongue, and the pharynx are attacked by the disease.

After the paralysis has reached its greatest extent there is usually a cessation. The condition remains stationary for months sometimes, and then a gradual improvement begins, which may go on to complete recovery; but often, of course, the recovery remains incomplete, so that the patient has a more or less marked disturbance of function for life. The "middle form of chronic poliomyelitis" described by Erb, in which there is only a partial reaction of degeneration in the paralyzed muscles, almost always gives a good prognosis. Those rare cases, however, in which the muscles of deglutition and respiration are involved, may have an unfavorable termination, although even then the possibility of an improvement is not to be entirely excluded.

Anatomical lesions, which confirm the hypothesis of a subacute (inflammatory?) affection in the anterior cornua of the cord ascending from below upward, are to be found, as we have said, only in an extremely small number of cases, and in part of them even they are not entirely trustworthy. A short time ago Oppenheim published an undoubted case of chronic poliomyelitis, which ran its course to a fatal termination in three years. There was finally paralysis and atrophy of the muscles of all four extremities without a trace of sensory disturbance. The anterior cornua of the cord were throughout markedly diseased, while only very slight changes were found in the peripheral nerves. Clinically, the forms of disease belonging in this category are well characterized, and are easy to diagnose with proper attention and knowledge. Further investigations must be made as to its anatomical basis and its relations to acute poliomyelitis and the primary neuritides.

As follows from the above description, the treatment is by no means fruitless, and electrical treatment especially may produce the most complete and rapid regeneration of the affected parts.

## CHAPTER XI.

### ACUTE ASCENDING SPINAL PARALYSIS.

(*Paralysis ascendens acuta.* Landry's Paralysis.)

In the year 1859 Landry described a disease under the name of "*paralysie ascendante aigue*," which is chiefly characterized clinically by the fact that first the lower and soon after the upper extremities, and finally a number of the muscular regions supplied by the medulla, are attacked by a rapidly advancing paralysis, while the sensibility and the functions of the bladder and rectum remain normal. In many cases the disease terminates fatally. Examination of the nervous system has so far, however, shown no lesion which can be regarded with certainty as the anatomical cause of the disease. Considering the continued and quite numerous observations of the disease, it seems questionable, at any rate, whether we can establish a uniform anatomical basis for it. The diversity of many symptoms (*vide infra*, the condition of the reflexes, the condition of the electrical excitability) points rather to the fact that the seat of the disturbance is not always the same. Nevertheless, we can not doubt the clinical resemblance of most cases, and we must regard it as possible that the same cause of disease does not always need exactly the same localization to provoke the disease. We may very well recognize the ætiological unity of "acute ascending paralysis," without claiming that all cases also agree completely in the clinical anatomical details.

**General Symptomatology.**—Acute ascending paralysis attacks chiefly persons previously strong and healthy in youth or middle life, somewhere between twenty and thirty-five years of age. Some cases have also been seen in children and older people. The disease seems to be more frequent in men than in women.

The affection almost always begins with certain prodromata. These consist of general malaise, moderate febrile symptoms, headache, loss of appetite, and quite frequently of dragging and tearing pains in the back and the extremities. After these symptoms have lasted some days, or more rarely some weeks, during which they are comparatively slight, or so severe that many patients are already confined to the bed, there usually comes on quite suddenly, or sometimes more gradually, a paresis, first of one but very soon of the other leg, which rapidly increases, and usually in a few days leads to an almost complete motor paraplegia.

The paralysis is flaccid in almost all cases. The legs may be moved passively without any muscular resistance, and the muscles show neither active nor reflex tension. Their electrical excitability remains perfectly normal in many cases, but there is sometimes a rapid loss of faradic muscular excitability. It is not yet proven whether complete reaction of degeneration occurs. The reflexes, both cutaneous and tendon reflexes, seem to be diminished or wholly lost in the majority of cases, but some exceptions to this rule have been known.

Sensibility is sometimes perfectly intact, but slight alterations do occur, and quite rarely there may be even marked anaesthesia. At times a noticeable delay of sensation is observed. We find no changes in the nerves of special sense. There is occasionally a slight cedema in the legs, which is perhaps to be regarded as a vaso-motor disturbance. The marked sweating, from which many patients

suffer, is also worthy of mention. The bladder and rectum in most cases are not at all affected, or they present merely slight and temporary disturbances.

A short time after the legs are attacked the arms also begin to be paretic. A marked motor weakness appears first in one, then in the other arm, and this may also increase to almost complete paralysis. The sensibility, the reflexes, and the electrical excitability show conditions like those in the lower extremities. The muscles of the trunk are also affected at the same time as, or still earlier than, the arms. The patient can no longer sit up in bed, turn on his side, or make similar movements. In some cases a paralysis of the muscles of the neck has also been observed.

The third and last stage of the disease is characterized by the appearance of respiratory disturbances and bulbar symptoms. Manifest signs of a beginning respiratory paralysis appear; the respiration is labored and difficult, the movements of the diaphragm grow less, and the paroxysms of coughing are weaker. Disturbances in swallowing, difficulty in articulation, and paresis of the soft palate and the lips may set in. In a few cases a facial paralysis and disturbances of the ocular muscles have been observed. The condition grows worse acutely, and, as we have said, in many cases death ensues.

Besides the symptoms thus far mentioned, referable to the nervous system, we find certain other symptoms in almost every case, which are less striking, but yet of greater significance in judging of the disease. The first of these is fever. The temperature is usually elevated from the beginning; it may temporarily show quite a considerable increase, up to  $104^{\circ}$  ( $40^{\circ}$  C.), and later it varies somewhere between  $100^{\circ}$  and  $102^{\circ}$  ( $38^{\circ}$ - $39^{\circ}$  C.), but between times it may even sink to normal. Of the internal organs the spleen shows the most frequent changes. It is usually swollen moderately, but still it is manifestly swollen. There is also sometimes a slight albuminuria.

In the cases with a fatal termination the whole duration of the disease is sometimes only a few days, and as a rule a week or two, or rarely more. Fortunately, however, all cases do not terminate fatally. The disease may come to a standstill at any time, even if the most threatening symptoms be present. Then the paralysis shows no further advance, the disturbances present disappear, and recovery ensues after a course of several weeks. It is, of course, usually quite a long time before the patient again feels himself in possession of his full powers.

**Pathological Anatomy and Pathogenesis.**—If we consider the whole picture of acute ascending paralysis, the idea is necessarily forced upon us that we have to do here with an acute infection of the body, with a predominating localization in the motor nervous system, an opinion which was first expressed by Westphal. The beginning of the disease with general malaise corresponds perfectly to the prodromal stage of many other acute infectious diseases. The fever, the acute splenic tumor, and the occasional albuminuria can also scarcely be explained in any other way, according to our present views, except by the above hypothesis.

The anatomical examination has, of course, as yet brought no absolute proof of this theory. A notable case, published by Baumgarten, in which many rods, like the bacilli of splenic fever, were found in the spinal cord, is at present wholly unique; but the completely negative anatomical lesions in many cases seem to point to the fact that we must look for the cause of the severe nervous symptoms chiefly in the disturbance of function excited by a toxic (infectious) influence. We have already signified that the point of attack of the infectious agent need not always be precisely the same. The condition of the reflexes and the rapid loss of electrical excitability, in connection with the pains at the beginning, seem to justify the hypothesis that the disturbance sometimes has its chief seat in the peripheral motor nerves, that the disease then exhibits the most acute form of

infectious "multiple neuritis" (*vide supra*). More accurate anatomical investigations directed to this point will perhaps procure some positive support for this theory. In other cases, however, the motor portions of the spinal cord, the lateral columns, and the anterior gray cornua, are perhaps chiefly affected. This idea is supported by the occasional discovery (R. Schulz and F. Schultze, Von den Delden) of an acute myelitic affection in the parts named.

**Diagnosis and Prognosis.**—In every paralysis of the lower extremities beginning acutely and accompanied by general symptoms and fever we must consider the possibility of an acute ascending paralysis, but only the further course of the disease can decide the question. Inasmuch as only a well-characterized clinical group of symptoms is meant by the above term, the diagnosis is always easy to make, with attention to the peculiarities given above. It is more difficult, however, to decide accurately whether the case corresponds rather to the type of an acute multiple neuritis or to the type of an acute ascending spinal paralysis. We can judge as to this point only by careful attention to the single symptoms, especially the condition of the sensibility (pains, anaesthesia), of the reflexes, and of the electrical excitability.

The prognosis must at first be made with great reserve, and we must especially bear in mind the possibility of a rapidly fatal termination. If the first acute stage pass off fortunately and there be a decided cessation in the extension of the symptoms of paralysis, the prognosis is quite favorable, for we may then expect that the patient will be completely restored.

**Treatment.**—We can not be certain whether an energetic "derivative treatment" is of advantage in the beginning of the disease. Dry cups along the vertebral column are recommended, and even the use of the hot iron to the back. We would hardly advise the latter. It may be recommended, however, to prescribe anunction with mercurial ointment, thirty to forty-five grains a day, as in anti-syphilitic treatment. Of internal medicines we may give iodide of potassium or ergotine. It also seems to be a good plan to begin galvanic treatment early, galvanism to the spine and peripherally. If threatening attacks of respiratory insufficiency come on, electrical excitement of the phrenic nerve and of the respiratory muscles sometimes affords relief to the patient.

If the symptoms be arrested, electrical treatment and the use of baths may do most to hasten convalescence.

## CHAPTER XII.

### NEW GROWTHS OF THE SPINAL CORD AND OF ITS MEMBRANES.

**Pathological Anatomy.**—Tumors of the spinal cord are rare. The commonest primary new growth is the glioma, which probably arises from the neuroglia, and is a cellular and vascular tumor. We often find in gliomata secondary softening (the formation of cavities, see the following chapter) and hæmorrhages. The tumor is situated most frequently in the cervical or upper dorsal cord, and may have a considerable longitudinal extent, and a transverse diameter of several centimetres.

Of other new growths in the spinal cord we may mention solitary tubercles, syphilomata, and myxomata (myxo-sarcomata).

In the spinal meninges have been found sarcomata, fibromata, lipomata, myxomata, and syphilomata. A carcinoma arising from the vertebræ may also reach the spinal meninges by direct invasion. Marked signs of compression, and the con-

sequent secondary degenerations, often show themselves in the spinal cord at the point where a new growth is situated in the meninges.

We know practically nothing of the aetiology of new growths in the spinal cord. It is merely worthy of note that in the cases of glioma of the spinal cord observed, an injury, such as a fall on the back, etc., very often preceded the appearance of the first symptoms.

**Symptomatology.**—A general description of the tumors of the spinal cord can not be given, since, of course, the individual symptoms must differ in almost every case, according to the seat and the extent of the new growth.

In tumors of the meninges the symptoms of compression of the cord are often quite prominent. In the beginning we notice pronounced "root symptoms"—that is, shooting pains, stiffness, paræsthesia, anæsthesia, etc. Later on the results of the compression of the cord show themselves: motor weakness, which may increase to a complete motor and sensory paraplegia. We can not here go more fully into the details. They follow of themselves from attention to the general laws to be considered for localization of lesions in the spinal cord.

In tumors of the spinal cord marked symptoms of sensory irritation are usually absent at first. A complicated type of spinal disease gradually develops, in which all those symptoms may be present in a single case which we have learned to recognize more exactly in the description of diffuse chronic myelitis. In fact, the differential diagnosis between tumor and transverse myelitis is often impossible, but certain peculiarities in the type of disease are sometimes present, which at least turn our suspicions to the possibility of a tumor. Among them especially is the early asymmetry of the symptoms on the two sides. Since a tumor may at first be confined to one half of the spinal cord (which scarcely ever happens in myelitis), the signs of a unilateral lesion of the spinal cord (*vide infra*, Chapter XV) are often observed in tumors in a more or less pronounced fashion. A certain change in the symptoms, improvements, and new and quite sudden changes for the worse, are sometimes noticed, a circumstance which is probably to be referred to a change in the fullness of the vessels, or to hæmorrhages in the substance of the tumor. The diagnosis of a tumor of the spinal cord, however, can be made best only with a certain probability. The decision as to the seat and the extent of the tumor is based upon precisely the same rules as in the diagnosis of the different forms of myelitis. We can hardly ever predict anything definite as to the kind of tumor.

The prognosis of tumors of the spinal cord is utterly unfavorable. The course of the disease is often protracted for several years, but the final termination is always fatal, from general weakness, cysto-pyelitis, and bedsores. The treatment is purely symptomatic, and is the same as in chronic myelitis. If there be a suspicion of a previous syphilis, we must try inunction and the internal exhibition of iodide of potassium. [In a few cases, where the growth has not involved the substance of the cord, it has been successfully removed by surgical interference.—K.]

### CHAPTER XIII.

#### THE FORMATION OF CAVITIES AND FISSURES IN THE SPINAL CORD.

**Pathological Anatomy and Pathogenesis.**—The abnormal formation of cavities in the spinal cord either arises from a dilatation of the central canal (hydro-myelus), or it develops outside of the central canal, and near it (syringomyelia).

The cases of pure hydromyelus are recognized by the fact that the cavity is found in the middle of the cord, corresponding to the position of the central canal, and that its walls are covered by cylindrical epithelium. Slight degrees of hydromyelus, in which the dilated central canal has a diameter of a millimetre, or a millimetre and a half, are quite frequently found. The dilatation usually extends over only a portion of the spinal cord. Higher degrees of hydromyelus, where the central canal is dilated to a diameter of half a centimetre, or a centimetre, are much rarer. In such cases the substance of the cord suffers from the internal pressure on it.

In regard to the origin of hydromyelus, following Leyden's example, we may consider anomalies of development in the formation of the central canal to be a cause in at least a part of the cases. Certainly only exceptionally do we have a process of stasis, as Langhans has found in some cases, which may have its origin in an increased pressure in the posterior fossa of the skull, from tumors, etc.

As to most cases of syringomyelia, however, the discoveries of Westphal, Simon, and F. Schultze leave scarcely a doubt but that they arise from a destruction of proliferated masses of neuroglia. We have the formation of a central glioma, probably arising usually from the ependyma of the central canal itself, or from its vicinity, with a secondary disintegration and the formation of a cavity. In these cases we can make out the newly formed masses of neuroglia about the cavities, either proliferating or disintegrating. The cavity is usually situated quite close to the center, and extends most frequently into the substance of the posterior columns. In its longitudinal extent it may involve a great part of the cord.

**Clinical Symptoms.**—We can not give a uniform picture for the formation of cavities in the spinal cord, since the symptoms, of course, must vary very much, according to the seat and the extent of the change. Slight dilatations of the central canal may run their course entirely without symptoms. In the cases of extensive cavity formation, with much damage to the surrounding substance of the cord, there usually arise a severe and complex array of spinal symptoms, whose correct interpretation can hardly ever be made with certainty during the patient's life. If the posterior columns and posterior cornua be chiefly involved in the cavity formation, the results of the disturbance of function of those parts are especially prominent. In the celebrated case of general anaesthesia which Späth and Schüppel have described, a very extensive syringomyelia was found in the spinal cord on autopsy. In other cases there exists a form of disease which resembles spastic spinal paralysis, or there develops a composite spinal affection in which the symptoms of unilateral lesion are to a degree prominent. In all such cases the diagnosis can be made with a certain probability by excluding other chronic morbid processes in the cord. A very slow course, extending over years and years, is especially worthy of consideration.

In one class of cases the symptoms of syringomyelia are more characteristic, and here, with due attention and knowledge, we can, in fact, often succeed in making a correct diagnosis. By many observations by F. Schultze, Kahler, and others, it has been proven that central gliosis with secondary cavity formation very often begins in the cervical cord, and gives rise to so characteristic a type of disease that the process may often be diagnosticated with great certainty during the patient's life. The morbid symptoms appear in the upper extremities. A gradually increasing muscular atrophy sets in, with a corresponding loss of strength and power to work; this is often precisely like true spinal progressive muscular atrophy in the small muscles of the hand, the forearm, the deltoid, etc. With this are next associated peculiar disturbances of sensibility, chiefly in the domain of the temperature sense (anaesthesia to heat and cold) and of the pain sense (analgesia), while the tactile sensibility for a long time remains normal. Trophic disturbances

are often observed and are very interesting; among them are atrophy of the fingertips, thickening of the joints, changes in the nails and skin, etc. Felons and similar inflammations, from which the patients often suffer, are either connected with these trophic disturbances or are due to external injuries, such as burns as a result of analgesia, etc. Anomalies of the sweat secretion have been repeatedly observed. The lower extremities remain for a long time normal; later spastic and paretic symptoms may come on in the legs.

With this type of disease, which we can usually distinguish sufficiently well from the very similar amyotrophic lateral sclerosis, progressive muscular atrophy, multiple neuritis, etc., and which has something very characteristic, as we can confirm from our own experience, we can make the diagnosis of syringomyelia of the cervical cord. The onset of other clinical symptoms corresponds, of course, to the further slow progress of the anatomical process.

The prognosis is, of course, always unfavorable, but the course is very slow, and there are long-continued apparent cessations of the disease.

The treatment is purely symptomatic, and follows the same rules as in chronic myelitis.

[MORVAN'S DISEASE.—*Analgesic Paresis with Panaritium*.—Morvan, a Breton physician, has described an affection which seems quite common in a small district in Brittany, some twenty cases having occurred in a population of 50,000. One or two cases have been reported in America. It is characterized by severe pains at the outset, paresis with analgesia, and the formation of panaritium (felons), which are usually painless. There is also tactile and thermal anæsthesia. The presence of tactile anæsthesia is considered the distinction between it and syringomyelia, but more recent observations indicate that the trouble is merely syringomyelia associated perhaps with neuritis.—K.]

## APPENDIX.

### SPINA BIFIDA.

(*Hydromyelia. Myelocoele. Meningocele.*)

We give the name of spina bifida to a congenital fissure-formation on the posterior side of the vertebral arches, due to anomalies of development, and associated with a hernia-like protrusion of the sac of the dura. The most frequent seat of the malformation is in the sacral and lumbar regions. Only rarely is the tumor so great as to hinder the birth of the child. Children afflicted with spina bifida are usually born normally, and only after delivery do we find the tumor in the sacral region; its size may be from that of a small nut to that of the fist or larger. The skin above the tumor is sometimes entirely normal, but in other cases very tense and reddened. If we have an opportunity to examine the tumor carefully anatomically, we usually find beneath the skin the protruded sac of the dura, and beneath it the arachnoid. Only rarely is the dura also fissured, so that the sac is formed exclusively of the arachnoid. It is filled with a clear fluid which is precisely identical with the cerebro-spinal fluid. In rare cases there is also a dilatation of the central canal, hydromyelia; then the substance of the cord is atrophied to a greater or less extent, and the central canal communicates directly with the cavity of the spina bifida. In other cases the condition of the cord is normal; sometimes its lower end is adherent to one spot of the sac. We must refer to the text-books of pathological anatomy in regard to the many further details of the anatomy and the history of development.

In regard to the clinical symptoms of spina  
dren at first is perfectly normal, apart from

most chil-  
mor itself

usually feels tense. If we exert pressure on it with the hand, we can often force part of its contents back into the vertebral canal. This causes an increase of the cerebral pressure, and we notice, besides the lessening of the spina bifida, a marked expansion of the fontanelles, and also the appearance of somnolence, contractions, and changes in the pulse and respiration, which demand a speedy interruption of this rather dangerous experiment. If such symptoms do not appear at all, we can conclude that the sac is completely constricted and closed.

Only rarely, however, does the child's condition remain normal later on. The tumor usually shows a slow growth, and the results of pressure on the spinal cord or on the cauda equina gradually appear. Paralysis, anæsthesia, vesical disturbances, bedsores, etc., develop, and these symptoms finally lead to death. Still more frequently the sac bursts, or its walls inflame, and this becomes fatal from the onset of a purulent meningitis.

The prognosis of most cases of spina bifida is accordingly to be regarded as unfavorable unless we succeed in curing the disease by surgical treatment. Recovery has been brought about in many cases by methodical compression of the sac, and by puncture, with evacuation of the fluid and a subsequent injection of a solution of iodine to obtain an obliteration of the sac; but, on the other hand, the operative treatment of spina bifida is attended with many dangers, such as meningitis, so that we can note frequent bad results as well as favorable ones. We can not here go into the details of the surgical methods for the cure of spina bifida; they can be found in full in the text-books of surgery.

## CHAPTER XIV.

### SECONDARY DEGENERATIONS IN THE SPINAL CORD.

ALTHOUGH the secondary degenerations in the spinal cord are chiefly interesting merely from an anatomical point of view, we must briefly describe them, because, in the first place, a clinical significance has been ascribed to them in certain quarters, and also because the study of secondary degenerations has been the starting-point of all our present knowledge as to the systemic diseases of the spinal cord.

1. *Secondary Degeneration in the Spinal Cord after Cerebral Lesions.*—We already know (compare page 538) that every lesion of the great motor ganglion-cells in the anterior cornua of the spinal cord, and every permanent break in conduction in the motor nerves themselves, is followed by a secondary degeneration of the peripheral portion of the motor fibers. We assume as the reason for this, as we have seen, a "trophic influence" of the said ganglion-cells on the motor fibers arising from them, so that the latter degenerate when the conduction of that trophic influence is interrupted, or when the trophic ganglion-cells themselves are destroyed. Precisely analogous conditions exist for the first great portion of the motor conducting tract, the lateral pyramidal tract, from the cortex cerebri to the anterior cornua of the spinal cord. The great ganglion-cells of the motor portion of the cortex cerebri also exert a trophic influence on the motor fibers arising from them, which extends to the motor ganglion-cells of the spinal cord. If there be disease situated in the motor portion of the cortex cerebri itself, or in any part of the motor tract in the brain (the motor fibers of the corona radiata, the internal capsule, the crus, or the pons), by which disease the conduction is interrupted—if there be disease there, we repeat, a secondary descending degeneration of the motor fibers ensues in the whole portion below, down to, but exclusive of,

the anterior cornua of the gray matter. This secondary descending degeneration of the pyramidal tract is found correspondingly in the pyramid of the same side on which the focus of disease in the brain is situated. From this point we can trace the main part of the degeneration farther down the lateral column of the spinal cord on the opposite side (secondary degeneration of the lateral crossed pyramidal tract) (see Fig. 96), while in many cases besides we find a slighter secondary degeneration in the anterior column of the spinal cord on the same side (secondary degeneration of the anterior uncrossed pyramidal tract). As we know from Flechsig's investigations, the relative amounts of the crossed lateral fibers, and the anterior fibers that remain uncrossed, vary in individual cases within certain limits. In the cases where no anterior pyramidal tract exists—that is, where all the motor fibers pass over to the lateral column of the opposite half of the spinal cord in the decussation of the pyramids—of course a descending degeneration in the anterior column is wholly wanting. We must add, however, that in some cases a small number of fibers seem to proceed uncrossed in the lateral column, so that accordingly we may also have a slight secondary descending degeneration in the lateral pyramidal tract of the same (affected) side (Pitres).

2. *Secondary Degenerations in the Spinal Cord in Transverse Affections of the Spinal Cord itself.*—If a lesion be situated in any part of the spinal cord, by which more or less of its transverse section is affected, the interruption of conduction in these fibers is also followed by the appearance of secondary degenerations which may be made out both in a descending and in an ascending direction (see Fig. 97). It is most frequently transverse myelitis, compression of the spinal cord, and tumors of the cord, which give rise to secondary degenerations. The latter, however, of course, are never due to the sort of lesion, but only to its seat, and to the interruption of conduction caused by it.

The secondary descending degeneration affects the pyramidal tract in a fashion precisely analogous to that which we have also learned to recognize in secondary degenerations after cerebral lesions; but since the primary affection usually affects the pyramidal tract on the two sides, the descending secondary degeneration of course develops in both lateral pyramidal tracts, and also in the anterior pyramidal tracts, if they exist below the point of lesion.

The secondary ascending degeneration, developing upward from the primary point of disease, affects two systems of fibers, the so-called columns of Goll (the internal portion of the posterior columns), and also at the same time the lateral cerebellar tracts\* on the periphery of the lateral columns and external to the lateral pyramidal tracts. Both

\* The area of the ascending degeneration of the "lateral cerebellar tract," as may be seen in the picture, shows at its anterior end a marked expansion. Possibly this anterior portion of the degenerated fibers corresponds to another system (Bechterew).

FIG. 96. — Secondary descending degeneration of the pyramidal tracts in a primary lesion of the left half of the cerebrum. The lateral pyramidal tract of the right half of the cord is degenerated down to the lowest part of the lumbar region (1-8); the anterior pyramidal tract of the left half of the cord is degenerated to the beginning of the lumbar enlargement (1-6).

systems of fibers mentioned, whose conduction is in a centripetal direction, must accordingly receive trophic influences from more peripheral ganglion-cells. The connection of the columns of Goll with the gray matter (spinal ganglia? posterior cornua?) is not yet accurately known. The fibers of the lateral cerebellar tracts, however, are certainly connected with the cells of the columns of Clarke. If these also be destroyed by any process in the lower dorsal and upper lumbar cord, an ascending degeneration of the lateral cerebellar tracts develops, which may be traced upward into the restiform body. The further course of the fibers to the cerebellum is not yet certainly known.

FIG. 97.—Secondary ascending and descending degeneration in a transverse affection of the upper dorsal region. The columns of Goll and the direct cerebellar tracts are degenerated upward. The lateral pyramidal tracts are degenerated downward.

Although no clinical significance at all can be attributed to secondary ascending degeneration, the theory first advanced by the French observers (Charcot and others) prevails almost universally, that secondary descending degeneration causes definite clinical symptoms. The secondary contractures and the increase of the tendon reflexes in the paralyzed limbs, occurring in hemiplegia, are especially referred to this. We shall see in a later section that this theory is by no means proven, and is even improbable, so that, in our opinion, the secondary descending degeneration also has no material clinical significance.

3. *Secondary Degeneration in the Spinal Cord after Injuries of the Cauda Equina.*—After injuries of the cauda equina—for example, after fractures or caries of the lower lumbar vertebrae and of the sacrum, in new growths in this region, etc.—a secondary ascending degeneration occurs in the spinal cord, if an actual solution of continuity of the fibers have existed for a long time, which depends exclusively upon the lesion of the affected posterior root-fibers. This is accordingly limited to the posterior columns of the spinal cord, and in its distribution it shows a great resemblance to

the condition of the degeneration in tabes dorsalis. In the lumbar cord the greater portion of the posterior columns is degenerated, with the exception of a little median zone and the most anterior portion (compare Fig. 87). The degeneration grows smaller upward, and finally limits itself in the cervical cord to the region of the columns of Goll. Thus this condition again affords a proof of the correctness of the statements advanced by Singer, Kahler, and others, that the columns of Goll form, at least in part, the prolongation of the fibers from the root-zones of the lumbar cord (compare page 510).

## CHAPTER XV.

### UNILATERAL LESION OF THE SPINAL CORD.

(*Brown-Séquard's Spinal Paralysis.*)

UNILATERAL lesion is not a definite disease of the spinal cord, but a peculiar group of symptoms, which occurs whenever an interruption of conduction is produced by any affection in one lateral half of the spinal cord. Since the symptoms in these cases were first carefully studied clinically and experimentally by Brown-Séquard in particular, we often call the type of disease in question "Brown-

Séguard's paralysis." We see this paralysis most frequently and in its purest form in injuries of the spinal cord. Almost perfectly exact sections of one lateral half of the spinal cord are often produced by stabs from a knife, a sword, etc. Inflammatory processes, compression, and especially tumors of the cord, may also, during a certain period of their course, cause the symptoms of a more or less sharply defined unilateral lesion.

The peculiar condition of the symptoms in unilateral lesion is easily explained by a consideration of the course of the fibers in the spinal cord. In the accompanying diagram (see Fig. 98) the motor fibers from the anterior roots are marked *v*, the sensory fibers from the posterior roots, *h*. As we have already said, the sensory fibers, *h*, pass at once into the opposite half of the spinal cord, and accordingly decussate with the corresponding sensory fibers of the other side. The motor fibers, *v*, however, pass upward uncrossed on the side they enter the spinal cord, especially in the lateral column. If now, for example, there be situated on the right side of the spinal cord at *a* a lesion, causing a section of one half the cord, the conduction of those motor fibers which come from the right side is interrupted, as well as the conduction of those sensory fibers which come from the left side. From this it follows that there must be a motor paralysis on the same side of the body as the lesion in the spinal cord, and a sensory paralysis (anæsthesia) on the other side of the body. If the affection be situated in the dorsal or lumbar cord, the leg on the corresponding side is paralyzed, and the leg on the other side is anæsthetic. If the lesion be situated in the cervical cord, above the entrance of the nerves for the upper extremities, the arm and the leg on the side of the lesion are both paralyzed (spinal hemiplegia), while the arm and the leg on the other side are anæsthetic, but their motility is normal.\*

On more careful examination, further conditions of physiological interest appear. The sensibility on the side of the motor paralysis is usually not only normal, but there is even a pronounced hyperæsthesia for all, or at least for some, of the forms of irritation. Slight pricks are very painful, and tickling the soles of the feet is felt with abnormal strength. The muscular sense alone (the feeling for passive motion) is a noteworthy exception, since it is usually markedly diminished on the paralyzed side. We can explain this fact only by Brown-Séquard's theory that the fibers for the muscular sensibility (see 2 and 2' in Fig. 98), in distinction from all the other sensory fibers, run their course in the spinal cord uncrossed, just like the motor fibers.

Fig. 98.—(From Erb.) Schematic representation of the course of the main tracts in the cord, represented for a single pair of roots. *v*, Anterior roots. *h*, Posterior roots. 1. Paths for motor and vasomotor conduction. 2. Paths for muscular sense. 3. Paths for cutaneous sensibility on the right. 1', 2', 3'. The same paths on the left. The arrows indicate the direction of physiological conduction.

\* (More recent investigations by Mott render this theory of immediate decussation somewhat doubtful, and unilateral lesion may not always present this group of

Above the hyperæsthetic territory in the skin we usually find a small anæsthetic zone (Fig. 99, *b*), and above this at times again a small hyperæsthetic strip (see Fig. 99, *c*). The anæsthetic zone is easily explained. It corresponds pre-

cisely to the level of the lesion in the spinal cord—that is, to those sensory fibers coming from the same side, which are immediately involved as soon as they enter the cord; but a satisfactory explanation is entirely lacking for the appearance of the hyperæsthesia on the paralyzed side, and for the origin of the uppermost small hyperæsthetic zone.

The reflexes, especially the tendon reflexes, are usually increased on the paralyzed side. There is often a vigorous ankle clonus, a symptom which must be explained by the loss of the reflex inhibitory influences coming from above. Finally, we often find on the side of the lesion the signs of a vasomotor paralysis, especially a marked rise in the cutaneous temperature of even 2° (1° C.), or more.

On the anæsthetic side, however, in pure cases, the motility and also the muscular sense are perfectly normal, in distinction from the other forms of sensation. Anæsthesia is not always complete, but it sometimes affects only single qualities of sensation to a greater or less degree. Thus we have often seen partial paralyses of the temperature sense, especially partial anæsthesia to cold. Above the anæsthetic region we also find frequently a small hyperæsthetic zone (see Fig. 99, *c*). The reflexes are usually normal, or only a little increased.

Of the other spinal symptoms we have still to mention the almost invariable disturbance of micturition and defecation, neuralgic pains now more on one side and now more on the other, muscular atrophy, changes in the electrical excitability, etc. All these symptoms are not characteristic of the unilateral lesion as such, and are always easily explained in any given case from the localization of the disease. We must also mention that the symptoms of unilateral lesion may not be perfectly pure, but we can

FIG. 99.—Schematic representation of the chief symptoms in unilateral lesion of the left dorsal cord. (After Ekm.) The oblique shading signifies motor and vasomotor paralysis; the vertical shading signifies cutaneous anæsthesia; the dots signify cutaneous hyperæsthesia.

often recognize only a few prominent features of them.

We need add nothing as to the prognosis and treatment of unilateral lesion, because, of course, they are governed entirely by the form of the primary disease.

#### IV.—The Diseases of the Medulla Oblongata.

##### CHAPTER I.

##### PROGRESSIVE BULBAR PARALYSIS.

(*Glosso-labio-laryngeal Paralysis.*)

DUCHENNE in 1860 described for the first time with completeness the symptoms of a disease to which Wachsmuth has since given the name of progressive bulbar paralysis. Duchenne did not, however, recognize the true seat of the disease, and it was not till 1870 that Charcot in France, and E. Leyden in Germany, were enabled to confirm the suggestion of Wachsmuth that the lesion is a progressive degeneration and atrophy of the nuclei in the medulla oblongata. Since then our knowledge of the disease has grown rapidly, both from the clinical and the anatomical standpoints; and Kussmaul and others have thoroughly investigated its relations to two other closely allied forms of disease—amyotrophic lateral sclerosis, and progressive muscular atrophy.

**Ætiology.**—We have scarcely any certain information about the cause of the disease. Heredity seems of slight importance. In some cases its origin is ascribed to catching cold, emotional excitement, traumatic influences, and excessive bodily exertion. Perhaps it is sometimes occasioned by excessive use of the muscles to which the disease is chiefly confined, as in playing on wind-instruments; but in many instances no possible cause can be found. Men seem somewhat more liable to be attacked than women. The disease hardly ever appears till middle or old age—that is, after thirty-five.

**Clinical History.**—The symptoms are almost always very slow in their development. There may be mild premonitory symptoms—such as painful sensations in the back of the neck. Then there is a very gradual appearance of difficulty in articulation. Many words are pronounced indistinctly. The first trouble is noticed especially with letters in the utterance of which the tongue plays an essential part: E, R, L, S, G (hard), K, D, T, and N.\* It is easily seen that the derangement is not aphasic. There is no forgetting or confounding of the words or letters; but the innervation of the tongue has become impaired. Long before the ordinary movements of this member are visibly embarrassed, the patient has lost the ability to make those more delicate manipulations of it which are essential to normal speech. This disturbance of articulation is termed *alalia* or *anarthria*.

By the time this has become somewhat marked, it is usually possible to detect, on close examination, that the tongue is beginning to atrophy. It seems flabby, thin, and less rounded. Here and there its surface presents furrows and depressions; and often the individual fasciculi exhibit active fibrillary contractions. Just as in progressive muscular atrophy, the impairment of motion usually keeps equal pace† with the atrophy. The greater the atrophy, the less is the

\* [Except as otherwise specified, the letters and words used as examples here and later on are to be given the ordinary English pronunciations.—TRANS.]

† At the commencement of the disease the paralysis may possibly seem greater than the atrophy, so far as the latter can be detected. Nor would it be impossible for a primary lesion of the nuclei of nerves to result in a paralysis before the secondary descending degeneration had become completely developed. On the other hand, it must be borne in mind that numerous individual fibers in the lip or tongue might be already atrophied before the eye or the touch could appreciate any change in bulk.

mobility. Finally it becomes quite impossible to project the tongue from the mouth or move it from side to side. The tongue lies flat and limp on the floor of the mouth. Its surface is often diversified with furrows and depressions, containing much desquamated epithelium or the like. Evidently any great impairment of motility in the tongue hinders not only speaking, but also chewing and swallowing. The organ can no longer bring out such portions of the food as get between the cheeks and the teeth, nor can it push the bolus backward within the grasp of the pharyngeal constrictors.

Even before the atrophy of the tongue becomes extreme, analogous disturbances usually appear in neighboring groups of muscles. As a rule, the muscles of the lips are next affected after the tongue. The first thing the patient notices is a peculiar feeling of stiffness or tension in the lips. Movement becomes gradually more and more difficult; and the patient becomes unable to pucker up his lips so as to whistle. Speech is also noticeably interfered with, for now all those letters the pronunciation of which demands labial movements are very imperfectly articulated, and at last can not be uttered at all. These are O, A (long), P, F, B, M, and V; and also the sound of double O, as in tool. It also becomes gradually evident that the lips atrophy. They grow thin, with sharp edges and wrinkled skin. Fibrillary contractions are not infrequently visible.

This atrophy of the orbicularis oris is followed by atrophy and paresis of some of the other muscles of expression supplied by the lower division of the facial nerve. The general facial expression of a patient with bulbar paralysis thus comes to bear a very characteristic stamp: the mouth remains half open, and seems to be broadened out, the lower lip hangs down, the naso-labial folds are deepened, and indeed the whole aspect is persistently lachrymose. Even in laughing, the lower half of the face relaxes comparatively little; while the region supplied by the upper division of the facial nerve, and the movements of the eyeball, remain as a rule perfectly normal.

The third group of muscles affected are those of the pharynx and larynx. The soft palate becomes paretic, and produces further trouble in swallowing. Quite often the liquid ingesta are regurgitated through the nose. The voice becomes nasal. The production of many sounds, and in particular of B and P, is now impossible, since, in addition to the labial paresis, a portion of the essential current of air escapes through the nostrils. This explains why the letters mentioned can sometimes be pronounced better if the nose be compressed. The paralysis of the constrictors of the pharynx impedes deglutition more and more, till the impairment of nutrition becomes extreme.

The enfeebled action of the laryngeal muscles is betrayed, in the earlier stages of the disease, by a certain weakness and monotony in speaking. Modulations of the voice, and the production of the higher notes, as in singing, are no longer possible. If the innervation of the larynx becomes still more impaired, it becomes a very serious matter. If the arytenoid cartilages do not press together firmly on swallowing, the entrance to the larynx is inadequately closed, and food is often swallowed the wrong way. Liquid and even solid ingesta get into the larynx, and excite a violent cough; or, being inhaled into the air-passages, they cause bronchitis or lobular pneumonia. The paralysis may reach such a degree that the voice is at best a hoarse whisper. With the laryngoscope we can see that the vocal cords are paralyzed. The inability to close the glottis tightly is extremely unfavorable, for it renders the patient unable to cough vigorously. Mucous accumulations may therefore come to be the source of extreme dyspnoea.

The catalogue of symptoms is not yet ended. As we have seen, the muscular atrophy of the tongue and lips can invariably be detected. That of the pharyngeal and laryngeal muscles can not be demonstrated during life, although it is to

be found post mortem. Inasmuch as the process is one of genuine degeneration with consequent atrophy, the affected fibers ought to give the reaction of degeneration to electricity; but this is difficult of actual proof, just as it is in progressive muscular atrophy, because numerous healthy fibers lie side by side with the degenerated ones. Still, in an advanced case, careful examination will usually bring out an evident degenerative reaction here and there in the tongue and lips.

The disturbance of reflex action is often striking. Usually the reflexes are greatly diminished or even absent, so that one can tickle the root of the tongue and the epiglottis without causing the patient to gag. In a few instances the facial muscles exhibit an increase of tendon reflex, as can be shown by tapping upon the tendons, the periosteum of the jaws, or the bridge of the nose. This behavior reminds one of the condition of the muscles in amyotrophic lateral sclerosis (*q. v.*).

Exceptionally, still other muscular groups are involved. Of such disturbances, the most frequent is in the region supplied by the motor branch of the trigeminus, impairing mastication. The impairment of these muscles now combines with the labial and lingual atrophy to render chewing almost impossible. In very rare cases the ocular muscles are also involved, with resulting ptosis and strabismus.

All the symptoms thus far enumerated are exclusively motor. Sensation is perfect to the end. The sensibility of the skin of the face and of the mucous membrane of the tongue and mouth, as well as the sense of taste, are unimpaired. Disturbances of sensation in the distribution of the trigeminus, and more or less deafness, have been reported in one or two cases; but there is some doubt about the observations. It does, however, seem certain that secretory and vaso-motor derangements are frequent. Salivation deserves especial mention. In many cases of bulbar paralysis it is a constant symptom, so that the patient is obliged to keep a pocket-handkerchief to his mouth, to catch the fluid as it dribbles away. This is due, to a certain extent, to the fact that the secreted saliva can not be swallowed, and, as the lips do not shut tightly, it naturally escapes from the mouth; but volumetric examinations have rendered it pretty certain that the amount of saliva is abnormally large. The explanation of this has not been determined. Nor as yet do we know much about the vaso-motor disturbances. Many patients complain of a feeling of heat and "boiling" in the head. We may also mention in this connection that occasionally, toward the close of the disease, the pulse becomes very rapid (140-160). This is probably due to paralysis of the vagus.

The course of the disease is invariably protracted. The order in which the symptoms appear is, as a rule, that in which they have just been described. The atrophy and paresis appear first in the tongue, then in the lips and the neighboring muscles of the face, and lastly in the muscles of the soft palate, pharynx, and larynx. Still, there may be some deviation from this. Usually the progress of the disease is very gradual. There may be an apparent arrest of the trouble; or less often there are quite sudden exacerbations. When all the different symptoms are well developed, the clinical picture is unusually characteristic. The peculiar immobility of expression; the broad, slightly gaping mouth, with the atrophied lips; the almost unintelligible speech, low, monotonous, and labored; and the inability to swallow—these often betray the disease at once. The last stage of the illness is the more distressing, in that the intelligence remains to the end entirely unclouded.

The entire duration of the disease is usually several years—say two to five. If death is not caused by some intercurrent trouble, it is brought about in one of three ways: either through inanition, due to the increasing difficulty of deglutition; or through pulmonary complications—namely, bronchitis, lobul

nia, or gangrene, as a result of food passing down the trachea ; or through sudden asphyxia or cardiac failure.

**Pathology. Nature of the Disease, and its Appearance as a Symptom of Progressive Muscular Atrophy or of Amyotrophic Lateral Sclerosis.**—If we seek the anatomical lesion corresponding to the group of symptoms above depicted, we shall find, on microscopic examination of the nervous system, in all cases of this description, a typical disease of the medulla oblongata. The ganglionic nuclei and the nerves, corresponding to those muscles which we have found to undergo atrophy in bulbar paralysis, present distinct evidences of degeneration. This is most readily demonstrated in the nucleus of the hypoglossus. The ganglionic cells have some of them entirely disappeared, while others are greatly atrophied. The connective tissue is increased in amount, and the walls of the blood-vessels traversing the nucleus are thickened. In the earlier stages there are often many cells which contain granules of fat. The same changes, though perhaps less pronounced, are exhibited by the common nucleus of the vagus and accessorius, that of the facial, and sometimes also that of the glosso-pharyngeal nerve. The other nuclei are perfectly normal. We never find a diffuse "inflammation," but in every case a primary degeneration of the nuclei, which spreads no farther.

Starting from these nuclei, the degeneration and atrophy may be seen to extend into the nerve-fibers which issue from them. The roots of the hypoglossus, vagus, accessory, and facial nerves can often be seen by the naked eye to be diminished in size and of a gray color. The microscope always shows a partial atrophy of their fibers. Finally, there is a corresponding atrophy of muscles of the tongue, lips, and other parts. We need not enter into detail, for the histological conditions are precisely those seen in the muscles of the trunk and extremities in the spinal form of progressive muscular atrophy.

Thus we find progressive bulbar paralysis perfectly analogous with progressive muscular atrophy. The nuclei in the medulla oblongata are the motor and trophic centers of the bulbar nerves and of the muscles which these nerves supply. The relation is precisely that which exists between the anterior cornua of the spinal cord on the one hand, and the spinal nerves and the muscles which they innervate on the other. In both diseases there is a degeneration and atrophy of the trophic and motor center and the corresponding nerves and muscles. In both diseases the atrophy and the functional disability of the muscles keep pace with each other, and in both the affection is strictly limited to the motor tract, sensibility suffering no impairment whatever. Certain questions about bulbar paralysis are as unsettled as similar ones about progressive muscular atrophy. It is uncertain whether the primary degenerative process is limited to the bulbar nuclei, and the degeneration of the nerves and muscles is to be regarded as secondary ; or whether the entire motor apparatus, from the ganglionic cell to the muscular fiber, is simultaneously attacked ; or, finally, whether, as Friedreich maintains, the atrophy begins in the muscles, and thence ascends along the nerve-fibers to the medulla. We think it improbable that these points will be cleared up very speedily. Their solution would seem to be only of theoretical interest.

We certainly must recognize, however, the essential identity of progressive bulbar paralysis and progressive muscular atrophy. The resemblance becomes even more striking if we consider that very frequently both diseases are present simultaneously. Often, after a case of progressive muscular atrophy has lasted for some time, the symptoms of bulbar paralysis also appear. And, on the other hand, an illness may begin with bulbar symptoms, and later on be complicated by atrophy of the muscles of the extremities—almost always first seen in the arms. If cases of this sort come to autopsy, we find a combination of the anatomical lesions of both diseases ; in addition to the degeneration of the nuclei in the

medulla oblongata, there is marked atrophy of the ganglionic cells in corresponding places in the anterior gray cornua of the spinal cord.

We must here refer again to the occurrence of the symptoms of bulbar paralysis in amyotrophic lateral sclerosis (see page 650). In this disease, too, there is the same combination of a degeneration of the nuclei in the medulla oblongata and of the anterior cornua of the gray matter of the cord; but in addition there is a derangement of the motor tract in the lateral columns. This addition modifies the picture, but otherwise the symptoms are almost precisely the same as in progressive muscular atrophy. Even the derangement of the crossed pyramidal tract is in perfect harmony with the other lesions, for it represents merely a further invasion of the tract by which motor impulses are conducted. It seems justifiable, therefore, to say that these three diseases—progressive bulbar paralysis, progressive muscular atrophy, and amyotrophic lateral sclerosis—differing as they do in the localization of their lesions, are yet closely allied. They are essentially—that is, pathogenetically, and perhaps also etiologically—different results of one disease; or, at least, the pathological process in each case must be nearly the same. In each there is a primary chronic degeneration of portions of the chief motor tract, varying only in region or in extent. If we accustom ourselves to regard these three groups of symptoms as really identical, we shall be less puzzled by the slight variations which different cases may present than if we attempt to differentiate the disorders too nicely on account of unessential variations.

**Diagnosis.**—The diagnosis of a typical case of progressive bulbar paralysis has no difficulties, if we only hold firmly to the definition of the disease and its symptoms as above depicted. Upon careful examination of the other muscles, and consideration of the course of the disease as a whole, we shall be able in each case to determine whether the bulbar trouble is the sole disease, or merely a part of a more extended degeneration of the motor tract. If there are no symptoms but those referable to the medulla oblongata, we must bear in mind that the phenomena of genuine progressive bulbar paralysis may be closely simulated by other bulbar diseases. The acute troubles, like thrombosis or hæmorrhage, although they produce similar symptoms, can easily be differentiated by the manner of their appearance, contrasting with the invariably slow development of genuine bulbar paralysis. It is, however, much more difficult to eliminate gradually forming tumors situated in the medulla oblongata or its vicinity. Here prolonged observation is frequently needed, until finally such phenomena appear as are foreign to typical bulbar paralysis. Such symptoms are disturbances of sensation and invasion of the upper division of the facial, the nerves of special sense, and the ocular muscles. The same is true of that rare trouble, diffuse sclerosis of the medulla oblongata.

It should also be mentioned that bilateral cerebral trouble may occasion so complete a paralysis of the tongue and lips, according to Lépine and others, as to simulate bulbar paralysis. Such cases have been termed "glosso-labio-pharyngeal paralysis of cerebral origin," or pseudo-bulbar paralysis. Indeed, in rare instances, a similar group of symptoms seems to be referable to unilateral cerebral disturbances. This is explained by assuming that the muscles involved upon both sides receive at least a portion of their motor nervous fibers from the same hemisphere. And yet in most of these cases of pseudo-bulbar paralysis the exclusion of the genuine disease is possible, because certain variations from the typical course of the disease are pronounced enough to set us right. Thus there is an abrupt onset, the paralysis is not perfectly symmetrical, or the lips and tongue react normally to electricity.

**Prognosis and Treatment.**—Despite the unfavorable prognosis of progressive bulbar paralysis, we must at least try to check the progress of the disease. Electricity might perhaps be regarded as the most promising means to employ. To influence the seat of the trouble, galvanization is chiefly used. The poles are applied

to the two mastoid processes, if possible, every day for two or three minutes, and the current is repeatedly reversed. We may also galvanize the sympathetic nerve and the affected muscles of the lips and tongue. Upon the muscles the faradic current might also be tried. When deglutition begins to be impaired, it is an excellent thing to excite the action of swallowing, by galvanism. For this the anode is placed upon the nape of the neck, and the kathode upon one side of the larynx. At every kathodic closure (KaS), or every time that the kathode is passed across the side of the larynx, there is a reflex act of deglutition. The current should be of medium strength.

It might be well to prescribe further a resort to treatment by baths, as at Rehme, or the "cold-water cure" might be cautiously tried. The same internal remedies are recommended as in the chronic diseases of the cord, especially argentic nitrate, ergotine, and potassic iodide. For salivation, atropine may prove beneficial, in pills of  $\frac{1}{12}$  of a grain (grm. 0.0005), three or four to be taken daily.

The way of giving nourishment is important if deglutition is impaired. We should try carefully to avoid having the food go down the wrong way, lest pulmonary complications ensue. It is therefore wise not to defer the use of the stomach-tube too long, through which we may introduce milk, eggs, wine, and the various infant foods.

In the distressing close of the disease, narcotics must be exhibited to lessen the patient's suffering, at least as far as we can.

#### APPENDIX.

##### THE RARER FORMS OF CHRONIC BULBAR PARALYSIS, AND PROGRESSIVE OPHTHALMOPLEGIA.

As we have seen, the typical form of chronic bulbar paralysis is practically limited in its effects to the distribution of the hypoglossus, the labial division of the facial, and the pharyngeal muscles. Possibly the reason it extends no farther is merely that death is so speedy. But there are a few rare cases where the chronic degenerative process comes to involve other motor nuclei, together with the corresponding nerve-fibers and muscles. Of course the clinical phenomena of these cases vary from the ordinary; and yet there is no real reason to distinguish these from common bulbar paralysis, particularly as all sorts of transitional forms are to be observed. Thus, we have ourselves noticed that there is sometimes a symmetrical and slowly progressive paresis of the upper division of the facial, and in particular of that portion which supplies the cheek, complicating the glosso-pharyngeal paralysis. In other cases we have seen the degeneration attack from the start the entire distribution of the facial, gradually producing a complete "*diplegia facialis*." Sometimes, also, the ordinary symptoms of bulbar paralysis are accompanied by disturbances in the area of distribution of the ocular nerves, the result of degeneration of the corresponding nerve-nuclei. Erb relates a few cases where there were not only ptosis and impairment in the movements of the tongue and in deglutition, but also paresis of the muscles supplied by the accessorius and the motor branch of the trigeminus.

What seems very remarkable is that the process may be confined entirely to the ocular muscles. A. von Graefe named this condition progressive ophthalmoplegia. Another name is "anterior bulbar paralysis." The disease progresses with extreme slowness and is perfectly symmetrical. The movements of the eye are impaired in all directions. Diplopia is never present. The pupil reacts to light, and usually the power of accommodation is preserved. Finally both eyeballs become absolutely motionless, and there is a well-marked though incomplete ptosis. There is, beyond a doubt, a progressive degeneration of the nuclei and

fibers of the corresponding nerves—i. e., the abducens and motor oculi; but with these the process may stop, spreading no farther. We have ourselves lately met with a patient who presented total bilateral ophthalmoplegia, and in whom this condition had existed without the slightest change for fifteen years.\*

We must add, in conclusion, that our anatomical knowledge concerning these rarer forms of chronic bulbar paralysis is very incomplete. The results of a few autopsies, however, join with the clinical phenomena in strongly confirming the surmise above expressed as to the pathological lesions.

## CHAPTER II.

### ACUTE AND APOPLECTIFORM BULBAR PARALYSIS.

#### 1. HÆMORRHAGE INTO THE MEDULLA OBLONGATA AND THE PONS.

HÆMORRHAGE into the medulla oblongata and the pons is much more frequent than into the spinal cord, but it is much rarer than cerebral hæmorrhage. As to its production, the same views are held as will be considered in detail under cerebral hæmorrhage, in the next section. In the first place, there is probably always some disease of the blood-vessels—that is, atheroma or miliary aneurism—and then some factor productive of increased arterial tension. There may be cardiac hypertrophy, nephritis, excessive bodily exertion, or alcoholism. Now and then injuries of the occiput are followed by an effusion into the medulla. It is not rare to have secondary and usually small ecchymoses in acute inflammation of the spinal cord (*vide infra*), and in purulent meningitis or in connection with new growths which are richly vascular.

The anatomical conditions produced by bulbar hæmorrhage are so completely analogous with those of cerebral hæmorrhage that the reader may safely be referred to the succeeding section about these also. The size of the lesion varies greatly. Bleeding extensive enough to affect the greater part of a transverse section is more frequent in the pons than in the medulla oblongata. If the blood is poured out close under the floor of the fourth ventricle, as has been repeatedly observed, it may break into the ventricle. If death be not speedy, the blood is mostly absorbed, and in its place develops either an "apoplectic scar" or an apoplectic cyst.

There may be slight prodromata, but the real symptoms of bulbar hæmorrhage are very sudden. There is almost always a pronounced apoplectic seizure. The patient has a shock, falls down, and becomes dizzy or even unconscious. In other cases there may be headache, vomiting, tinnitus aurium, and clonic spasms, or even a typical epileptiform attack.

In most cases death is speedy, if not immediate. This is probably due in every instance to grave lesions of the respiratory and circulatory centers, rendering continued existence impossible. Sometimes the initial symptoms abate, whereupon the local results of the lesion become appreciable.

One of the characteristics of bulbar paralysis now seen is, that disturbances are particularly great in the distribution of the bulbar nerves. In cerebral apoplexy they never appear in the same way. Another point is, that these paralytic symptoms are combined with paralysis of the extremities in a peculiar way, as a result

\* It seems that total ophthalmoplegia may also appear as one of the symptoms of locomotor ataxia or of general paralysis. It has been observed by Mendel as a sequel to diphtheria. In these cases, however, the symptom is probably in part due to a degeneration of the fibers of the peripheral nerves.

of the anatomical relations. For the same reason, the order of the paralysis in the extremities may also be peculiar. Of the bulbar paralyses we may mention more or less complete paralysis of the tongue, and a consequent difficulty in articulation (anarthria); frequent inability to swallow; and paralysis in the distribution of the accessorius, facial, and trigeminus. If there is a lesion of the pyramidal tracts in the pons or medulla, we have paralysis of the extremities in addition to the specific bulbar symptoms. If the hæmorrhage be extensive, all four extremities may be more or less completely paralyzed; but in most instances the paralysis is unilateral. In the larger number of hæmorrhages into the pons there is crossed paralysis. The paralysis of the extremities is upon one side, and that of the facial is on the other side. This is a great aid to diagnosis. It is easy to see how this happens if we bear in mind that the cerebral fibers of the facial cross at a point certainly much higher than the decussation of the pyramids, in which latter place the motor fibers of the extremities cross. Now a hæmorrhage may be situated in one side of the pons, above the decussation of the pyramids but below that of the facial. This would occasion (*vide* Fig. 100, *y*) a paralysis of the facial on the same side with the lesion, and of the extremities upon the opposite side; but if the lesion be higher, above the place where the facial crosses over, all the paralytic symptoms would be on the opposite side of the body (*vide* Fig. 100, *x*).

In other, rarer instances we observe similar combinations; only some other bulbar nerve replaces the facial, such as the hypoglossus or abducens. In a few cases the lesion is at the very decussation of the pyramids. This is extremely rare in hæmorrhage, though somewhat more frequent in troubles of a different nature. The result may be that the motor fibers for one extremity are cut off before they cross, and those of the other extremity after they have crossed. Thus is produced the rare phenomenon of a crossed hemiplegia—i. e., paralysis of the arm on one side and of the leg on the other.

Disturbances of sensation in the skin of the paralyzed extremities sometimes result from trouble in the pons, but they are very seldom extreme, and can not be made available for making out the exact locality of the hæmorrhage, since the course of the sensory fibers through the upper extremity of the spinal cord is still almost unknown. The anaesthesia sometimes observed in the distribution of the trigeminus is of more value, as this may be due to a lesion of the nucleus or root of the nerve.

There are other symptoms, which are indeed rare, but which bear an important relation to certain nervous centers of the medulla. Thus, there may be marked respiratory disturbance; the pulse may become rapid or irregular; there may be vaso-motor derangement, as shown by a rise of the cutaneous temperature and by a subjective sensation of warmth; and occasionally there are temporary albuminuria and glycosuria. The temperature of the body is generally normal at first, or nearly so; but in case of a fatal termination it often rises greatly, even to  $107^{\circ}5'$  ( $42^{\circ}$  C.) and higher.

As to the prognosis of bulbar hæmorrhage, speedy death has been repeatedly observed, as we have said. If the immediate effects be successfully withstood, the prospect becomes more favorable. The effusion is gradually absorbed, the symptoms of compression abate, and there is a steady progress toward comparatively good or even perfect health. More often, however, some of the paralytic symp-

FIG. 100.—Diagram of focal diseases in the pons.  
L, Left. R, Right. P, Pons. Mo, Medulla oblongata. DP, Decussation of the pyramids. E, Fibers to the extremities. F, Facial fibers. x, Lesion in the upper half of the pons. y, Lesion in the lower half of the pons.

toms remain stationary, either in the distribution of the bulbar nerves (like the lingual or pharyngeal), or in the extremities, as shown by persistent hemiplegia. If this latter be the case, the subsequent contractions and other symptoms are the same as in ordinary cerebral hemiplegia.

The diagnosis of bulbar hæmorrhage is based upon the apoplectic onset, and upon the presence of specific bulbar symptoms, such as disturbance of speech and of deglutition, and, most characteristic of all, if it occur, a crossed hemiplegia. The differential diagnosis between embolism and hæmorrhage can hardly ever be made with certainty (*vide infra*).

The treatment, not only of the seizure but of the persistent paralysis, should conform to the principles which will hereafter be set forth in describing the treatment of cerebral hæmorrhage. If the bulbar nerves present obstinate symptoms, we must employ the same means as in chronic bulbar paralysis, the most effective being electricity.

## 2. EMBOLISM AND THROMBOSIS OF THE BASILAR ARTERY.

The medulla and pons receive their blood chiefly from branches of the anterior spinal, vertebral, and basilar arteries. These branches penetrate the anterior median fissure and then proceed to the nerve-nuclei. A far smaller portion of the circulation flows through the "arteries of the roots." These are minute offshoots of the lateral branches of the basilar and vertebral arteries, which enter the cord at the roots of the nerves and penetrate to the corresponding nuclei. According to Duret, the nuclei of the hypoglossal and accessory nerves are supplied from the anterior spinal and vertebral arteries; those of the vagus, glossopharyngeal, and auditory nerves by branches of the upper end of the vertebral arteries; and the nuclei of the facial, trigeminus, and the three nerves to the ocular muscles by branches of the basilar. There may be individual exceptions to these rules. Occlusion by embolism or thrombosis of the arteries just named must occasion a secondary softening in corresponding portions of the medulla, and is, therefore, a not very infrequent cause of apoplectic, or at least very rapidly developed, bulbar paralysis.

The causes of thrombosis or embolism in the arteries just mentioned are the same as we shall consider minutely when treating of cerebral softening. Emboli are most frequent in cardiac disease. They occur only in the vertebral arteries, oftenest in the left one, and are never primary in the basilar artery; but an embolus may be enlarged by thrombosis after lodging in one of the vertebral arteries, and then block up the basilar. Thrombosis is of more frequent occurrence, and results from chronic changes in the arteries, mainly atheroma or syphilitic endarteritis. The latter disease, one favorite locality for which is the basilar artery, is the commonest cause of acute softening of the pons.

The anatomical condition is likewise similar to that in cerebral softening (*q. v.*). In the region which is deprived of arterial blood by the occlusion of the affluent vessel, the acute anemia entails necrosis and disintegration of tissue. A spot of "softening" results, made up mainly of vestiges of nervous tissue and numerous cells filled with granules, of fat.

When the basilar artery is blocked up, the symptoms appear very suddenly. There is either an apoplectic seizure, or at least a very rapid development of paralysis (occupying only a few days). The symptoms of the first onset are, in all essential points, those of bulbar or even of cerebral apoplexy. Although there is usually no marked loss of consciousness in apoplectic bulbar paralysis, yet no great diagnostic significance can be assigned to its absence. The sudden obstruction of the basilar artery produces such a disturbance of the circulation even in anterior portions of the brain as may suspend consciousness. In some few instances this cir-

culatory derangement may even give rise to choked disk, as seen by the ophthalmoscope. Often there are noticeable respiratory and cardiac symptoms, such as Cheyne-Stokes' respiration, and rapid pulse.

If death be not immediate, and we are therefore enabled to make out the symptoms due to the local disturbance, we usually observe the same phenomena as have just been described under bulbar hæmorrhage. There is sometimes paralysis of all the extremities, but usually there is trouble only upon one side. Then we have the characteristic crossed hemiplegia. The facial nerve or the nerves of the ocular muscles may be paralyzed. It has repeatedly happened that the paralysis seemed at first much greater upon one side, but after a few days changed over to the opposite one. This must be due to changes in the circulation; the thrombus grows larger, or a collateral circulation is developed. The specific bulbar symptoms are the familiar ones of all bulbar derangements—namely, lingual paralysis with resulting difficulty in articulation, pharyngeal paralysis, and rarely deafness, as a result of lesion of the acoustic center. Of course, the severity and extent of all these symptoms must vary according to the location and size of the spot of softening.

The prognosis of cases of this sort is almost always unfavorable. Death results at latest after a few days. It is often ushered in by a high temperature. Exceptionally, there is a transition into a chronic form.

We need say nothing about treatment, except that the same remedies are employed as in other acute bulbar diseases.

### 3. ACUTE, OR INFLAMMATORY, BULBAR PARALYSIS.

(*Acute Bulbar Myelitis.*)

"Acute bulbar paralysis," in the stricter sense of the term, means a form of disease where marked symptoms of bulbar derangement appear acutely—that is, within a few days or weeks. The anatomical lesion is probably an acute inflammation of the medulla oblongata. It is a rare disorder, and its ætiology is doubtful. There are usually mild prodromata: vertigo, headache, and, in one case of our own, painful sensations in the back of the neck. Evident bulbar symptoms very quickly follow. Usually the first of these is dysphagia. Not only is deglutition impaired, but the paresis of the soft palate and of the laryngeal muscles allows liquids to enter the nostrils or the larynx. The tongue also becomes gradually paralyzed, speech becomes indistinct, and, if the soft palate be involved, nasal.

Sometimes the extremities also become paretic, as a result of the extension of the disease to the region of the pyramids; but in many instances the extremities remain unimpaired to the end. Paralysis of the facial nerve and of the ocular muscles are somewhat more frequent. The temperature is sometimes a little elevated ( $100^{\circ}$ – $102^{\circ}$ ,  $38^{\circ}$ – $39^{\circ}$  C.), but not always. The pulse is almost invariably rapid; in our patient it was 148.

The prognosis is apparently always bad. Often death takes place in four to eight days, or it may be not till the end of two or three weeks. It is invariably preceded by all the tokens of paralysis of respiration. In our case there was well-marked paralysis of the diaphragm at the end.

As yet, few autopsies have been reported. Generally the medulla presents no macroscopic changes. Exceptionally, it can be seen to be softened and mottled with minute hæmorrhages. The microscope detects abundant evidence of inflammation: granule-cells, infiltration with nuclei around the blood-vessels, thickening of the walls of some of the blood-vessels, small extravasations, swollen axis-cylinders, etc. It should also be borne in mind that precisely similar clinical phenomena seem often to be referable to peripheral changes, such as multiple neuritis affecting the bulbar nerves.

The treatment of acute bulbar paralysis is, of course, almost hopeless. In early stages we should apply counter-irritation to the nape of the neck; and we might prescribe mercurial inunction. It might also be well to employ the constant current, applied at the back of the neck, and also used to excite the movements of deglutition. We found injections of strychnine useless. Toward the end, narcotics are indispensable.

### CHAPTER III.

#### COMPRESSION OF THE MEDULLA.

ACUTE compression and other injuries of the medulla are most frequently due to fracture or dislocation of the atlas and axis. As is well known, dislocation of the axis, or backward dislocation of the atlas, usually causes instant death.

Gradual compression is seen in chronic disease of the bones around the medulla, in caries and tumors of the occiput and of the first two vertebræ. Enchondroma of the base of the skull; new growths of the sphenoid, at its junction with the occipital; tumors of the dura; and sometimes even tumors of the cerebellum—may all excite by their pressure the gravest bulbar symptoms. We should also mention aneurism of the vertebral artery at its upper end, and of the basilar, as capable of doing similar harm. In all these cases the main cause of disturbance is undoubtedly the mechanical pressure, either directly destroying the nervous tracts or interrupting the transmission of nervous influences; but the circumstances may be further complicated by hæmorrhages, and sometimes perhaps by inflammation of the medulla itself.

The clinical phenomena of gradual bulbar compression resemble those of spinal compression, in that they usually begin with symptoms of irritation in the distribution of those nerves the roots of which are first affected. There are neuralgia of the trigeminus, twitching of the facial muscles, tinnitus aurium, etc. If the compression becomes greater, there are more serious bulbar symptoms: disturbances of speech and deglutition, paralysis of the tongue, soft palate, face, and very likely motor and sensory symptoms in the extremities. Usually we also see general cerebral symptoms, such as vertigo, headache, vomiting, and sometimes epileptiform convulsions.

We can not, of course, draw up a definite and rigid list of symptoms, since both the individual symptoms and the general course of the disease exhibit great variations according to the way in which the compression is brought about. The diagnosis can be made in those cases only where some ætiological factor like trauma or caries of the vertebræ is known to exist. Aneurism of the vertebral artery is said by Möser sometimes to give rise to a loud systolic murmur heard between the mastoid process and the spine. In all other cases we can seldom do more than surmise the truth. Slow compression is distinguished from genuine progressive bulbar paralysis chiefly by the course it pursues—that is, there are initial symptoms of irritation—by the greater complexity of the clinical phenomena, like sensory lesions and hemiplegia, and sometimes by the asymmetry of certain symptoms. If the anterior part of the medulla is compressed, in the region of the pyramids, there may for a time be no bulbar symptoms, but merely motor symptoms in the extremities. These are chiefly paretic or spastic.

The prognosis is almost always bad, as can be inferred from the nature of the causative disease. Death is brought on either by inhalation-pneumonia, or paralysis of respiration. Treatment must be purely symptomatic, and should follow the same rules as in progressive bulbar paralysis.

## V.—The Diseases of the Brain.

### SECTION I.

#### *DISEASES OF THE CEREBRAL MENINGES.*

#### CHAPTER I.

#### **HÆMATOMA OF THE DURA MATER.**

*(Internal Hemorrhagic Pachymeningitis.)*

**Ætiology and Pathology.**—Hæmatoma of the dura mater is the name given to effusions of blood found on the inner surface of the dura mater. They are of considerable area, but of moderate thickness, and are usually encapsulated. There has been much discussion as to their mode of origin, and views still differ. One is that the hæmorrhage is the primary lesion, and that the connective-tissue membranes are developed only by the organization of the clot. This conception was originally the prevailing one, but was opposed by Virchow, who was led by the results of his own investigations to maintain that the hæmorrhage was always secondary. The primary process he believed to be a peculiar sort of inflammation—"hæmorrhagic pachymeningitis." This gave rise to a new growth of richly vascular connective tissue, into which the hæmorrhage took place. Of late, however, the tendency is again to regard the hæmorrhage as the initial change, at least in certain cases, and to refer it to an affection of the walls of the blood-vessels which diminishes their power of resistance.

The mildest forms of internal pachymeningitis present a delicate membrane upon the inner surface of the dura mater, quite easily separable, of a reddish color, and dotted with numerous red and brownish spots. These spots are due to minute hæmorrhages and collections of hæmatoidin. The membrane itself is a delicate interstitial tissue, traversed by numerous wide capillaries.

In more advanced cases the thickening is much greater. There are usually several layers, the newest and most superficial being nearest the brain. The oldest, which is in apposition with the dura mater, is composed of connective tissue that has already become rather firm and fibrous. It is evident from this lamellar structure that the whole process goes on by fits and starts. The clinical course of the disease will be seen below to agree well with such a view. The effusions are sometimes very extensive, even larger than a hen's egg, and exercise no slight pressure upon the underlying cerebral parenchyma. The hæmorrhage always takes place inside the mass, or between its layers. The effusion may, however, break through the innermost layer, so that the blood flows into the arachnoid spaces; this is known as "intermeningeal apoplexy."

The favorite location of the hæmatoma is the parietal region. It is sometimes found at the base of the brain, in the posterior or middle fossa. Occasionally the hæmatoma is bilateral.

Hæmorrhagic pachymeningitis is not a rare disease. It is sometimes found to exist in a moderate degree in chronic cardiac, renal, or pulmonary cases, which come to autopsy. Usually there have been no special symptoms, the lesion being discovered incidentally. It has been found in like manner in connection with

a great many acute infectious diseases, like typhoid fever and small-pox. It is a more important and more frequent complication in other chronic cerebral diseases, in particular such as induce marked atrophy of the brain as a whole. It is especially common in general paralysis of the insane and in other forms of dementia. Chronic alcoholism is also regarded as a potent ætiological factor. In toppers it is not very unusual for the hæmatoma to be so extensive, if it occurs at all, as to cause grave cerebral derangement. Very likely changes in the vascular walls, like atheroma and fatty degeneration, contribute an important part to the result in such patients. Hæmatoma may also occur in all diseases where there is a general hæmorrhagic diathesis. Thus it is seen in pernicious anæmia, leukemia, and scurvy. Here certainly the hæmorrhage is the primary event, as it also is in the traumatic cases, of which a number have been observed.

As might be inferred from the ætiological factors enumerated, the disease is found chiefly in advanced life, and much oftener in men than in women.

**Symptoms.**—Not infrequently a hæmatoma of the dura is found post mortem, which had during life been entirely unsuspected. Either the hæmorrhage was not extensive enough to cause any symptoms, or the brain exercised that remarkable tolerance which it sometimes shows even when there are wide-reaching lesions; or such symptoms as there may have been escaped particular notice, in the severity of the more general symptoms (of typhoid fever or some similar disease). But in other cases hæmorrhagic pachymeningitis excites grave symptoms, although they are seldom so characteristic as to reveal the diagnosis; for individual cases vary greatly, according to the size of the hæmorrhages, their location, and the frequency of their recurrence.

Almost always the beginning of the disease is rather sudden. It may even be like an apoplectic seizure. The symptoms are referable partly to the general effect of the hæmorrhage upon the brain, and partly to the exact locality of the hæmorrhage. The more general symptoms comprise headache; impairment of intelligence (that is, stupor or even complete coma); slow or irregular pulse; vomiting; and contracted pupils—all being symptoms of cerebral compression. Now and then we even find choked disk. Other phenomena are added to the above when the hæmatoma occupies its usual position, upon one side and in the neighborhood of the motor cortical region, or central convolutions. The hemiplegic symptoms are not infrequent, such as hemiparesis, and, from the irritation which the effusion produces in the motor centers, twitchings and convulsions in one half of the body. Sometimes these symptoms are limited to a single extremity or to the distribution of the facial nerve. Aphasia has been repeatedly observed when the hæmorrhage was near the island of Reil. If the effusion increases, the motor disturbance becomes correspondingly aggravated, and may become bilateral. Sensation is usually little impaired.

The further course of the disease varies greatly in different cases. In the worst cases there is speedy death, usually ushered in by deep coma. In others, the first symptoms are followed by improvement, although mild indications of cerebral pressure persist, such as headache or vertigo, or else local symptoms, like hemiparesis. It is possible for the effused blood to be absorbed, and complete recovery to ensue; but usually new hæmorrhages and corresponding symptoms arise. It is precisely this appearance of the symptoms in separate attacks, this frequent recurrence of severe cerebral disturbances, that is characteristic of hæmatoma of the dura mater. As already intimated, the way in which the anatomical lesions develop explains this perfectly. Thus the disease may drag on for months and years, sometimes improving and sometimes aggravated. Then some attack at last proves fatal. Arrest and actual improvement are still possible even in the later stages, although often the features of the case have meanwhile undergone essen-

tial alteration because of the progress of some causative disease. In general, the clinical phenomena of hæmatoma of the dura are often complicated and obscured by the co-existence of the primary disease.

The **diagnosis** is therefore difficult. The main points may be recapitulated as follows: First, the existence of ætiological factors, like alcoholism, or chronic cerebral disease; second, the sudden onset, and also the abrupt appearance of further symptoms, the alternation of rapid aggravation and improvement; and third, the existence of symptoms which experience has taught us to refer mainly to the cortex of the brain, namely, unilateral convulsions, monoplegic paresis and contractures, and contracted pupils. Nevertheless, frequent errors in diagnosis can not be avoided.

**Treatment.**—The possibility of therapeutic interference being successful is very small. In apoplectic shocks, ice to the head is useful; and if the patient be robust, it may also be advisable to use local depletion, by leeches on the temples or behind the ears. It is also customary to prescribe some such thing as senna or calomel for "intestinal depletion."

If the first onset is successfully withstood, the main things as to further treatment are general hygienic and dietetic directions, so as to guard as far as possible against fresh hæmorrhages. Alcohol and excessive bodily or mental exertion should be forbidden. Of course, paralysis or other persistent disturbances may call for special treatment.

## CHAPTER II.

### PURULENT MENINGITIS.

(*Purulent Cerebral Leptomeningitis. Meningitis of the Convexity*)

**Ætiology.**—Purulent inflammation of the dura mater has no clinical importance, for it is very rare, and occurs only as the result of the extension of disease from neighboring parts. We shall accordingly consider below purulent inflammation of the pia mater only. One important variety of this disease has already been discussed (see page 103 *et seq.*) as one of the infectious diseases, under the name of epidemic cerebro-spinal meningitis. There we saw also that the occasional sporadic cases of primary or "idiopathic" meningitis are probably identical ætiologically with those of epidemic meningitis. In all other instances, purulent meningitis is a secondary disease—that is, the specific agent, which excites the purulent inflammation, originates in some other organ primarily, and affects the meninges only secondarily. We should, therefore, seek most carefully in every case of purulent meningitis, at the bedside and more particularly at the autopsy, to discover the way by which the pathogenetic virus reached the meninges. We have no right to say that the case is one of primary meningitis, strictly so called, until we have made a most careful examination with a negative result. From a clinical standpoint, it is true that many cases of secondary meningitis do seem as if they were primary, because not infrequently the really primary disease excites insignificant symptoms, or perhaps no symptoms at all.

Secondary purulent meningitis is most often due to disease of the cranial bones, and in particular to disease of the petrous portion of the temporal bone, with the auditory apparatus therein contained. If we consider the anatomical relations of the middle and internal parts of the ear, we can easily understand why inflammation in them is not infrequently followed by meningitis. Usually it is a caries of the petrous portion, itself due to an otitis media, which leads to an irruption into the cranial cavity. This is especially apt to take place through the thin vault of

the tympanic cavity. It may also extend from the mastoid cells, or by direct propagation along the sheaths of the acoustic or facial nerves, or along the vessels which lie in the petroso-squamous suture. The dura is first attacked, and then the pia. In many instances, the neighboring venous sinuses (transverse, cavernous, and superior petrosal) transmit the inflammation, being first attacked by a suppurative thrombo-phlebitis. Again, exceptionally, a purulent inflammation in the upper part of the nasal cavity may lead to meningitis.

Another and frequent source of meningitis is found in the various traumatic injuries of the cranium. In the great majority of these cases there is an open wound, admitting infectious agents which are suspended in the air. The suppuration often commences in the spongy texture of the diploë, thence extending to the dura and pia, either directly or by way of a purulent thrombosis of some sinus into which the veins of the diploë enter. It is, indeed, generally affirmed that we may have a traumatic purulent meningitis without any open wound; but this is not easily explained, according to our present views as to the origin of purulent inflammations. It is equally difficult to understand, what many authors affirm, that the heat of the sun's rays, striking upon an uncovered head, may excite purulent meningitis. In most cases of sunstroke we find marked hyperæmia of the meninges, but no inflammation.

Meningitis may have an intra-cranial origin; it is sometimes the sequel of cerebral abscess. No matter what starts the abscess, if it extends to the surface of the brain, it causes a more or less extensive purulent meningitis at that point. An abscess may burst into one of the lateral ventricles, and the infection be carried from that point to the pia at the base of the brain.

All the cases thus far contemplated allow of the explanation that the inflammation reaches the meninges by direct extension; but there is another group of cases where the agent that infects the pia mater originates at some distant part of the body, and is probably conveyed by the blood or lymph currents. These cases are often termed metastatic meningitis.

Of this sort is the secondary meningitis seen in connection with genuine lobar pneumonia, a combination already discussed (see page 198). The meningitis is also sometimes a complication of empyema, rarely of pyæmia and septicæmia, ulcerative endocarditis, and very rarely of typhoid and the acute exanthemata (small-pox, scarlet fever), and of acute articular rheumatism. In each case we must, of course, determine whether the meningitis may not have a connecting link between itself and the primary disease, such as otitis in scarlatina, or secondary empyema in typhoid fever.

**Pathology.**—For the pathological anatomy of purulent meningitis, we may refer mainly to the statements made on page 94, under epidemic meningitis, for the lesions are similar. The only way to determine whether a meningitis is secondary or primary is by finding or failing to find disease in neighboring or remote parts, for example pneumonia. The seat of the meningitis will vary according to that of the primary inflammation, if there be any. If the meningitis is due to caries of the petrous bone or to an injury of the skull, the purulent exudation is usually most abundant in the immediate neighborhood of the primary lesion, between the pia and arachnoid. Thence it gradually extends along the surface of the brain, sometimes chiefly on the convexity and sometimes at the base. But in general it may be said that both the secondary and the metastatic varieties of meningitis as a rule affect the convexity, although this is by no means invariably the case. This rule explains why these cases are sometimes termed meningitis of the convexity, in contrast to tubercular meningitis, which latter, as we shall find, has a preference for the base of the brain, and hence is called basilar meningitis. The spinal pia mater is sometimes simultaneously attacked, but not so constantly as in primary, or epi-

demic meningitis. The brain is almost always involved—the inflammation extends along the vessels which dip from the pia mater into the cerebral parenchyma. It is not a rare thing to find minute abscesses or ecchymoses in the interior of the brain. The whole parenchyma is usually moist, cedematous, and of a doughy consistence. The meningeal exudation exerts upon the brain a pressure which gives rise to important symptoms; by it the superficial cerebral convolutions are often considerably flattened. The lateral ventricles almost always contain more or less sero-pus.

**Clinical History.**—So varied are the primary diseases which may entail a meningitis, that it is hardly possible to make a sketch of the disease which would suit all cases. If the meningitis comes on during the course of pyæmia, pneumonia, or some other severe illness, its proper symptoms are often inextricably confused with those of the primary trouble; and when the skull or the brain has been mechanically injured, it is very hard to determine whether a meningitis has been excited, because the trauma may of itself produce such serious effects. The following description, therefore, applies chiefly to cases of apparently primary meningitis, or to cases where the meningitis, although secondary, is well marked.

The beginning in such cases may be sudden, or it may be somewhat insidious. Sometimes the grave symptoms appear almost at once, accompanied by a chill and high fever. Sometimes there are for a while indefinite and more or less ambiguous prodromata, but almost always it is the headache which first attracts attention. This grows worse with more or less rapidity, and almost always becomes very violent. Exceptionally it may be insignificant. Not infrequently it varies considerably, being much worse at some hours or on some days than on others. The location of the pain is sometimes frontal, sometimes occipital, and sometimes over the whole head. Next in prominence to the headache, particularly in the later stages of the disease, is the mental disturbance. The patient complains of vertigo, becomes dull and stupid, or begins to wander. The delirium may be extremely violent, but usually there is depression rather than exaltation, and the stupor merges into coma. That the headache still continues may be inferred from the frequent raising of the hand to the head and the grimace of pain whenever the head is moved, till finally the coma becomes so profound that even these reflex actions cease.

Usually these general cerebral symptoms are attended by others referable to the particular locality affected. The neck is rigid. This is most marked when the posterior fossa and the medulla are affected. Then there are all sorts of paralytic or irritative symptoms in the distribution of the cranial nerves, mainly due to lesions of the nerves where they emerge from the base of the brain; there is derangement of the *motores oculi*, as shown by paralysis or nystagmus: the pupils are unequal, or are contracted or dilated, and do not react to light; there is paresis of the facial, or trismus, or grinding of the teeth. All these symptoms may appear equally plainly in other forms of meningitis. Sometimes we can detect optic neuritis with the ophthalmoscope. Other symptoms are due to cerebral disturbance, often apparently located chiefly in the cortex. Thus there may be twitchings of individual muscles, or even pronounced convulsions in one or more limbs, or paralysis of one extremity or of half the body. Sometimes the autopsy explains these phenomena, but often we fail to find any marked anatomical lesion to correspond to them, and are obliged to ascribe them to circulatory or functional derangement.

Of the remaining symptoms, the fever is most important. Almost always the temperature is decidedly elevated, not infrequently reaching  $104^{\circ}$  or  $105^{\circ}$  ( $40^{\circ}$ – $40.5^{\circ}$  C.). The fever is, however, very irregular. There may be repeated chills with great elevations of temperature. The pulse is generally rapid, and often some

what irregular. Exceptionally it is less frequent than normal, because of cerebral compression. Vomiting is not a rare symptom, particularly at first. There is almost invariably constipation, and the abdomen is often tense and concave. The urine is scanty, and often contains a trace of albumen. Secondary diseases are sometimes found post mortem, such as lobular pneumonia, due to inhalation of food during the comatose state.

The entire course of the disease occupies only a few days in very acute cases, and scarcely ever exceeds a week or ten days. The termination is almost sure to be fatal. In the few cases of recovery which have been reported the diagnosis is doubtful. In most instances deep coma precedes death, though sometimes it is ushered in by convulsions. There is often a great rise of temperature ( $107.5^{\circ}$ ,  $42^{\circ}$  C., or higher) before the close of life.

**Diagnosis.**—The diagnosis of purulent meningitis is sometimes pretty evident; but it may be very obscure, so that we can not always avoid confounding it with other severe acute diseases, such as typhoid, pyæmia, and general tuberculosis. In general the most characteristic symptoms of any variety of meningitis are intense headache, rapid onset of grave cerebral disturbances, delirium and insensibility, stiffness of the neck, and disturbances in the distribution of the cranial nerves (especially impaired motion of the eyeball and optic neuritis). These last, although often slight, are generally present; and in connection with these separate symptoms we must also always consider the whole course of the disease and any ætiological factors which may exist. Typhoid fever is excluded by its usually slower onset, the greater delay in the appearance of grave cerebral symptoms, the rose-spots, the greater size of the spleen, the characteristic stools, and the peculiar fever-curve. Severe septic and pyæmic diseases, including ulcerative endocarditis, likewise excite cerebral disturbances which might be misleading, but these diseases are to be recognized by their ætiology (external wounds, abortion, etc.), cutaneous ecchymoses, septic retinitis, swelling of the joints, and repeated rigors. Uræmia may also simulate meningitis. Sometimes the character of the urine, and the predominance of convulsions, will set us right, but not always. We may state in conclusion that every one who sees many cases (including ourselves), must repeatedly have met with patients presenting the symptoms of a severe and acute cerebral affection apparently primary, without demonstrable cause, and seeming to justify a diagnosis of meningitis, but yet yielding post mortem no signs of disease beyond "hyperæmia," "œdematous swelling," and similar changes of only secondary importance. We are as yet wholly unable to explain such cases.

Granting that meningitis exists, what variety is present? The ætiology is a great help in answering this question. We should endeavor to learn whether there has been traumatism or some old ear trouble. It is well to employ the aural speculum. We can not say that a patient has epidemic meningitis unless several cases occur simultaneously, although herpes is very characteristic, as it appears only exceptionally in other varieties. Usually tubercular meningitis also can be diagnosticated only by means of the ætiology. Its symptoms, of course, are in almost all particulars identical with those of purulent meningitis. Sometimes, however, tubercles can be detected in the choroid by means of the ophthalmoscope. For further particulars see the next chapter.

**Treatment.**—The treatment of the different forms of meningitis varies but little. Locally, the favorite remedies are ice applied to the head, which should be shaved if practicable, and local depletion by means of leeches behind the ears or on the temples. Many physicians recommend cutting off the hair and rubbing in antimonial ointment, or applying ethereal tincture of iodine. We have never tried this. Cool baths with douching can not be employed unless the patient can be moved without too much pain. For violent pain or great restlessness we must

use narcotics. The best is morphine subcutaneously. We can not hope for much benefit from other internal remedies, such as iodide of potassium or calomel.

Prophylaxis demands, above all, prompt recourse to the otologist for aural trouble of any kind, and strictly antiseptic treatment of all injuries of the skull.

### CHAPTER III.

#### TUBERCULAR MENINGITIS.

(*Basilar Meningitis.*)

**Ætiology.**—Tuberculosis of the leptomeninges is always a secondary affection—a sequel to previously existing tubercular disease of some other organ. Why the pia mater should be so often singled out for secondary infection with the tubercular virus, or what path that virus traverses to reach the pia—about these questions we know very little. We can merely state what the other tubercular diseases are, which, as experience shows, entail tubercular meningitis most frequently. These primary affections may be of themselves productive of grave clinical phenomena, the meningitis merely adding to the complexity of the picture. Again, the primary trouble may not have betrayed itself at all, or its symptoms may have been long ago arrested, so that the meningitis seems to be a primary disease. In some cases even the most careful examination will fail to detect the origin of the trouble.

Tubercular meningitis is oftenest a sequel to pulmonary tuberculosis. It may appear as a terminal complication in cases of advanced phthisis, or it may come on while the signs of pulmonary disease are as yet very slight. Next in order as a causative affection comes tubercular pleurisy. This origin is not infrequent. As we have already seen, most cases of apparently primary pleurisy are due to tubercle. This statement is supported by the fact that it is not very exceptional for the symptoms of tubercular meningitis to supervene suddenly upon what had seemed to be genuine convalescence from pleurisy. In children, and sometimes in adults, the virus may be carried to the meninges from cheesy, tubercular, bronchial or mesenteric glands, or from tubercular or "fungous" disease of the bones or joints. Another danger to adults is tubercular disease of the genito-urinary apparatus. It should also be noticed that a single large tubercle in the brain may lead to miliary tuberculosis of the meninges. In short, we see that it is not impossible for any tubercular infiltration, wherever situated, to communicate infection either to the meninges alone (in some remarkable way), or simultaneously to them and many other organs. In this last case, where in all probability the blood carries the virus through the system, the meningitis is merely a part of a general miliary tuberculosis (see page 236). When the meninges are alone or predominantly affected, there must be some peculiar manner of infection, about which, however, as we have already confessed, we have no information.

We sometimes hear the attack ascribed to such causes as over-exertion, mental excitement, or traumatism; but we need hardly say that these can not be properly regarded as ætiological factors, and that usually they are merely coincidences. Age, however, does have an influence; children are much oftener attacked than adults, although the latter also are liable to it.

**Pathology.**—As in tuberculosis of serous membranes, so in tuberculosis of the pia, there are two effects of infection to be distinguished from each other: (1) the development of the specific new growth—that is, of miliary tubercles; and (2) the inflammation. The relative degree of these two varies. Sometimes the

tubercles are very abundant and the inflammatory exudation comparatively scanty; and in other cases the inflammation is considerable, although relatively few tubercles are discoverable. The tubercles are usually found in greatest number along the course of the larger blood-vessels, and therefore chiefly in the furrows and clefts of the surface of the brain, in the fissure of Sylvius, at the chiasma, the pons, the medulla, and the cerebellum. And, in general, the base of the brain is usually more affected than the convexity—hence, as we have said, the name of “basilar meningitis.” There are, however, exceptions to this rule. We very often find that the region supplied by one or more arteries suffers above other parts; this must be due to the manner of infection. The inflammatory lesions consist of hyperæmia, usually well marked, and a sero-gelatinous exudation of variable amount. That this exudation is partly cellular can always be proved by the microscope, and often even macroscopically from the great cloudiness of the pia; but still we seldom find enough to justify us in calling the process one of genuine purulent inflammation. Small hæmorrhages into the pia are quite often found. The brain itself is usually flattened from the pressure of the meningeal exudation. Often the inflammation involves the brain-substance itself, as shown microscopically by tubercles, inflammatory changes, and capillary hæmorrhages. The ventricles usually contain, although not invariably, a hydrocephalic effusion. This led earlier observers to term the disease “acute hydrocephalus.” The effusion is serous, but generally turbid from cellular constituents, and not infrequently tinged with blood. The choroid plexus is engorged, and may present tubercles. The spinal cord, in the majority of cases, shares in the tubercular disease. Here, too, we find inflammation of the pia and miliary tubercles. This fact has a clinical bearing, being explanatory of many of the symptoms.

**Clinical History.**—Tubercular meningitis almost always begins with a prodromal stage, which is often brief, but may last one or two weeks, or even longer. The patient may be apparently well (*vide supra*) until this comes on, or he may have already shown signs of some other tubercular affection. He now feels badly, at any rate, and begins to complain of headache, worse at some times than at others. There is anorexia and very often constipation. Another frequent prodrome is an attack of vomiting, which may or may not recur. Sleep is disturbed, either by the headache or by a certain general restlessness. We have occasionally met with cases where the illness began with pronounced mental disturbance. The patient became irrational and said and did queer things, and then a few days later there appeared distinctive meningeal symptoms. In two patients, who were topers, the disease began just like delirium tremens.

After an initial period of variable duration, the general health becomes more and more impaired. The headache increases. The patient takes to his bed, begins to be delirious, and soon presents well-marked symptoms of grave brain trouble. Intelligence becomes more and more impaired. The patient is sleepy, and can be roused imperfectly by the voice, if at all. At the same time he is usually quite restless at first, grasping at invisible objects in the air, picking the bed-clothes, and continually moving his legs. The delirium may be low or noisy; the patient may keep up a constant singing or screaming or whistling. The persistence of the headache even in this stage is shown by the facial contortions and complaints of the sufferer, whenever there is a temporary approach to consciousness. There is also, as a rule, decided tenderness in the nape of the neck on pressure, frequently accompanied by great stiffness of the neck. Sometimes there is stiffness of the entire spinal column, and pain in the same. This is certainly due to the coincident spinal meningitis.

Another group of symptoms in the distribution of the cranial nerves are identical with those seen in the other forms of meningitis. Ptosis is not infrequent,

on one or both sides, due to paresis of the motor oculi. There is strabismus, either internal or external. Symptoms of irritation of the nerves governing the movements of the eye are very frequent, especially in the early stages of the disease. Thus we see slow involuntary lateral movements of the eyeballs, and sometimes nystagmus. The pupils are often unequal; they may be enlarged or contracted, and often they undergo marked and repeated variations in size. The reaction of the pupils to light is usually sluggish, and may be absent. With the ophthalmoscope we find not infrequently neuritis, or choked disk. In some instances, but not in all, we find also tubercles in the choroid, which, of course, greatly assists diagnosis. Sometimes there is occasional twitching in the distribution of the facial nerve, or a slight tonic contraction, or again paresis on one side. The natural explanation of all these phenomena is that the nerve-trunks are interfered with at the base of the brain, whether by the pressure of the exudation or by participation in the inflammatory process, or by the minute hemorrhages which sometimes take place into the sheath of the nerves.

Disturbances in the extremities may be caused by various lesions. Motor symptoms of irritation are apparently referable for the most part to changes in the cortex of the brain. We see occasional twitching of larger or smaller groups of muscles, or rarely convulsions. These latter may be unilateral, or in a single extremity. Sometimes there is well-marked paresis of one half the body or paralysis of one limb, or there may be aphasia, although it is only in a part of the cases that we find post mortem any lesion which explains these symptoms. In most cases there is a particularly large collection of tubercles in certain places upon the cortex cerebri, occasioning a local compression or an inflammatory edema, which in its turn excites the phenomena mentioned. Sometimes the brain-substance itself is found in a state of red softening underneath these spots. Another and not very rare symptom is a peculiar stiffness of the limbs, due either to direct irritation or to reflex action. The reflexes in the lower extremities are generally exaggerated at first, but later on become diminished, and finally abolished. The reflexes upon one side may be more vigorous than upon the other. As to sensation, it is hard to reach definite conclusions, because of the patient's stupor. Sometimes there is well-marked cutaneous hyperaesthesia, probably referable to an implication of the spinal cord in the process.

The behavior of the pulse and temperature is interesting. The temperature is usually elevated, but often only to a slight extent—that is, varying between  $100.5^{\circ}$  and  $102^{\circ}$  ( $38^{\circ}$  and  $39^{\circ}$  C.). Often the temperature falls quite low, only to rise again, the alternations being at irregular intervals. Exceptionally the temperature may remain high ( $104^{\circ}$  F.,  $40^{\circ}$  C.) most of the time. Toward the end there is usually a decided change in temperature, either upward or downward. In many instances there is a very low temperature before death; in two cases we have seen a temperature of  $87.8^{\circ}$  ( $31^{\circ}$  C.). Or the temperature may rise to  $106^{\circ}$  ( $41^{\circ}$  C.) or higher just before death. The pulse is often abnormally slow in the early stages of the disease, even numbering only 40 to 50 beats per minute. This is referable without doubt to the increased intra-cranial pressure. Later on the pulse becomes small and rapid. The transition may be very sudden. The vagus is at first irritated, and then paralyzed. The pulse is often irregular.

Respiration is generally moderately accelerated. If the breathing is very deep and rapid, we should always think of simultaneous miliary tuberculosis of the lungs. Toward the close of the disease the respiration often assumes the Cheyne-Stokes type: there is a long pause, followed by very superficial and gentle respiration, which gradually grows deeper and deeper, then diminishes again, and is succeeded by another complete pause. This symptom is always most ominous, for it indicates that the excitability of the respiratory center is already greatly impaired.

Symptoms referable to still other organs are few. Vomiting is rare in the later stages of the disease. The abdomen often presents a "boat-shaped" concavity, as the result of tonic muscular contraction, and is hard and tense. There is almost always constipation. The spleen may be somewhat enlarged. The urine sometimes contains a trace of albumen. On account of the drowsiness, it is usually voided in the bed or retained in the bladder. Almost invariably there is rapid marasmus.

The entire duration of tubercular meningitis varies somewhat, chiefly because of the varied length of the first stage. When the disease is once fully developed, the illness seldom lasts more than three to ten days longer. Frequently the illness is divided into three stages: 1. The stage of cerebral irritation, with headache, stiff neck, vomiting, and delirium; 2. The stage of cerebral compression, chiefly due to the hydrocephalus, and causing drowsiness, slowness of the pulse, paralysis of the *motores oculi*, hemiplegia, etc.; and 3. The paralytic stage, presenting deep coma, relaxation of the previously contracted muscles, accelerated pulse, and marked variations of temperature. Such a division is too diagrammatic to correspond accurately to the real phenomena, but will, nevertheless, often aid us in getting a general idea of the course of the disease.

The termination of tubercular meningitis seems to be inevitably fatal. Sooner or later the patient loses consciousness completely, his pulse grows very small and rapid, his respirations irregular and intermittent (Cheyne-Stokes), his temperature, as we have said, either rises high or falls far below normal, and, finally, death is ushered in by a paralysis of all the vital functions. A few physicians have reported cases of recovery; but was the diagnosis correct? While we would by no means absolutely deny that recovery from tubercular meningitis might occur, it would certainly be very difficult to prove, in any particular instance, that such a thing had happened.

**Tubercular Meningitis in Children.**—The disease is so prone to attack children that it seems desirable to subjoin a few remarks about the peculiarities of the affection as observed in them.

Often the little patient is pale and weakly, with tubercular antecedents; but sometimes apparently healthy and vigorous children are attacked. Tubercular meningitis may be the sequel of measles, whooping-cough, or some other disease, which has occasioned the development of the tubercular process. Usually the severer symptoms are preceded by a rather long prodromal stage, during which the child is fretful, eats little, and grows thin and pale. In children as well as adults, the second stage is generally ushered in by headache and vomiting. The headache is not very often violent; but children complain with remarkable frequency of pain in the abdomen and chest. The cause of this symptom is unknown. The pulse is almost invariably slow, often somewhat irregular, and it frequently undergoes surprisingly rapid changes in rate—for example, varying twenty or more beats inside of a few hours. Very early the child becomes dull and drowsy. Frequently it emits a peculiar deep sigh, or that sudden loud scream or "cephalic cry" which physicians long ago learned to recognize and fear. The symptoms referable to the cranial nerves and the nervous disturbances in the limbs are similar to those seen in adults. Strabismus is almost constant. Very often there is trismus, and a distinctly audible grinding of the teeth, most distressing to the by-standers. Trousseau laid weight upon the appearance of red spots (*taches cérébrales*) upon the skin after it has been mechanically irritated; but these have no diagnostic value. They are due to increased reflex action, and are seen in all sorts of acute diseases. The fever is generally, as in adults, not very high, 100° to 102° (38°-39° C.). Respiration is usually rapid, and often is irregular.

The change from bad to worse is almost always announced by a rapid increase in the pulse-rate, to 160 or 200. The child becomes completely comatose. Very often there are repeated epileptiform convulsions, either universal or affecting single extremities. Death is usually preceded by a decided rise in temperature.

**Diagnosis.**—When the symptoms are pronounced, the diagnosis of meningitis is easy, and we have merely to determine just what variety is before us. That the disease is due to tuberculosis is never to be ascertained by means of the meningeal symptoms themselves, but is rendered possible only by the ætiology, if that be discoverable. Here, as in all tubercular diseases, we have chiefly to consider (1) heredity and (2) the evidence of previous or existing tubercular affections in other parts of the body. Under this second head are to be considered scrofula, diseases of the bones and joints, pulmonary tuberculosis, pleurisy, and tuberculosis of the genitals or of the choroid. If our search be unsuccessful, we may sometimes get a hint of the truth from the general appearance of the patient: for example, he may be pale, or narrow-chested. And, again, the absence of trauma, aural disease, or epidemic meningitis will make tuberculosis more probable.

In its early stages, or when it varies from the usual course, tubercular meningitis may be very difficult to diagnosticate. This is particularly true when the patient is a child. The early malaise and vomiting are treated as "ordinary gastric catarrh" until the grave cerebral symptoms disclose the mistake in diagnosis. In such cases we should be careful not to disregard the initial slowness and irregularity of the pulse. This alone should make our prognosis guarded. The fever may be prominent at the commencement, and tempt us to call the case one of incipient typhoid fever; and, indeed, the correct diagnosis is often impossible until the disease develops further. In regard to this, see the preceding chapter on purulent meningitis, where the exclusion of severe septic diseases and of uræmia is also considered.

Before the autopsy we must remain in great uncertainty as to the number and distribution of the tubercles, the existence of a large effusion into the lateral ventricles, etc. We are often amazed at the post-mortem examination by the apparent insignificance of the lesions. Paralysis of the cranial nerves (eyes, face) implies that the base of the brain is gravely affected. If such symptoms are absent, and there are mental disturbances, and motor symptoms of irritation displayed in the extremities, we are led to infer meningitis of the convexity. If the nervous disorder be mainly unilateral, we may assume that one hemisphere is more affected than the other.

**Treatment.**—However hopeless the prospect, we are nevertheless bound to employ all the remedies at our command, as in other forms of meningitis. Above all, we should be thorough in applying ice to the head, and may also try local depletion and lukewarm baths, with douching. The inunction of mercurial ointment has also been recommended. The most common internal remedies are calomel—half a grain to a grain (grm. 0·03–0·05) for a child every two hours—and infusion of senna. Iodide of potassium may also be freely given, fifteen grains daily to a child, and two or three times as much to an adult. Whether it does any good is extremely doubtful. If the patient is very restless, narcotics are indispensable. Stimulants are often given in the last stage of the disease, but generally without effect.

About prophylaxis, we need merely refer to the general statements on page 231, in regard to prophylaxis from the various tubercular diseases.

## CHAPTER IV.

## THROMBOSIS OF THE CEREBRAL SINUSES.

**Ætiology and Pathology.**—The sinuses of the dura mater sometimes present a thrombosis, under circumstances similar to those which induce the same process in other veins. The most frequent occasion for such thrombosis is marasmus, however brought about, with the accompanying feebleness of circulation. This is the explanation of those not very rare cases found among wretched and ill-nourished children in the first year of life, and also among adults in a similar physical condition, as in phthisis. In many of these instances passive congestion also seems to contribute to the formation of the thrombus.

Half way between marantic thrombosis and the inflammatory variety immediately to be described, come those cases which are seen in typhoid fever and other severe acute infectious diseases. Here the specific virus apparently plays an important part (just as in thrombosis of the femoral vein), although very likely the cardiac weakness also promotes the thrombosis.

Genuine inflammatory thrombosis—that is, thrombosis in connection with real phlebitis of the sinus—is almost always due to the extension of inflammation from some neighboring part. The most fruitful cause is suppuration in the petrous bone, the result of otitis or caries. This spreads to the walls of the transverse or petrosal sinuses, which are close by. Also wounds, necrosis, or other affections of other cranial bones may excite thrombosis; likewise, although seldom, deep-seated inflammation of the soft parts of the head and face, like large furuncles or erysipelatous abscesses, may produce the same result.

Thrombosis due to marasmus is most frequently found in the superior longitudinal sinus, while the inflammatory variety usually occupies either the transverse, petrosal, or cavernous sinuses. Of course the thrombus may grow out from its original sinus into neighboring ones. Important clinical symptoms are caused by secondary venous stasis in the veins which empty into the occluded sinus. These symptoms are most pronounced when the longitudinal sinus is affected; objectively, we find the meningeal veins which lie on the surface of the brain distended and tortuous; and often there are extensive meningeal ecchymoses. Even the cerebral parenchyma beneath shows distinct evidence of passive congestion, and minute capillary hæmorrhages have been repeatedly found in it.

**Symptoms.**—In some instances moderate thrombosis of the cerebral sinuses has been found post mortem, although there had been no symptom suggesting it before death. In other cases the thrombosis does excite undeniable cerebral disorder, but the symptoms are so general and ambiguous that the most we can do is to suspect the existence of the clot without being at all certain about it.

Sinus thrombosis in marantic children usually causes coma, stiffness of the neck and back, strabismus, nystagmus, and sometimes clonic spasms in the face and limbs. The symptoms in adults are similar, comprising headache, drowsiness, occasionally delirium, sometimes coma, and varying symptoms of irritation or of paralysis in the distribution of the cranial nerves (nystagmus, strabismus, trismus) and in the extremities. But even all these symptoms are insufficient to make the diagnosis certain. They must be re-enforced by certain other phenomena more distinctly referable to the peculiar circulatory disturbances occasioned by the thrombosis. Occlusion of the cavernous sinus sometimes excites well-marked symptoms of stasis in the ophthalmic veins. Thus the retina may be seen through the ophthalmoscope to be passively congested, there is œdema of eyelids and the conjunctiva, the eyeball is unusually prominent, and the frontal

vein is distended. In case of an inflammatory thrombosis, the periphlebitic swelling may cause symptoms in the distribution of the neighboring nerves, especially paresis of the oculo-motor or abducens, or trigeminal neuralgia. In thrombosis of the transverse sinus an cedematous swelling is occasionally seen behind the ear, near the mastoid process. If the clot projects into the petrosal sinus or even actually into the internal jugular, the lower part of this vein collapses. And inasmuch as the external jugular can empty itself with unusual ease into the unfilled internal jugular vein, the external jugular is also affected and becomes less prominent upon the affected than upon the normal side. Sometimes it is even possible to feel the thrombus in the internal jugular. Such thrombosis causes pain and swelling in the neck on the abnormal side. When the superior longitudinal sinus is blocked up, there are symptoms of nasal engorgement (epistaxis), and distention of the veins about the temples, which veins are connected with the longitudinal sinus by emissary veins. We must confess, however, that all these special symptoms are comparatively rare, and often difficult of demonstration even when present.

The symptoms become more complex where there is a suppurative phlebitis, because there are usually pyæmic symptoms as the disease progresses. Thus, there may be rigors and high fever, pulmonary abscess, suppurative arthritis, etc. We have already mentioned the combination of thrombosis of a sinus with purulent meningitis.

The prognosis is almost always bad, both because of the nature of the causative disease and because of the grave cerebral derangement or the secondary pyæmia. Treatment can be only symptomatic.

## SECTION II.

### *DISEASES OF THE BRAIN-SUBSTANCE.*

#### CHAPTER I.

#### **DISTURBANCES OF CIRCULATION IN THE BRAIN.**

*(Cerebral Hyperæmia. Cerebral Anæmia.)*

It is presumable that so sensitive an organ as the brain is much influenced even by slight disturbances of circulation; but as yet we have comparatively little knowledge of the production and character of such disturbances, their very existence being very difficult to demonstrate. There are many instances where marked cerebral symptoms justify the assumption that the brain is in some abnormal condition, and yet where there are many arguments against any marked anatomical lesion. Here we surmise that there is some circulatory derangement, although we have no actual and direct arguments to rely upon. For example, we refer to this cause certain cases of headache, sensations of pressure in the head, vertigo, general hyperæsthesia, and of that protean and nevertheless easily distinguishable disease known as cerebral neurasthenia (*q. v.*). At present, however, we can not determine how far circulatory disturbances are actually concerned in these cases, or of what kind they are, or whether there may not be purely functional disease of the brain entirely independent of changes in the blood-vessels.

Certain groups of cerebral symptoms, which come on in paroxysms, seem the most clearly referable of all to circulatory disturbance. There can hardly be a

doubt that the phenomenon known as fainting or syncope is due to sudden cerebral anæmia. As is well known, fainting is usually the result of a clearly demonstrable cause. Frequent and familiar causes are emotional excitement, terror, unusual psychical impressions (like the sight of blood), the influence of great heat, or great physical strain, as by long standing. The condition of the stomach has certainly a great influence in many cases. There are many persons who, if they go long beyond the usual time without eating (particularly without breakfast), are very liable to syncope. Some individuals are especially subject to fainting fits. Such persons are often slight and anæmic (for example, convalescents), but some are in appearance robust and vigorous. Many children are subject to fainting.

Just what causes the cerebral anæmia in all these cases is doubtful. Mental excitement is usually supposed to lead, in fainting, to a contraction of the minute cerebral arteries. It is not, however, impossible that in these cases also, as in others, sudden cardiac weakness is one factor, although, if so, it is strange that we never see a trace of cyanosis. Where the attack is apparently connected with unusual conditions of the abdominal organs we are reminded of the relations of the splanchnic nerve to the heart (Goltz's experiment of beating the belly of a frog), and of the possibility that the brain might be left anæmic if the abdominal vessels suddenly dilated and absorbed a large proportion of the whole blood-supply.

The symptoms of an ordinary fainting fit are known to every one. There are usually certain prodromata. The person begins to "feel badly." Dizziness comes on, the senses are confused, the ears ring, there are spots before the eyes or total darkness, the floor seems to move, and surrounding objects begin to spin around. All this is almost always accompanied by nausea, and sometimes there is actual vomiting. If the person can lie down promptly the attack is sometimes averted without complete loss of consciousness. Otherwise there is unconsciousness for a time varying from some minutes to even a half-hour or longer. What the bystander notices most, even at the first, is the pallor which overspreads the face and often becomes extreme, and which is the visible expression of the coincident cerebral anæmia. Very often the face and body are bathed in cold perspiration. The pulse is usually small and rapid.

There is no real danger in an ordinary attack. The most important therapeutic measure is to lay the patient horizontally as soon as possible, to favor the return of blood to the brain. Mild stimulants should also be employed; the face should be sprinkled with cold water, the temples rubbed with vinegar or cologne-water; brandy or wine should be administered. We can overcome a tendency to fainting fits only by strengthening the constitution.

The results of chronic cerebral anæmia are observable when the cerebral condition is part of excessive general anæmia. Almost all cases of chlorosis, pernicious anæmia, and acute anæmia from loss of blood (as in ulcer of the stomach) display most plainly the symptoms of cerebral anæmia. The phenomena are essentially the same as in syncope, only less in degree. Consciousness is maintained, except in the worst cases. A sort of persistent drowsiness, however, often attended by frequent gaping, is one of the most constant symptoms. The patient is most distressed, as a rule, by loud tinnitus aurium, persistent nausea, and sometimes by obstinate headache. All these symptoms are aggravated if the patient sits up in bed, and are least marked when he lies as quietly as possible in a horizontal position. The treatment of this condition is of course identical with that of the causative disease and the general anæmia.

Cerebral hyperæmia, like cerebral anæmia, may be either chronic or paroxysmal. Of the chronic variety we know almost nothing. It seems doubtful, to say the least, whether there is really a "general plethora," or whether the headaches

and vertigo that "full-blooded" persons complain of are due to hyperæmia of the brain. Nor have we any direct proof that the cerebral symptoms resulting from chronic poisoning (alcohol, tobacco), or from persistent mental over-exertion, are brought about by hyperæmia, as some assume, and not rather by functional disorder of the nervous elements themselves.

We have the best reason to claim cerebral hyperæmia as the cause of cerebral symptoms in instances of "cerebral congestion" or "rush of blood to the head." There is a more or less sudden appearance of general excitement, with a sensation of warmth in the head and neck, strong pulsation of the carotids, a red face, general hyperæsthesia and irritability, headache, vertigo, tinnitus, spots before the eyes, and nausea. An attack lasts half an hour to an hour. Apparently there is vaso-motor disturbance, causing a sudden enlargement of the cerebral blood-vessels, and due either to a paralysis of the vaso-constrictors or to a stimulation of the dilators. In severe cases there may be maniacal excitement, or there may be stupor and drowsiness and other symptoms of lowered intellectual activity, resembling a slight apoplectic attack (see a later chapter). In such a case we can not determine whether there is hyperæmia alone, or whether there is not some further lesion, like a small hæmorrhage.

In treating congestion we should keep the patient as quiet as possible, with head and shoulders raised; and, secondly, we should endeavor to draw the blood away from the brain. This purpose will be served by hot foot-baths, sinapisms applied to the chest and the calves, and purgatives, like senna or colocynth. It is also beneficial to apply cold to the head. In a severe case it is proper to put leeches to the temples or the mastoid processes.

To prevent, as far as possible, the recurrence of the attacks, we must have regard to the general constitution of the patient. We may mention, as of chief importance, diet (no alcohol) and a course at some watering-place, or "cold-water treatment."

## CHAPTER II.

### GENERAL PRELIMINARY REMARKS UPON THE LOCALIZATION OF CEREBRAL DISEASES.

*(Topical Diagnosis of Cerebral Lesions.)*

THE physiological relations of the brain are such that the symptoms of cerebral disease are determined to a greater extent by the locality than by the nature of the lesion. If, for example, there arises at any place a break in the continuity of the cerebral motor tract, the result, as we already know (see page 536), is hemiplegia upon the opposite side of the body. The result is precisely the same, whether the interruption is due to a hæmorrhage, an abscess, a new growth, or an embolic softening. If in any way the function of the motor fibers is suspended, then the necessary sequence in every case is a paralysis of definite extent and definite characteristics. Much the same may be said of many other symptoms which appear when there is a lesion of one or more definite places, but which are never referable to a special abnormal process, regardless of the portion of brain thereby affected.

However self-evident these simple statements may appear, it required a long time for them to gain universal acceptance among physicians. The chief cause of this was the conception entertained by the older physiologists in regard to the functions of the brain. Flourens, in 1842, taught that functionally all parts of the cerebrum were alike, and therefore any one part could act vicariously for any

other; and this view had numerous adherents among physicians, as well as physiologists. It was nevertheless experience at the bedside and the autopsy-table which first led to observations and discoveries irreconcilable with this view. Above all, it was the lesions found in aphasia which forced men to localize one cerebral symptom as due to an affection of one particular spot in the brain. In 1861 Broca announced that the appearance of aphasia is always due to a lesion of the third left frontal convolution; and this was the starting-point of the doctrine of localizations in general. Nine years later (1870) appeared the famous treatise of Fritsch and Hitzig detailing successful attempts at irritation of the surface of the brain in animals, and thus overthrowing the old idea that the gray cortical substance could not be irritated. It was shown that irritation of certain places in the cortex is followed by muscular contractions in well-defined portions of the opposite side of the body, so that we are justified in assuming the existence of a number of cortical centers, the boundaries of which are comparatively narrow. These results were soon confirmed by numerous observations in cerebral pathology in man; and to-day our information about the motor functions of the cerebral cortex forms the best-known portion of the doctrine of cerebral localization. Of late years successful work has been done in this exceedingly difficult field by Meynert and Flechsig among anatomists; Ferrier, Munk, Goltz, and other physiologists; and such pathologists as Charcot and his pupils, Nothnagel and Hughlings Jackson. It is true that we are only just beginning to know something about the subject. There are numerous contradictory views asserted, and numerous questions unanswered. The following summary, therefore, is to be regarded merely as expressing the prevailing opinions now existing. Much in it will surely be altered in the course of time; but still this doctrine of special localization of the various cerebral functions marks out in general outlines the only foundation upon which we can hope to erect a system of cerebral pathology and diagnosis. In the following sketch we shall, for practical reasons, put the results of clinical observations in the foreground, and merely speak incidentally of the corresponding experimental achievements. This will be the quickest way to gain acquaintance with the practical points in the diagnosis of what Griesinger called the "focal diseases"; and then, when we take up the separate varieties of cerebral disease, we shall have these general remarks to refer to.

#### 1. THE MOTOR REGION OF THE CORTEX CEREBRI.

Clinical observation and the results of experiment both teach that a part of the cerebral cortex is distinct from the rest, inasmuch as it is the exclusive seat of motor functions. This "motor region" (*vide* Figs. 102 and 103, page 713) is made up of the two central convolutions (*gyri centrales anterior et posterior*, in Fig. 101), and the paracentral lobule (*vide* Fig. 103), which lies on the median surface of the cerebrum. It is also anatomically different from the other regions of the cortex, as Betz was the first to point out, for it alone possesses certain large pyramidal ganglion-cells, which are in all likelihood motor. However extensive the destructive processes which attack other parts of the surface of the brain, provided they do not involve these particular convolutions, they cause no paralytic symptoms; while all diseases which destroy any considerable portion of the "motor" region inevitably result in a paralysis on the opposite side of the body.

We can differentiate still further. There are separate regions which act as special centers for the various groups of muscles. The center for the movements of the facial muscles (lower division of the facial nerve) lies, as it would seem, at the lower end of the central convolutions, and particularly of the anterior central convolution. Near by, apparently still lower, is found the center for the movements of the tongue. The center for the movements of the arm lies somewhat

higher than the center for the facial, occupying roughly the middle portion of the anterior central convolution. The center for the lower extremity is found partly in the uppermost portions of the central convolutions, but apparently lies for the most part in the paracentral lobule. Any minuter division is not yet possible.

There are already quite a large number of cases of hemiplegia known which were caused by some disease in the motor region, like a tumor or spot of softening. We should add, in regard to the pathological anatomy of these cases, that they all, without exception, presented a secondary descending degeneration of the pyramidal tract (compare page 680), extending through the internal capsule, crus cerebri, and medulla into the corresponding lateral and anterior columns [that is, on the same side in the anterior columns and on the opposite side in the lateral]. The hemiplegia due to cortical lesion does not differ from that due to focal disease lower down in the motor tract (compare page 536) in its clinical aspects. We shall consider the symptoms more particularly in the chapter on cerebral hæmorrhage.

FIG. 101.—Lateral aspect of the brain (from ECKER). The gyri and lobules are in Roman type, the sulci and fissures in Italian.

It is nevertheless possible in many instances to decide that the disease involves the motor portion of the cortex of the brain. This is due to the following peculiarities:

In the first place, we have already remarked (page 536) that the relative positions of the motor centers for the face, arm, and leg are such as to allow readily of isolated paralysis of any one of these portions of the body—that is, "monoplegia." In fact, we already possess a long series of observations where circumscribed lesions in the motor area of the cortex produced paralysis of one side of the face, or of one arm or leg, and of no other part. Such paralysis is termed monoplegia of the face, or the arm, or the lower extremity. And it follows, from what has been said, that even during life we can state, with considerable accuracy, the spot on the surface of the brain where the disease must be situated. Still more frequently, a combined paralysis of two portions of the body is to be observed as a result of cortical lesion; the commonest is a simultaneous paralysis of the arm

and face; more rarely we see the arm and leg paralyzed together. On the other hand, we may feel certain, from the position of the motor centers, that no single center of disease could paralyze simultaneously the leg and the face, while the arm escaped injury. As a matter of fact, no such combination has ever been observed.

FIG. 102.—Lateral aspect of the brain (after Ecker). The motor region of the cortex, consisting of the anterior and posterior central convolutions, as well as of the paracentral lobule shown in Fig. 103, is shaded.

FIG. 103.—Aspect of the median surface of the cerebrum, which is shown when the two hemispheres are separated from each other by a sagittal section. B. Corpus callosum. The differences in the type have the same meaning as in Fig. 101. The paracentral lobule, as a part of the motor region of the cortex, is shaded. (Copied from Ecker, only the paracentral lobule is made more sharply prominent than in the original).

Beside this limitation of the paralysis just discussed, localized disease of the cortex has another characteristic. In it the symptoms of irritation of the motor

centers are noticeably frequent. There are tonic and clonic spasms, which, like the paralysis, not infrequently affect a single arm, or an arm combined with half the face. Sometimes, however, they involve the entire half of the body. These paroxysmal spasms are termed "cortical epilepsy," or partial epilepsy, or Jacksonian epilepsy; for the movements are just the same as in genuine epilepsy. Numerous cases of disease have taught us that these circumscribed epileptiform attacks occur almost exclusively in affections of the motor cortex. They furnish information as to the precise locality of the lesion; for spasms in the distribution of the facial nerve imply that mainly the lower third of the central convolutions is affected; of the arm, the middle third; and of the lower extremity, the upper portions of the same. At the same time, the spasms and the paralysis vary greatly in their relations to each other. Often, for example, when there is hæmorrhage into the central convolutions, violent unilateral convulsions come

FIG. 104.—(Drawn according to ECKER.) Explanation of the topographical relations between the surface of the brain and the skull. *c*, Fissure of Rolando. *HC* and *FC*, Posterior and anterior central convolutions. *S*, *Sl* and *Sn*, Fissure of Sylvius. *P1*, *P2*, Upper and lower parietal lobes. *O*, Occipital lobe. *Cb*, Cerebellum. *T*, Temporal lobe. *F*, Frontal lobe.

on simultaneously with the paralysis. In the case of tumors and other lesions which develop slowly, partial epileptiform spasms will often appear quite a long while before there are symptoms of paralysis. Finally, it is not rare for epileptiform attacks to occur repeatedly in regions that are already paralytic. Either of the occurrences described in the two preceding sentences are particularly strong evidence that the cortex cerebri is diseased. Beside the pronounced epileptic attacks, disease of the motor region of the cortex may give rise to less violent symptoms of motor irritation, like occasional twitching, rhythmical twitching, and tonic contraction.

About the condition of sensation when there is cortical paralysis we know as yet too little. The late experimental researches of Munk have led to the conclusion that, in animals, the so-called "sphere of sensation" lies in the same region as the motor centers of the cortex. We might, therefore, be somewhat inclined to presuppose that a disturbance of sensation would invariably accompany cortical paralysis in man also, but about this point clinical observations do not yet give perfectly harmonious results. In many cases sensation is undoubtedly normal,

while in others simultaneous disturbances of sensation have been clearly demonstrated. Of especial interest is the well-attested fact that the muscular sense may be diminished in the extremities involved—that is, the patient can not tell, with eyes closed, the position of the affected limbs.

## 2. THE OTHER PARTS OF THE CORTEX CEREBRI, EXCEPT THE CENTER FOR SPEECH.

1. *Frontal Convolutions*.—Unilateral disease of the anterior portion of the brain may be quite extensive without causing notable disturbance of any kind. Certainly the upper two frontal convolutions have no motor functions. It is, however, maintained that the portion contiguous to the anterior central convolution, called the foot of the frontal convolutions, does contain motor centers; but even about this doubt has lately arisen. The third (lowest) frontal convolution on the left side has, as we shall soon see, an undoubted connection with the motor processes of speech.

There is a quite generally accepted view that the cortex of the frontal portion of the brain is to be regarded as the "seat of the higher psychological functions." Some few cases are on record where extensive bilateral lesions of these parts had for their only symptoms mental disturbances. In general paralysis also, and in other forms of dementia, it is very probable that the atrophy is greatest in the anterior part of the cerebrum. Nevertheless, we can not emphasize too much the fact that, at present, we have no certain knowledge about the minute relations of the psychological functions to the different sections of the brain.

2. *Parietal Convolutions*.—We know practically nothing about the functions of the cortex of the parietal lobe, and the symptoms which might imply disease of that portion of the cerebrum. The results of clinical observations thus far made with these points in view are quite contradictory. In regard to the motor functions of the parietal region, apart from the posterior central gyrus, we know only that in the supra-marginal and angular gyri seem to lie the centers for associated conjugate movements of the eyes. In the angular gyrus is perhaps also a center for the ocular portion of the facial nerve, orbicularis oculi, and levator palpebræ superioris. The parietal lobe seems to have important relations to sensibility. According to Flechsig, most of the sensory fibers of the tegmentum seem to have their central termination here. Disturbances of the muscular sense seem to be especially common with lesions in the parietal region.

3. *Occipital Convolutions*.—The clinical and experimental investigations of the last few years have all shown that the occipital portion of the cerebrum contains the cortical center for visual sensations. It is here, in all probability, that the fibers of the optic nerve terminate in the cortex cerebri. A glance at the following diagram (Fig. 105) will make it easy to understand the disturbances of vision which result from lesions of the occipital lobe. *L* represents the left eye and *R* the right, *Ch* the optic chiasma, where, as is now certain, some of the fibers of the optic nerves cross to the opposite side. The fibers (distinguished by a broken line) from the outer or temporal half of each retina extend, without crossing, into the corresponding optic tract (*Tract. opt.*), while those from the inner or nasal half of the retina cross over in the chiasma. The right occipital lobe, for example, comes in this way to receive the fibers from the outer half of the right retina and from the inner half of the left. If the right occipital lobe becomes disorganized, then the images formed upon the parts of the retina just named, belonging to the left half of the field of vision, are unperceived. With each eye the patient sees only such objects as lie in the right half of his field of vision, and is blind to all that lies upon his left. This sort of visual disturbance, where each

eye becomes blind to the same "homonymous" portions of the field of vision, is termed hemianopsia, or hemiopia.

A lesion of the right occipital lobe causes, therefore, left-sided hemiopia, and, *vice versa*, destruction of the left occipital lobe entails right-sided hemiopia.

FIG. 105.—Diagram of the course of the optic fibers in the chiasma.

It may also be well to mention briefly another peculiar disturbance of vision which is perhaps due to a lesion of the occipital cortex. Fürstner noticed certain phenomena in the insane, which implied that the patient, although he could see, and could not therefore properly be called blind, yet did not recognize the objects—that is, was no longer able to interpret the meaning of the visual image. Munk has given to this condition the name of "soul blindness," conceiving it to be a "loss of visual memory." Soul blindness seems to occur chiefly in superficial lesions in the occipital region, while the special visual center itself seems

to lie chiefly in the cuneus and the first occipital convolution.

4. *Temporal Convolutions*.—The relation of the temporal lobe to hearing is apparently analogous with that of the occipital to vision. Whether extensive disorganization of the temporal lobe, or of the fibers that enter it, can produce actual deafness of the opposite ear, has not yet been proven, inasmuch as very few cases have yet been studied. It may, however, be regarded as extremely probable that a lesion of the first, or uppermost, temporal convolution occasions that peculiar phenomenon known as "word deafness" or "soul deafness," with which we are at once to become more intimately acquainted.

### 3. THE CENTERS OF SPEECH AND THE DISTURBANCES OF SPEECH.

(Aphasia and Allied Conditions.)

**The Various Forms of Aphasia, and their Anatomical Localization.**—As we remarked at the very beginning of this chapter, the peculiar derangements of speech observed in many cerebral diseases were the first symptoms which were found to be caused by a distinctly localized cerebral lesion. For the better understanding of this extremely interesting subject, it is necessary that we should enter somewhat minutely into the processes connected with normal speech.

Incitement to speech—that is, to the oral expression of our thoughts to others—comes either from an internal impulse or from external causes which excite this impulse. Speech always requires internal mental activities—the presence of ideas and their transformation into that which we wish to communicate by speech. Where there are no conceptions there can be no words. The idiot is silent, because, like the newborn infant or the brute, he has nothing to say; but, on the other hand, the impulse to speak must also be present. In melancholic insanity we sometimes observe persistent loss of speech, not from any lack of something to say, but because there is no incitement to the act, or because inhibitory influences immediately repress any tendency to utter words. If we take for granted that the mental material for speech exists, then the transformation of this material into actual speech is a result of the following complicated processes, the disturbance of which, individually, produces the various forms of aphasia.

In the first place, the speaker must be acquainted with the word which ex-

presses the mental conception. If, for instance, he wishes to tell another the name of some animal, he must know the appropriate word—"dog," "sparrow," "frog." This knowledge, which, as far as our mother tongue is concerned, we all acquired in childhood, may, as experience shows, be lost again in case of cerebral disease. Just as we may ourselves forget a word momentarily, or as any healthy person may, at the sight of an animal that is perhaps rather rare, be "unable at the minute to think of its name," so in disease one may forget all or a greater or less number of words. Such a patient sees a dog, and knows well enough that it is an animal possessed of such and such qualities, but he has forgotten its name. The association between the conception "dog," and likewise between the perception of a dog by the eye, and the appropriate vocal representation "dog," is lost. This condition is termed amnesic aphasia, because it is due to complete or partial loss of the memory for words. The patient knows perfectly well what he wishes to say, but the words escape him. At the same time, in cases of pure amnesic aphasia, the power of repetition is unimpaired. As soon as we say "dog" to the patient, he repeats the word perfectly well; and sometimes he also perceives that this is really the correct word; but in other instances, although the word is correctly repeated, the patient does not become conscious of its meaning (*vide infra* "word deafness").

Of great interest are certain cases where there is only partial amnesia. These have been repeatedly observed. Thus a patient forgot nothing but his own name, remembering all other words perfectly; or the loss of words may be confined to but one language, the patient being still able to express himself tolerably well in another tongue. In a case observed by Graves, the patient still knew the initial letter of all words; if, for example, he saw a cow, he would know that the corresponding word began with C, and would look under C in a dictionary till he found the word.

If the memory for words be retained, the next requisite for speaking is the transfer of the word image into such action of the muscles of our organs of speech as is calculated to produce the word in question as an actual sound. This motor process is so complicated that an extremely accurate co-ordination of movements is demanded for the correct pronunciation of the word. Man therefore possesses a separate center, in which this transfer of the word image into the motor processes of speech takes place. If this center be diseased, there again results a loss, or at least a greater or less impairment, of speech. The patient is in this case well aware of the word he wishes to say, but he can not pronounce it. He has, if we may use the expression, forgotten the movements that are essential to speaking. His tongue and lips are not really paralyzed, but the patient no longer knows how to make use of them for talking. He has reverted to the condition of childhood, before he had learned to talk. The patient often makes the greatest effort to speak. The word he wishes to utter "keeps hovering before him"; he moves his mouth in the most striking manner, but brings out only an occasional sound, and that incorrect. This form is known as ataxic aphasia. Of course it is equally impossible for the patient to repeat a word after some one else. He keeps his eyes fixed on the mouth of the speaker, and endeavors to imitate the motions of his mouth, but he is either partially or totally unable to reproduce the sound.

Ataxic aphasia exhibits many degrees of intensity. On the one hand there are cases of complete aphasia, where the patient can utter only such separate sounds as "a," "e," etc. And, on the other hand, there are also very mild cases where there are merely slight errors in pronunciation. The patient pronounces many words correctly, but with others there are such mistakes as the transposition of individual letters, the misplacement or omission of letters, or, finally, the adding on of letters. For example, he will say thens instead of then, widow instead of

window, dipter instead of dipper, hefd instead of held, wrelster instead of wrestler, and belnow instead of below. This mildest form of ataxic disturbance is termed "stumbling over syllables" (*Silberstolpern*), or "literal ataxia." In most instances the patient can pronounce some words tolerably well, others only imperfectly and with difficulty, and still others not at all. Usually the patient gradually learns a few common words and expressions (e. g., "good morning") by means of persistence in repeating them as they are uttered by another, so that he pronounces them better and better. What is very remarkable, and not so very rare, is that a patient will be able when in a passion to pronounce a word, such as an oath or an exclamation, perfectly well, because it is done to a certain extent involuntarily, while he can not utter the same words if he wishes to say them. Association also often exerts an appreciable influence; for example, a patient who finds it absolutely impossible to pronounce "six," utters it with perfect distinctness if he begins to count from one, in the ordinary way, up to six. There are many facts connected with this subject which can not here be discussed. Each case demands separate and earnest study, and will usually be found to present an abundance of interesting peculiarities.

Allied to ataxic aphasia are two other disturbances of speech, known as monophasia and paraphasia. Monophasia is very rare; in it the patient has command of but one single syllable, or a single short phrase, and this is pronounced whenever he attempts to talk. A patient of our own could for a long while utter nothing but meaningless words, "*selber sag ich nümlich selber*" (self say I namely self). The entire verbal thesaurus of another (female) patient whom we saw consisted of the meaningless sounds "bibi" and "eibibi." Still a third could say only "tinne, tinne." The patient is quite well aware that what he says is wrong, but, despite all his efforts, every attempt to speak excites these same sounds. It produces a comical impression to see the patient use the same invariable word, with all sorts of facial expression. Thus the woman mentioned above begged for things, with "bibi," in a coaxing tone, while sometimes she would give vent to violent anger with a loud "bibibibi."

Paraphasia is a confounding together of words. The association between the idea and the corresponding word is broken up, and instead other words come to the tongue. Some of these are proper words enough, but others are quite meaningless. Such a patient may talk a long while without conveying any idea to the listener, inasmuch as he says "brush" instead of "bed," or "gove" instead of "give," etc. It is a very interesting fact that in paraphasia the influence of certain associations are often manifest. The patient, for instance, utters a wrong word which has a certain resemblance in sound to the right one, begins with the same syllable, etc. Purely ideal associations sometimes also play a part; thus one of our patients called a white handkerchief "snow," etc.

As has been already shown, in amnesic aphasia the connection between the word and the conception it represents is so imperfect that the rising up to consciousness of the idea fails to call up the corresponding word. Now, on the other hand, the opposite may occur; the word, when it is heard, may fail to call up the appropriate mental image. Kussmaul has given this condition the name of word deafness (Wernicke's sensory aphasia). The patient is not really deaf, for he hears everything, but he no longer understands what he hears, and he has forgotten what the words signify. The vernacular sounds to him as a foreign tongue would to a healthy but unlearned man. A moderate amount of word deafness is very frequent in aphasia, particularly in the amnesic variety; but this last, and word dumbness, are not identical. A person may forget the word corresponding to some idea and yet understand the meaning of that word perfectly when he hears it. It is an easy matter to prove whether word dumbness exists or not by asking the

patient to do something—for example, to touch certain parts of his body, or to perform certain motions (without, however, making any explanatory gestures ourselves), and seeing whether he understands and complies. Of course, the demonstration of word deafness can usually be made with regard to the names of concrete things only, and certain verbs and adjectives, but is hardly practicable in other cases (for example, with abstract words and adverbs), particularly if there be aphasia at the same time.

These various forms of aphasia, just described, seldom occur singly and unmixed. They are usually found in combinations, which vary greatly, so that a complete idea of the derangement existing in any case can be obtained only by careful examination and continued observation of the patient. Granting, however, that the variety of aphasia has been determined, what light will this throw upon the localization of the cerebral disease?

As early as 1825 Bouillaud affirmed that disease of the anterior lobes of the brain is alone capable of producing disturbances of speech. In 1836 another French physician, Marc Dax, pointed out for the first time that only lesions of the left half of the brain cause aphasia; and in 1861 Broca was able, as already stated, at last to declare that the "center for speech" lies in the third left frontal convolution. This statement has since been confirmed innumerable times, although it must be added that disease here is a cause of ataxic or motor aphasia alone. Still more accurately, it is the posterior portion of the third left frontal convolution, the pars opercularis, so called, which gives rise to this symptom. It is in this region, therefore, that those complicated processes of motor co-ordination which are essential to the utterance of a word take place. Word deafness, on the other hand, according to all the newer observations of Wernicke, Kahler, and Pick, seems invariably to be referable to disease of the first or uppermost left temporal convolution. Probably the same is true of amnesic aphasia. It is apparently, then, this region which is essential to the normal association between the auditory image of the words we hear and the appropriate mental conceptions. Any minuter localization of these and the remaining forms of disturbance of speech is at present impossible. It is probable, though not certain, that the left island of Reil also has some connection with aphasic disorders. However this may be, the corresponding portions of the right hemisphere are not usually connected with this sort of disturbance—a fact perhaps analogous with the predominant use of the right hand; that is, of the left cerebral hemisphere. It is only in a few exceptional cases—for example, of left-handed persons, or of such as present congenital defects in the left half of the brain—that observers have noticed aphasia in connection with disease of the corresponding frontal and temporal convolutions of the right side.

The diagnosis of aphasia in general is an easy matter if we stick closely to the true conception of aphasia. The examination would have to be a superficial one to lead to confounding it with bulbar symptoms such as dysarthria (*vide supra*, page 685), or with the disturbances of speech which result from other lesions which entail paresis or paralysis of the hypoglossus or certain fibers of the facial.

No general rules can be laid down as to the prognosis and treatment of aphasia, inasmuch as everything must of course depend upon the nature of the disease which excites this symptom. We will merely emphasize here the therapeutic fact that methodical exercises in speaking and in language may be decidedly beneficial. In ataxic aphasia such instruction may be imparted in about the same way as to the deaf and dumb, sight and touch being invoked to aid in a fresh training of the appropriate muscles. In amnesic aphasia the memory must be trained, that the forgotten words may once more be "stamped" upon it. Of course, all such efforts demand great tact and patience, and accomplish little unless they are methodical and persistent.

**Disturbances Allied to Aphasia: Agraphia, Alexia, Amimia, and Apraxia.**

Aphasia is very often accompanied by a group of other symptoms, which are likewise due to disturbance of the processes of association. Besides the language of words we possess two other means of expression—writing and gesticulation. Our mental concepts are associated not only with certain sounds but also with certain visible forms, so that, on the one hand, we use them to impart our thoughts to others, and, on the other, by their aid we learn the thoughts of other people. In aphasia this capability also is often more or less lost. If it be impossible for the patient to make himself understood by means of words, and we give him a pen, that he may write down his wishes, it is often found that this, too, is out of the question. The patient tries to write, and may indeed set down one or two words, or one or two letters, but he is no longer capable of writing a single sentence, or perhaps even a single word, correctly. This is termed "agraphia." Probably, in most instances, the agraphia is amnesic. The patient has forgotten the written characters. Usually, although not in every case, he can copy correctly what another has written. When the patient writes a wrong word in place of the right one, we call it paraphasia. Here, too, processes of mental association become manifest as in paraphasia (*vide supra*). With the disturbance in writing is often associated alexia; the patient can not read any better than he can write—that is, the characters which he sees fail now to call up the associated mental conception. Alexia is not inseparably connected with word deafness. It is possible for a patient not to understand a spoken word, and yet to recognize it at once if written.

The aphasic are also quite often unable to express themselves by pantomime or "dumb show." Frequently the patient makes no effort whatever of this kind, or what signs he does make are evidently wrong and misleading. We have repeatedly seen an aphasic patient nod his head, when it was plain that he meant to say No, and *vice versa*.

Finally, there is apraxia, a disturbance which, to be sure, is often associated with aphasia, but implies more extensive lesions. The essential point in apraxia is that the patient has more or less completely forgotten what the different objects about him really are. The condition must be closely allied to that in so-called "soul blindness." The patient sees the objects, but fails to recognize them for what they are. He takes a knife for a spoon, the washbowl for the chamber-pot, the soap for a piece of bread, and acts accordingly!

A definite anatomical localization of all these disorders which have just been briefly alluded to can not at present be given. Alexia, and still more apraxia, suggest lesion of those tracts which are connected with, or situated in, the posterior part of the cerebrum, the region of memory for visible objects.

#### 4. THE CENTRUM OVALE, INTERNAL CAPSULE, CENTRAL GANGLIA, AND REGION OF THE CORPORA QUADRIGEMINA.

**Centrum Ovale.**—The white substance of the hemispheres is made up, so far as we know at present, both of commissural fibers, which connect the various cortical centers together, and of fibers which proceed downward from the centers of the cortex and connect these centers with peripheral parts of the body (corona radiata). As to the symptoms caused by diseases which destroy the commissural fibers, there is hardly anything known. We can only surmise that in case of disturbances of association, such as we have studied under aphasia and kindred disorders, there may sometimes be a lesion of commissural fibers, as of those connecting together the temporal and frontal lobes. A break in the continuity of the fibers of the corona radiata must of course result in the same symptoms as if

the corresponding center were itself destroyed. This explains why circumscribed lesions of the centrum ovale, if they involve the motor fibers of the corona radiata, which proceed from the central convolutions (and only if they do this), cause hemiplegia, or, if very limited, monoplegia. In an analogous manner, disease of the white substance of the occipital lobe may entail hemiopia; of the temporal lobe, auditory disturbances, such as word deafness. More than once, quite extensive disease of the white substance of the frontal lobe on one side has been discovered post mortem, although no symptoms whatever had been caused by it. Only when the coronal fibers which proceed from the third left frontal convolution are involved in disease is motor or ataxic aphasia inevitable.

**Internal Capsule.**—The most important facts relating to the functions of the internal capsule, as far as at present known, have been already stated. In particular, it was pointed out that through the posterior limb of the internal capsule, in a comparatively narrow space, passes the pyramidal tract on its way from the central convolutions to the crura cerebri (see Fig. 64, page 534). Here, then, even a very limited focal disease must lead to complete hemiplegia on the opposite side of the body. Clinical experience also shows that the largest number of cases of persistent hemiplegia are occasioned by disease in this spot. In these cases the facial nerve is usually also involved, although its fibers apparently lie somewhat further forward than the tracts which are destined for the extremities.

The sensory tract (compare page 511, and Fig. 64, page 534) lies at the posterior extremity of the internal capsule, and apparently includes not only the fibers for cutaneous sensation, but also for the organs of special sense. Complete disorganization of this spot ought therefore to cause, in the opposite half of the body, not only anaesthesia of the skin, but also simultaneously a corresponding impairment of smell, taste, and hearing, and hemiopia—in short, a so-called complete cerebral hemianæsthesia. Still, in regard to this very point we are much in need of further and definite observations. Charcot's statement that in these cases the disturbance of vision is not hemiopia, but total amblyopia of the eye opposite to the focal lesion, has caused great confusion, for such a fact would of course be hard to reconcile with the appearance of hemiopia in diseases of the occipital lobe, although this latter occurrence is well established. However, this statement of Charcot's is by no means absolutely proven, so that meanwhile we are at liberty to maintain the view that the visual disturbance in cerebral hemianæsthesia may be hemiopia.

Certain practical conclusions in regard to diagnosis can be deduced from the preceding facts. A purely motor hemiplegia, unattended by impairment of sensation, implies a lesion that does not involve the posterior portion of the internal capsule; but probably this portion is also affected, when there is not only paralysis, but considerable sensory disturbance. The sensory disturbance does not invariably extend to all the senses; quite often there is nothing but cutaneous anaesthesia.

About the importance of the other parts of the internal capsule, not mentioned here, nothing is known. A statement made by Charcot should be added in conclusion—namely, that when there are also post-hemiplegic symptoms of irritation, such as post-hemiplegic chorea, there is very probably a lesion of the posterior extremity of the internal capsule.

**Central Ganglia; Caudate Nucleus (Corpus Striatum proper), Lenticular Nucleus, and Optic Thalamus.**—Before the course of the pyramidal tract had been accurately determined, ordinary cases of cerebral hemiplegia were almost universally ascribed to lesions of the central ganglia, and in particular of the caudate and lenticular nuclei. At present, however, observations seem to force one to the conclusion that a complete hemiplegia can be produced only by a cutting off of

the pyramidal tract. There are, indeed, numerous cases of hemiplegia presenting circumscribed disease of the central ganglia; but they can probably all be explained by supposing either that the pyramidal tract, as it lies in the contiguous internal capsule, is directly involved in the disease, or that its functions are suspended by the indirect effects of the neighboring lesion—for instance, by the pressure it exercises. Accordingly, we find that circumscribed lesions of the central ganglia in the neighborhood of the internal capsule generally produce a temporary hemiplegia—that is, the paralysis gradually improves as the indirect influence of the focal disease upon the internal capsule ceases. Chronic and incurable hemiplegia, however, if due to a lesion anywhere in this region, always implies an actual lesion of the pyramidal tract in the internal capsule. In regard to hemianæsthesia, also, the facts seem to be quite analogous. It was formerly held that this phenomenon was especially connected with a lesion of the optic thalamus, the reason being that the sensitive fibers lie so close to the thalamus in the posterior extremity of the internal capsule that they become themselves involved.

About the symptoms which lesions of the central ganglia directly produce little is definitely known. The results of both clinical observation and experiment are quite contradictory, and in repeated instances quite extensive disorganization of these parts has existed without producing any symptoms to speak of during life. In particular, it should be borne in mind that softening may occur in the lenticular and caudate nuclei, and yet not a trace of hemiplegia be observable. It seems probable also that the optic thalamus has nothing to do with voluntary motion; but it seems to have some importance for movements of mimetic expression (Beecherew, Nothnagel). In hemiplegics we sometimes see that one half of the face can not be moved voluntarily, but it is moved very actively in emotional expression, such as laughing or crying. In such cases we can decide that the thalamus is intact, while in lesion of the thalamus the contrary is observed—the affected half of the face can be moved voluntarily, but it remains completely rigid in emotional expression. As to perceptive functions, there is only one which the optic thalamus is certainly known to possess: the central termination of some fibers of the optic nerve lies in its posterior portion (known as the posterior tubercle or pulvinar), while other fibers go to the corpus geniculatum externum. Destruction of the hinder part of the thalamus accordingly produces complete hemiopia (*vide* page 716) of the opposite side. It has been affirmed that the optic thalamus has connections with other sensory tracts, but definite proof is lacking. Focal disease of the thalamus has repeatedly occasioned “post-hemiplegic chorea” and other post-hemiplegic symptoms of irritation. According to recent experiments, the lenticular nucleus contains centers for regulating heat.

**Corpora Quadrigemina and Crura Cerebri.**—Diseases of the corpora quadrigemina are infrequent, and usually, when they do occur, they are merely a part of more extensive lesions of the brain. They are therefore very rarely considered from a diagnostic point of view.

The anterior tubercles are certainly connected with the fibers of the optic nerve. If both of the anterior tubercles be destroyed, total blindness is inevitable, while if only one be disorganized, hemiopia is to be anticipated. Still, these symptoms are, of course, too ambiguous ever to be regarded as pathognomonic of localized disease of the anterior corpora quadrigemina. Another point to be considered, whenever the corpora quadrigemina are diseased, is the position of the nuclei of the nerves which preside over the motions of the eyeball, and in particular of the oculomotor nerve. This explains why unilateral, or even bilateral, paralysis of the oculomotorius has been repeatedly observed in connection with lesions of the corpora quadrigemina, as have also nystagmus and immobility of the pupil.

[Nothnagel considers that a staggering gait, resembling that of a drunken man, associated with oculomotor paralysis, if associated with general symptoms of tumor, is strongly indicative of tumor of the corpora quadrigemina. The eye paralysis must, however, be an early symptom in order to be of value. The paralysis in such cases is apt to be of irregular distribution, often involving upward and downward movements of the eye.—K.]

Should the crura cerebri become involved in the disease, the resulting symptoms are often very characteristic of the locality affected; there is paralysis of one side of the body (arm, leg, facial nerve), and at the same time a crossed paralysis (that is, one situated upon the opposite side) of the motor oculi. A glance at Fig. 65 (page 535) will explain this phenomenon. Thus, a circumscribed lesion on the right side would destroy the fibers of the third nerve on that side, and therefore produce a right-sided paralysis of the oculomotor nerves, and at the same time, if extensive enough, the lesion would involve the pyramidal fibers of the right crus, and thus occasion left hemiplegia. That disease of the tegmentum would necessarily entail sensory disturbances may be taken for granted, although there is as yet very little clinical proof of it.

##### 5. THE CEREBELLUM.

Quite extensive destruction of the cerebellum may take place without any symptoms to indicate it. In such cases, however, the disease is almost invariably confined to the hemispheres; but, if the central portion or vermiform appendix be attacked to any great extent, peculiar symptoms almost always result, pointing in many instances with considerable certainty to disease of the cerebellum.

There are two especially characteristic symptoms—a peculiar uncertainty of gait (cerebellar ataxia), and troublesome vertigo.

Cerebellar ataxia affects only the trunk and lower extremities. Both standing and locomotion are interfered with. When the patient is lying in bed he can move his legs almost as well as ever, and with normal vigor; but as soon as he gets up, the characteristic motor disturbances become very evident. Even while standing still the whole body can usually be plainly seen to sway back and forth. This becomes more marked if the patient bring his heels together. If he stand with his legs widely apart, the trouble is less noticeable. Closing the eyes, as a rule, does not aggravate the swaying, inasmuch as the cutaneous and muscular sensibility of the lower limbs remains normal in uncomplicated cerebellar disease. When the patient tries to walk, he sways and totters, precisely as if he were deeply intoxicated, but usually in a very different way from that seen in *tabes dorsalis*. Instead of the uniform stamping and pitching gait of the latter, cerebellar ataxia causes a real staggering of the whole body, so that in severe cases the patient loses entirely the ability to walk straight, but seems to fall forward, as it were, in a zig-zag line, now to the right and now to the left. Sometimes, but by no means invariably, it is noticed that, in walking, the body sways principally in one particular direction, either forward or backward, or to one side. Such peculiarities, however, do not enable us, with our present knowledge, to determine with certainty just what position in the cerebellum the lesion occupies. The most we can do is to surmise, in such a case, that the middle peduncles of the cerebellum (*vide infra*) are involved. It is worthy of note that, with few exceptions, the ataxia does not involve the upper extremities. Many a patient who can scarcely walk unaided is still able to perform the most delicate manipulations with his hands. This shows that it is only in maintaining the bodily equilibrium—essential to standing and locomotion—that the function of the cerebellum is important.

As already stated, this cerebellar ataxia is in most cases attended with pro-

nounced vertigo. There is not, however, a complete correspondence between the locomotor disturbance and the dizziness. Exceptionally one symptom may be present without the other. The vertigo is usually felt only when the patient stands or moves about, being almost always absent when he lies quietly in bed. We are as yet ignorant just how it is produced. Vertigo is quite frequently produced by other cerebral diseases. It can not, therefore, be regarded as indicating disease of the cerebellum unless it is very persistent and decided, and is associated with the characteristic cerebellar gait.

Little is known about other symptoms of disease in the cerebellum. There may be some diagnostic value in persistent occipital headache, particularly if other cerebellar symptoms be present. If they do not exist, the headache is too ambiguous to be of much value; and, besides, an affection of the cerebellum may exceptionally be attended by pain in the side of the head or in the forehead. Vomiting is of still less value. It is, to be sure, frequently occasioned by chronic disorders of the cerebellum, and by tumors in particular, but may be equally well the result of disease elsewhere. Tumors of the cerebellum are very apt to cause disturbances of vision; but it is certain that these are not a direct result of the cerebellar lesion, but are occasioned by the development of a choked disk (*vide* chapter on cerebral tumors).

We must add in conclusion a few words about diseases of the middle peduncles (*crura ad pontem*). Usually it is an irritation of these which causes those peculiar symptoms known as forced movements and forced positions. Thus, in such a case, the patient always lies upon one particular side in bed. He may be quite conscious, or in a state of complete unconsciousness. If he is put in any other posture, he at once involuntarily reassumes his former position. Not infrequently this forced position of the trunk is accompanied by a corresponding forced position of the head and eyeballs, while the extremities are seldom affected. Genuine forced movements are seen far less often. They produce either often-repeated rotations of the body on its longitudinal axis, or, if the patient be able to walk at all, involuntary circular movements ("circus movements"), etc. It is not possible, even by minute analysis of these symptoms, to determine in which of the two peduncles the source of irritation exists. In a few very rare cases of brain disease these same symptoms have been observed, although no affection of the middle peduncles of the cerebellum could afterward be detected.

---

For convenient reference we subjoin a summary of the most important facts bearing upon the localization of cerebral diseases.

1. The most frequent cause of ordinary hemiplegia is a lesion of the pyramidal tract in the posterior limb of the internal capsule. If the hemiplegia be persistent, then this tract is actually destroyed; if temporary, the tract has been functionally deranged for a time by focal disease in neighboring parts of the brain.

2. Monoplegic cerebral paralysis is usually due to affections of the cortex of the brain, that is, the central convolutions and the paracentral lobule. Monoplegia of the face and tongue is the result of lesions in the lower extremity of the anterior central convolution. Monoplegia of the arm is referable principally to some lesion of the middle third of the anterior central convolution. Monoplegia of the lower extremity implies some affection of the paracentral lobule.

3. Hemiplegia or monoplegia, if associated with epileptiform convulsions affecting either one half or one particular portion of the body, are almost always caused by cortical lesions. These same symptoms of motor irritation without accompanying paralysis are likewise ascribable to some irritation of the above-mentioned regions of the cortex.

4. Hemiplegia with crossed paralysis of the oculomotor nerve indicates a lesion of the crura cerebri.

5. Hemiplegia with crossed facial paralysis implies, with an approach to certainty, that the lesion is situated in the pons.

6. Post-hemiplegic chorea (*vide infra*) seems to occur especially when there is focal disease in the neighborhood of the optic thalamus or of the posterior part of the internal capsule.

7. Hemianæsthesia (of the skin and of the organs of special sense) seems to result principally from lesions of the most posterior portion of the internal capsule.

8. Hemipopia may be due to a lesion of the occipital lobe. Probably, also, a lesion of the posterior extremity of the internal capsule may cause it, in which case it is usually associated with hemianæsthesia. Finally, it may be produced by affections of the posterior tubercle of the optic thalamus, or of one of the anterior corpora quadrigemina, or of one of the optic tracts.

9. Genuine motor aphasia indicates disease of the third left frontal convolution.

10. Word deafness seems to be due to disease of the first left temporal convolution.

11. Difficulty in articulation implies disease of the medulla, as does also dysphagia.

12. Staggering gait and vertigo are the most constant symptoms of cerebellar disease. Forced positions and forced movements are seen chiefly in connection with lesions of the crura cerebelli ad pontem.

[13. Staggering gait and ocular paralyses are indicative of lesions of the corpora quadrigemina.—K.]

### CHAPTER III.

#### CEREBRAL HÆMORRHAGE.

**Ætiology.**—The cause of cerebral hæmorrhage should always be sought in some disease of the coats of the minute cerebral arteries. In 1868 it was first shown by Charcot and Bouchard that in almost every case of cerebral hæmorrhage there are miliary aneurisms of the small arteries of the brain substance, some one of which has burst and allowed the blood to escape. All later investigators have confirmed their statements about the occurrence and importance of these miliary aneurisms. The aneurisms may attain a diameter of a millimetre or more. They usually appear like spindle-shaped dilatations of the entire circumference of the vessel, although sometimes the bulging is confined to one side of it. So far as has yet been learned, the process of development starts with disease of the intima. This layer presents at first proliferations and also a fatty degeneration of the endothelium. Later on, however, the intima atrophies, just as the muscular coat does. Inasmuch as the intra-cerebral arteries possess almost no true adventitia, it is easy to see that these vessels are especially predisposed to aneurismal dilatation. It has been affirmed that the disease of the vascular wall, which leads to the formation of these aneurisms, is identical with ordinary arterio-sclerosis (*vide* page 231) or atheroma. Charcot denies it, but the later investigations of Eichler make it seem very probable. Indeed, we very often, although not invariably, find that cerebral hæmorrhage attacks persons who present either a general arterio-sclerosis or a more limited atheromatous disease of the cerebral arteries; and most of the factors which are said to promote cerebral hæmorrhage are the same as favor the development of arterio-sclerosis.

It has long been recognized that age has an important bearing on these cases. Although exceptionally a younger individual may be attacked, the majority of sufferers are over fifty years old—that is, at the time of life when arterio-sclerosis usually becomes most fully developed. Again, cerebral hæmorrhage is decidedly more frequent in men than in women, which is also true of atheroma. Alcoholism, syphilis, and gout are also reckoned among the ætiological factors of both disorders, and in both a hereditary predisposition is not very rarely demonstrable. What is called the “apoplectic habit” also deserves brief mention. Although there is no variety of constitution which exempts its possessor from the possibility of cerebral hæmorrhage, yet it can not be denied that often the victims of apoplexy do exhibit a certain “habit.” Such persons are not very tall, but are corpulent, broad-chested, with a short, thick neck and round face. They have not been disinclined to the pleasures of the table and the bottle, and sometimes they suffer from emphysema, moderate hypertrophy of the heart, and general arterio-sclerosis, as the condition of the radial and temporal arteries may disclose even during life.

Granting, therefore, that disease of the arteries, and more particularly miliary aneurisms resulting from chronic endarteritis of the smaller cerebral arteries, must be regarded as the chief cause of cerebral hæmorrhage, then, on the other hand, the question suggests itself whether an abnormal elevation of the blood-pressure may not have some part in determining the hæmorrhage. If the coats of the arteries be normal, surely they would not be torn, no matter how great the arterial tension became; but if aneurisms have already been developed, then there can be no doubt that a persistent or even a temporary elevation of the blood-pressure must favor the bursting of the vessels.\* In this sense a cerebral hæmorrhage, occurring in patients with certain forms of cardiac hypertrophy (contracted kidney, idiopathic hypertrophy, etc.), combined with disease of the vessels, may be referred in part to the increased arterial tension; but it is most of all with regard to many exciting causes, which are immediately followed by a cerebral hæmorrhage, that increased blood-pressure assumes great importance. Here it is temporary. Cerebral hæmorrhage may, for example, follow excessive muscular exertion, the ingestion of a large amount of food, indulgence in alcohol, taking a cold bath, or violent mental excitement. In all such cases, however, the change in the arteries is a necessary prerequisite.

It should be mentioned, in conclusion, that quite considerable hæmorrhage may also take place in the course of such general diseases as are associated with impaired nutrition and a consequent diminution in the resisting power of the vascular walls. Cerebral hæmorrhage under these circumstances is merely symptomatic of a general hæmorrhagic diathesis, as we find it in leukaemia, pernicious anæmia, and those affections which are called, in a stricter sense, hæmorrhagic diseases, such as scurvy and purpura hæmorrhagica. The grave infectious diseases, including septicæmia, typhus or typhoid fever, and variola, may occasion hæmorrhage into the brain as well as into other organs. The hæmorrhages are generally, however, from capillary vessels, and are very rarely extensive.

**Pathology.**—The miliary aneurisms do not develop in all the cerebral arteries with equal frequency, and accordingly we find certain regions particularly liable to cerebral hæmorrhage, being very much oftener affected by it than others. It is the large central ganglia in the neighborhood of the lateral ventricles that

\*[Mendel has found that the normal blood-pressure in the lenticulo-striate arteries, which are most prone to rupture, is much higher than it is in the cortical and many other small arteries of the brain.—K.]

suffer most frequently — namely, the optic thalamus, caudate and lenticular nuclei, and also the adjacent white matter of the internal capsule and centrum ovale. Hæmorrhages in other portions of the brain are much less frequent — such as hæmorrhages into the convolutions, the pons, the cerebellum, the crura cerebri, or the medulla. If the blood escapes into the neighborhood of a ventricle, it may burst into the latter. Likewise, in rare instances, an effusion of blood near the cortex may make its way out upon the surface of the brain.

An extensive collection of blood in one of the hemispheres may exercise so decided a pressure upon surrounding parts that the results of increased tension upon the affected side are at once recognized when the skull is opened. The dura on that side is more tightly stretched, the falx is crowded over to the opposite side, the convolutions on the convexity seem flattened, and the furrows are shallow. Exceptionally, when there is a very large effusion reaching nearly to the surface, we may even detect fluctuation.

On cutting through the brain-substance we find the seat of hæmorrhage, and are enabled to determine its position and extent. Its size, of course, varies considerably in different cases; it may be small, or it may occupy a large part of an entire hemisphere. The wall of the effused mass is made up of ragged and torn cerebral tissue, and the mass itself contains *débris* of the nervous elements entangled in the coagulated blood. The blood-clots are almost always very dark-colored when fresh. Later on, the mass changes to a chocolate-colored or more brownish-yellow pulp, composed of the disintegrated remnants of the nervous substance and the clotted blood. The microscope reveals, particularly in the immediately surrounding tissues, numerous fatty granular cells. These are white blood-corpuscles which have absorbed the fat resulting from the decomposition of the myeline substance. There is also always an abundance of hæmatoidine crystals, due to the disintegration of the red blood-globules. At a greater distance from the effusion the tissues present a yellowish tinge, from the imbibition of such blood-pigment as has reached them in a state of solution; and there is also usually an oedematous softening of the parts not too far removed from the hæmorrhagic focus.

If the patient survive, the mass is gradually absorbed. It slowly diminishes in size, and the surrounding parts tend to reassume their normal relations. The final result in many cases is a cavity filled with serous fluid and bounded by smooth walls. This "apoplectic cyst" remains stationary. In some instances, however, and particularly if the effusion be rather small, the walls approach each other as more and more of the fluid is absorbed; there is a great hyperplasia of connective tissue; and so, finally, there is nothing left but a so-called apoplectic scar, usually of a yellow color, due to vestiges of the blood-pigment. The position and dimensions of the permanent lesion determine, of course, the question of secondary descending degeneration (*vide* page 680), as well as the nature and extent of the persistent clinical symptoms.

**Clinical History.**—The symptoms of cerebral hæmorrhage agree closely with the anatomical lesions just described. The miliary aneurisms themselves, even when numerous, seldom excite any symptoms. Sometimes, however, it is possible that the slight circulatory disturbances they occasion produce the mild headache and similar annoyances which often precede, for a longer or shorter time, the occurrence of cerebral hæmorrhage.

As soon as an aneurism bursts, however, and blood escapes into any part of the brain-substance, there is immediately seen a group of grave cerebral symptoms, collectively termed an apoplectic attack, or "shock." As the blood escapes under a pressure nearly equal to the general arterial pressure, and doubtless much greater than that to which the soft substance of the brain is normally exposed,

the affected portion of the brain is at once subjected to a considerable increase of tension, which is transmitted for various distances in all directions. It need not be said that the destructive influence of the hæmorrhage may vary exceedingly, and that therefore the symptoms are by no means equally severe in all cases. The larger the rent in the blood-vessel, and the more rapid and abundant the consequent hæmorrhage, the worse is the apoplectic attack. Bleeding from larger vessels is therefore usually attended by graver symptoms than from the minute arterial twigs. An extensive cerebral hæmorrhage sometimes causes the patient to fall down suddenly in complete unconsciousness, while smaller hæmorrhages may occasion only a temporary attack of vertigo and slight cloudiness of intellect. If the tear in the wall of the artery be very small and narrow, permitting the blood to escape but slowly, then there may be no sudden attack at all, the phenomena requiring a certain length of time for their development.

There is also an important relation between the location of the hæmorrhage and the severity of the apoplectic attack. The chief symptom of these cases is loss of consciousness (about which we shall soon speak at length); and as this certainly is due to an interruption of the functional activity of the cerebral cortex, it is plain (1) that the nearer the cortex is to the hæmorrhagic focus, the more apt are the symptoms to be serious. It is confirmatory of this that hæmorrhage into the more deeply situated portions of the brain, like the *crura cerebri* or the pons, quite often occasions comparatively slight symptoms. But (2) there is a fact about the circulation in the brain that often causes the shock from hæmorrhage into the brain-stem to be greater than the shock following hæmorrhage into the cortex or the white substance of the hemispheres. The explanation is that the brain-stem has comparatively much larger arteries than the other parts just mentioned, which contain only minute blood-vessels. Furthermore, as Duret and Heubner have shown, the blood-vessels are so distributed that the arterial tension in the brain-stem is not a little higher than in the other portions. This renders intelligible the clinical phenomenon that hæmorrhages in the territory of the main arteries, besides being, as we have said, the most frequent of any, produce apoplectic symptoms even when the effusion is comparatively small; while sometimes hæmorrhages of about the same size in the cortex or white substance may not be noticed.

The clinical phenomena of the apoplectic attack will now be considered in detail. The onset is sometimes absolutely without warning, but in other cases it is preceded for a greater or less length of time by certain prodromata. These are either the result of the disturbance of circulation caused by the disease of the blood-vessels in the brain, and then, as already stated, they comprise occasional headache, vertigo, tinnitus aurium, spots before the eyes, languor, and muscular weakness; or they are caused by minute hæmorrhages, which seem not infrequently to precede a greater one. In such a case, the friends relate that of late the patient has had one or more slight and brief attacks, characterized by faintness, temporary trouble in speaking, sudden but temporary weakness of an arm or leg, and similar symptoms. The prodromata may extend over several days or even weeks and months preceding the severe attack.

In other cases there are no such premonitory symptoms. The apoplexy occurs unexpectedly and suddenly. In the midst of apparently vigorous health the patient sinks down "as if he had been struck." In still other cases there are indeed no prodromata, but the symptoms do not at first appear in all their severity, and occupy some hours or even a whole day in their gradual development. This is due to a slow and gradually increasing hæmorrhage, and is termed a slow or delayed apoplectic attack. The patient grows confused, anxious, and delirious (a case of our own had pronounced hallucinations of sight); the arm and leg on one

side become paretic, and gradually more and more completely paralyzed; and after a few hours complete unconsciousness comes on.

The attack may be rapidly fatal. In such cases the abnormal pressure probably involves the medulla oblongata and paralyzes the cardiac and respiratory centers there situated. Usually, however, there is merely a complete loss of consciousness, more or less rapidly developed. Sometimes the patient has time to lie down. He usually sinks back in his chair or falls to the floor, and becomes deeply comatose. The face is often noticeably flushed, and the pulse full and tense, but not infrequently somewhat slow, because of the increased cerebral pressure. The respirations are deep, noisy, stertorous, and likewise often slow. The relaxed cheeks and lips are often drawn deeply in at every inspiration, and puffed out at every expiration. The temperature is usually subnormal at first, later regaining the normal, or even a higher point. In a rapidly fatal case, however, the temperature remains depressed till death. It is not very rare in severe cases to observe a peculiar position of the head and eyeballs, they being all turned in one direction. This phenomenon is termed by Prévost conjugate deviation (*déviatiôn conjuguée*) of the eyes and head. It is generally temporary, and is said by Landouzy to be connected principally with a lesion of the lower temporal lobe. There is no perfectly constant relation between the lateral deviation and the half of the brain affected. Apparently in most cases the eyes are directed toward the injured side, and so to a certain extent "look toward the lesion" and away from the paralyzed side of the body (*vide infra*). The pupils present no constant peculiarities. Often they are of normal size. In other cases they are contracted, dilated, or unequal. No definite diagnostic conclusions can be drawn from them. In the worst cases the pupils will not react to light; in other cases they react, but often sluggishly.

During the deep apoplectic coma the extremities generally lie completely motionless and limp. In the worst cases reflex action is wholly suspended; but sometimes the vigorous thrust of a pin or the pinching of the skin will excite an occasional slow reflex twitch, or a motion as if to ward off the tormentor. Whether the apoplexy has caused hemiplegia at all, and if so on what side, can not always be easily determined during the initial coma. Still, it is often to be observed, even now, that one angle of the mouth hangs down lower than the other, and that the corresponding cheek is more puffed out during expiration than is the other; that the extremities of one side are even more completely relaxed and limp than those on the opposite side of the body, and that the reflex action and defensive movements are almost absent upon one side (the paralyzed side), while they can be clearly demonstrated on the other.

In contrast to the usual laxness of the arms and legs during the apoplectic coma is the tonic rigidity sometimes seen in the extremities, particularly on the side opposite to the hæmorrhage. This symptom seems to be especially, although not exclusively, connected with a bursting of the escaping blood into a lateral ventricle. It is rather exceptional for cerebral hæmorrhage to be attended with general or unilateral epileptiform convulsions—a symptom which, as we have seen, is referable to irritation of the motor regions of the cortex.

It should be mentioned that in many cases of cerebral hæmorrhage the urine passed after the attack has been found to contain small amounts of albumen or sugar. This symptom is usually ascribed to compression of the medulla from the effusion. There is usually retention of urine; in other cases there is involuntary micturition.

A certain number of patients never awake from the initial coma. Death may not be immediate, but they remain completely unconscious; the respirations become more rapid and irregular (sometimes of the Cheyne-Stokes character),

and there is a rattling in the throat, because mucus and saliva run down into it; the pulse, which was at first retarded, now becomes accelerated; the face grows paler and more and more sunken; the eyes are deep in their sockets; the cornea becomes opaque; and at last, after the coma has lasted some hours, or even one or two days, death occurs, often attended by a considerable rise in temperature.

This termination is, however, by no means the usual one. More frequently the patient survives the attack. The bleeding ceases, the clot contracts, and begins to be disintegrated and absorbed. At the same time the pressure exerted upon surrounding parts grows less and less, the more distant parts of the brain gradually recover from the shock, and consciousness slowly returns. The patient begins to open his eyes when he is spoken to in a loud tone; he raises his hand to his head, sighs, and yawns; gradually the intellect clears up, he tries to talk, or to express himself by signs; memory returns, and he recognizes those about him once more. Exceptionally, recovery is interrupted by a fresh and perhaps a fatal relapse. This may result from a renewal of the hæmorrhage. Generally, however, improvement persists, the patient fully regains his consciousness at the end of a few days, and it now becomes possible for the first time to "estimate the damages."

The symptoms thus far described belong to severe apoplectic attacks. There are also, as we have said, cases of all degrees of mildness, as regards the first onset. In these there is no deep and persistent coma. The patient loses consciousness only temporarily, if at all. He is seized with vertigo, or with sudden headache, and is for a time stupefied. Nausea and vomiting are of quite frequent occurrence, just as in ordinary syncope. Yet cases presenting these comparatively slight early symptoms, and with few even of these, may exhibit the genuine focal symptoms referable to the hæmorrhage, such as hemiplegia, in all their severity. These latter phenomena must now be considered.

Among the symptoms of impairment of function resulting from cerebral hæmorrhage, only those are to be regarded as direct focal symptoms which are caused by the actual destruction of a region of the brain. Where the hæmorrhage takes place we have seen that a larger or smaller extent of the brain-substance is completely destroyed by the sudden and forcible escape of the blood. The dimensions of this lesion are represented later by the apoplectic scar or cyst, and its position by the nature and extent of the persistent, and for the most part irreparable, loss of function (*Ausfallserscheinungen*). But there are, in addition to these direct symptoms, other indirect focal symptoms, which outlast the apoplectic shock, and vary with the locality of the hæmorrhage. These do not, however, correspond to the territory actually destroyed. They are due to the influence exerted for a certain length of time by the hæmorrhagic focus upon the immediately surrounding structures. The pressure of the effusion, the disturbance of circulation resulting from it, the collateral œdema, and perhaps also the imbibition of the soluble products of disintegration, are the chief factors in exciting these indirect symptoms. They do, indeed, outlast the initial shock, but are nevertheless temporary, vanishing sooner or later, at the end of several days or weeks, or even months.

Even if the character of the initial attack and the symptoms still exhibited have been minutely determined, yet we are unable to say, at first, whether the existing focal symptoms are direct or indirect. We can decide about this only after further observation. If the early symptoms disappear within the next few days or weeks, or after the first two or three months, we can then affirm, retrospectively, that they were indirect. Such as outlast the first six months are to be regarded as direct, and as not destined to improve much. From a practical

point of view this distinction is of extreme importance. We shall revert to the subject when considering the course of cerebral apoplexy.

A minute description of all the focal symptoms which might occur after cerebral hæmorrhage, and of the light thus thrown upon the location of the hæmorrhage, need not be attempted here, for it would necessitate a repetition of all the facts enumerated in the preceding chapter. It is only requisite to describe, in detail, the chief and by far the most frequent result of a cerebral hæmorrhage—ordinary cerebral hemiplegia.

It has been mentioned that most of these hæmorrhages occur near the lateral ventricles. Hence, in a majority of instances, the motor pyramidal tract, as it traverses the internal capsule, is either directly destroyed or at least indirectly affected. Consequently, most patients who survive the apoplectic shock present a paralysis of that half of the body which is opposite the seat of hæmorrhage. On minute examination we usually find, in the first place, that even in the distribution of the facial nerves there is a distinct difference between the two sides, the lower division of the facial (which supplies the muscles of the cheek, nose, and mouth) being evidently paralyzed on one side, while its upper division (going to the eyes and forehead) is entirely, or almost entirely, intact. The forehead can be wrinkled on one side as well as on the other; but if the patient tries to turn up his nose, or alter the shape of his mouth, the paralysis becomes evident. Often indeed, while the face is quiet, it can be noticed that one naso-labial fold is obliterated, or that one corner of the mouth hangs down. It is an interesting fact that the paresis of the lower division of the facial is much more noticeable during voluntary efforts, as in showing the teeth, than when the patient smiles involuntarily. A patient will sometimes try in vain to draw back the corner of his mouth, then begin to laugh at his own awkwardness, and thereupon open his mouth in an almost perfectly normal manner. We have seen above, in the chapter on cerebral localization, that this condition can probably be explained by the relation of the optic thalamus to the movements of mimetic expression. Why there is such a difference between the upper and lower divisions of the facial nerve in cerebral hemiplegia is not certainly known. Possibly it has some connection with the fact that the muscles supplied by the upper division (frontalis, corrugator supercilii, and to a certain extent the orbicularis) are very seldom exercised upon one side alone, but always bilaterally. Perhaps both sides receive nervous fibers from each cerebral hemisphere, so that, if a single center be intact, it alone answers for the muscles on both sides.\* Sometimes, however, careful examination shows a slight paresis of the frontalis muscle on the paralyzed side. In the distribution of the lower division of the facial, also, ordinary cases of cerebral hemiplegia present almost always a more or less marked paresis, and only exceptionally a complete paralysis.

There is quite often a slight impairment of the hypoglossus in addition to the paresis of the facial nerve. If the patient puts out his tongue, its tip deviates toward the paralyzed side. This is a result of paresis of one of the genio-hyoglossi. When both these muscles contract, they may be said to push the tongue forward. If this thrust be more vigorous on one (the healthy) side, the tongue is deflected toward the other (paralyzed) side. In ordinary cerebral hemiplegia this is almost always the sole way in which the movements of the tongue can be seen

\* There is a remarkable general rule which should be mentioned here, and which is perhaps to be explained in the same way, namely, that those muscles which are usually called into play in pairs are never completely paralyzed in cerebral hemiplegia. Furthermore, it is impossible for us to contract most of these singly, on one side alone, or at least not without special practice; this applies, for instance, to the corrugator supercilii, the frontalis, the *motores oculi*, and the muscles of mastication and respiration.

to be impaired. Sometimes, however, the slight paresis of half of the tongue, combined with the facial paresis, entails a noticeable difficulty in articulation. This, to be sure, is not great, and is often appreciated by the patient alone, who is conscious that an effort is required in order to speak.

The soft palate is rarely much affected. It may, however, hang rather lower down on the paralyzed than on the unaffected side, and move less. The uvula is inclined sometimes toward the healthy and sometimes toward the paralyzed side. There are no special disturbances of function as a result of these changes.

The trapezius is the only muscle of the trunk which is ordinarily much affected in cerebral hemiplegia. As a result of the paresis of this muscle, the shoulder sags and can not be raised as high as on the normal side. If the patient tries to take a very deep breath, it is in some cases possible to see that the paralyzed side lags behind a little in respiration, which is undoubtedly due to a paresis of the respiratory muscles on that side. It is perhaps due to this that the pulmonary diseases which attack hemiplegic patients frequently develop in the lung on the affected side, where respiration is deficient.

The most important element in the hemiplegia is the paralysis of the extremities. Immediately after the hæmorrhage it is often so complete that even the slightest voluntary motion in the affected arm and leg is impossible. Other cases, however, exhibit only a more or less severe paresis (hemiparesis) from the first; or the complete paralysis at any rate is confined to certain groups of muscles, the others still retaining vestiges of their normal contractility. Even when there is total hemiplegia at first some of the muscles usually regain a certain amount of their old power later on (*vide infra*).

The behavior of the reflexes is comparatively constant in nearly all cases. Almost invariably there is increased tendon reflex on the paralyzed side. If, however, the initial shock be very severe, there may at first be no tendon reflex whatever. In all cases of any duration it is always exaggerated, and often very much so. A tap upon the tendons and bones (periosteal reflex) of the arm, as well as of the leg, excites the most vigorous and manifold contractions. Very often a persistent ankle clonus can be obtained. It is noteworthy that even on the normal side, particularly in the lower extremity, it is almost always possible to demonstrate an exaggeration of the tendon reflex, although less pronounced than on the paralyzed side. Many have expressed the opinion that the increased tendon reflex upon the paralyzed side is a result of the secondary degeneration of the pyramidal tracts in the spinal cord. In our judgment this view is entirely unfounded, inasmuch as the exaggeration of the tendon reflex often appears within a few days, or even hours, after the apoplectic attack—that is, before a secondary degeneration in the spinal cord is to be thought of. We would rather seek to explain the phenomenon as being due to the suspension of certain reflex inhibitory influences because of the cerebral lesion.

There is very often found, particularly in cases of long standing affected with well-marked contractions, an increase of "direct mechanical excitability" in the paralyzed muscles, such that a tap upon them causes them to contract vigorously. We are, however, of opinion that, in part at least, this is also a reflex symptom, to be referred to the mechanical irritation of the fascia of the muscles (fascial reflex).

The skin reflexes in hemiplegia behave in precisely the opposite way from the tendon reflexes, being almost invariably decidedly diminished on the paralyzed side. In the paralyzed arm it is usually impossible to excite any skin reflex whatever; and in the corresponding leg there is either no, or at any rate a greatly diminished reflex. The difference is seen especially well in the abdominal and cremaster reflexes (*vide page 543*); on the paralyzed side they are almost or quite

absent, while they remain normal upon the opposite side. This contrast often is of service in determining the location of the hemiplegia when the patient is in a stupor or coma.

Sensation is but little impaired in most cases of cerebral hemiplegia. It is usually possible, in a hemiplegia occasioned by this particular lesion (cerebral hæmorrhage), to find at first, by careful testing, a slight blunting of cutaneous sensibility; but this is seldom very great, and later on frequently becomes even slighter than at first. Slight paræsthesia is not infrequently complained of on the affected side, especially at first. Any marked disturbance of sensation indicates, as has been seen (compare page 721), that the posterior extremity of the internal capsule is involved. Such cases are rare. In them we may observe a complete cerebral hemianæsthesia combined with the hemiplegia. According to Gowers, a temporary hemiopia is often present directly after the occurrence of a cerebral hæmorrhage. Nor is it very exceptional to find a persistent hemiopia associated with hemiplegia; but as yet little is known about the pathological anatomy of such cases. The most likely thing would seem to be some lesion of the fibers of the optic nerve in the internal capsule or in the posterior tubercle of the optic thalamus. The muscular sense is not usually affected in hemiplegia. Lately it has been affirmed that paralysis of cortical origin invariably causes anomalies in the muscular sensibility of the parts which are paralyzed, but the statement lacks confirmation. Our own observations would certainly lead us to doubt whether it is universally true.

Turning now to the further course of hemiplegia, we find a new group of important symptoms. First of all should be considered the changes in the paralyzed muscles. If the hemiplegia be incomplete, even from the start, almost the normal degree of motility may in a comparatively brief period be regained by the affected side. At most there will persist a certain slight amount of weakness and stiffness; and even these will gradually diminish. From what has been already said, it is evident that in these cases the initial paresis is an indirect focal symptom, and accordingly vanishes as soon as the effusion ceases to affect the tissues not immediately involved.

But even where there is a complete hemiplegia it is exceptional for this condition to remain unabated throughout the entire region affected. After a few weeks, or even a few days, one part and another of the paralyzed half of the body begin to recover their former motility. The improvement goes on slowly, and in the most favorable cases the paralysis may for the most part have vanished at the end of some months. Usually, however, the improvement never becomes more than partial. It is noteworthy that the lower extremity almost always improves more than does the upper. Many patients gradually become able to walk alone once more, perhaps with the aid of a cane, although the arm remains almost useless. It must be confessed that the gait is seldom perfectly natural. The patient takes short steps, drags the affected limb more or less, and in many cases does not move it straight forward, but with an outward sweep. Very often the functions of the ileo-psoas and quadriceps return. The patient can then walk alone even if the other muscles remain paralyzed, because by these muscles the leg can be held firm like a wooden leg. In the arm, the chief improvement is usually in the fingers and the elbow-joint, the movements of the shoulder-joint recovering least.

The explanation of this improvement during the first few months is not fully ascertained. Probably it is largely true that only the persistent paralytic symptoms are direct focal symptoms, while the temporary motor disturbances are only an indirect result of the hæmorrhagic focus, and vanish when once the pressure, cedema, etc., have ceased. It is, however, not absolutely impossible that gradually

new tracts (perhaps originating in the sound hemisphere\*) assume vicariously some of the functions which are at first arrested. That fibers which have been destroyed are ever actually regenerated is very improbable; and, as has been mentioned already, there is not much improvement after the first six months.

The permanently paralyzed muscles become very often contracted later on. The appearances produced exhibit considerable uniformity. The arm, which suffers more from paralysis than the leg, is also usually more contracted. The fingers are almost invariably flexed; the forearm contracted in a position of pronation, and usually flexed rather than extended; and the upper arm adducted (the pectoralis major being chiefly affected). These contractures correspond to the natural positions which the paralyzed arm almost always assumes if left to itself. This, taken alone, is a reason for ascribing the contractures chiefly to the fact that the arm moves less than normal, and that, as a necessary sequel, certain muscles become permanently shortened. This view would make the changes "passive contractures." Another argument in its favor is that the deformity can to a certain extent be prevented by the persistent use of passive motion, which renders any permanent shortening of the muscle impossible. Nevertheless, Charcot and his pupils, including Bouchard, hold an entirely different opinion—namely, that the contractures are due to the secondary degeneration of the pyramidal tract. In defense of their position no fact can be adduced, save that fatal cases exhibiting hemiplegic contractures do invariably present the secondary degeneration mentioned; but of course this is no proof that the two things have any causative relation to each other. A contracture occurs only in connection with persistent paralysis; a persistent paralysis never is seen unless the pyramidal tract be destroyed; and if it be destroyed, a secondary degeneration must result. The contractures and the secondary degeneration are therefore two sequelæ, independent of each other. And that the degeneration should "irritate" the fibers, and thus excite muscular contractions, is extremely improbable; for, according to all analogy, fibers which are undergoing degeneration can not be stimulated, and can not therefore transmit any sort of stimulus to the paralyzed muscles.

If the contractures become marked in the lower limb, they may involve either the extensors or flexors. In the leg a moderate contracture of the calf is the most frequent condition. Hitzig has called attention to a remarkable fact, which is that often the contractures are very slight in the morning, when the patient first wakes up, becoming aggravated after he has moved about a little. Hitzig refers this phenomenon (which has not yet been at all satisfactorily studied) to abnormal "associated movements" of the paralyzed muscles. Such associated movements do occur: movements of the sound side excite associated movements in the opposite members; and efforts to move the paralyzed parts excite in their turn associated contractions of the normal muscles. Sometimes, also, involuntary movements of the lower limb on the paralyzed side are observed when the patient exerts himself to move his corresponding arm all he possibly can. Very often on drawing the affected leg up on the trunk we observe a marked dorsal extension of the foot as an associated movement.

Another peculiar phenomenon must be mentioned here. It is what Weir Mitchell has termed post-hemiplegic chorea. Some time after the paralysis begins

\* As has been already stated (page 731), it seems proper to assume that certain muscles enjoy a double innervation—that is, from each hemisphere. This applies particularly to such muscles as usually are exercised in pairs. We might perhaps in this way explain why the lower extremity is capable of more improvement after hemiplegia than is the arm. The legs have to be used simultaneously or consentaneously, as in walking, much more than the two arms. Another fact deserves brief mention: on careful examination, it is sometimes possible to make out a slight paresis in the sound side, which may perhaps be referable to lesion of the direct motor fibers (Pitres).

the parts affected by it exhibit involuntary movements, reminding one of chorea or athetosis (*vide* page 541). Sometimes these movements are continuous, sometimes they occur only as associated movements in connection with voluntary motions of the paralyzed, or even of the sound, side. Hemiplegia due to cerebral hæmorrhage very seldom exhibits this phenomenon. It is said to occur chiefly in focal disease of the posterior extremity of the internal capsule, and of the optic thalamus. It is much commoner in cerebral infantile paralysis (*vide infra*).

It is interesting to observe the trophic and vasomotor changes in the paralyzed parts. At first the skin may be somewhat redder and warmer on the paralyzed than on the sound side. Nothnagel has shown that, even in the distribution of the cervical sympathetic, symptoms of vasomotor paralysis occur. They are partly temporary and partly persistent, and comprise increase of temperature and color in the paralyzed side of the face, swelling of the eyelids, and contraction of the pupil; but they are usually slight. We very frequently find, especially on the back of the hands, more or less puffiness, which is likewise usually regarded as of vasomotor origin. It should, however, be considered that the natural movements of any part of the body greatly promote the nervous and lymphatic circulation, and that the quietude of paralysis may therefore have much to do with the œdema. In hemiplegia of some duration the extremities upon the paralyzed side are always cooler than normal, and the hand in particular is very often deeply cyanotic. The skin sometimes becomes harsh and fissured, and often is thickened. The internal surface of the hand, in case of contracture, is frequently quite damp with perspiration.

Among the specific trophic symptoms of hemiplegia Charcot includes "acute malignant decubitus." This sometimes develops with extreme rapidity within a few days after the shock, and usually occupies the buttock on the affected side. There appears a circumscribed redness with the formation of vesicles, which is soon succeeded by a deep-reaching necrosis of the soft parts. We have ourselves never met with this in a case which has been properly nursed, and we can not therefore help thinking that its development is not wholly due to trophic disturbance, but to pressure and to the penetration of septic matter below the skin. Of course, patients long confined to bed with hemiplegia are as liable to bedsores as are any others similarly situated.

The permanently paralyzed muscles gradually atrophy somewhat in the course of years; yet, in uncomplicated cases of cerebral hemiplegia, this atrophy is never of the degenerative sort, nor is it usually very great. The paralyzed muscles therefore continue to react perfectly to faradism (see page 547). The joints of the paralytic extremities, and in particular the knee and shoulder, may exceptionally become inflamed. The arthritis is sometimes acute, and sometimes more of a chronic variety. Its cause is not evident. Charcot thinks that it is probably a neurotrophic symptom, and he is of the same mind with regard to the rarely seen swellings of the peripheral nerve-trunks of the paralyzed side ("hypertrophic neuritis").

Mental symptoms are rare, except the initial loss of consciousness. There is sometimes, however, a persistent general uneasiness of mind, accompanied by great excitability and wakefulness. In a large number of cases of persistent hemiplegia there finally come on, in the course of years, constantly increasing indications of mental weakness. The patient grows dull and forgetful. Very often he exhibits a peculiar tendency to weeping, bursting into tears at the slightest provocation. But frequently he is subject to quick alternations of feeling, weeping and laughing in the same minute.

The general nutrition is often good for a long while. Sometimes there is even a decided tendency to corpulence. In other cases, and especially in the bedridden,

marasmus gradually comes on and hastens the fatal termination, particularly if there be some intercurrent trouble, such as a bed sore or bronchitis.

We have detailed the peculiarities of hemiplegia somewhat minutely, because the statements will apply to all cases of cerebral hemiplegia, no matter in what place the pyramidal tract is interrupted or by what sort of a lesion. It is needless to enter into the diverse symptoms which are caused by diversity in the exact location of the hæmorrhage. The hemiplegia itself is the same, whether the effusion be in the cortex, internal capsule, crus cerebri, or pons. It is easy to infer from the preceding chapter what the accessory symptoms are which would enable us to localize the trouble. We need here mention only the frequent combination of right hemiplegia and aphasia. This occurs when there is a large effusion in the left hemisphere, extending from the internal capsule to the neighborhood of the third frontal, or possibly the uppermost temporal (compare page 716) convolution.

**Diagnosis.**—The diagnosis of cerebral hæmorrhage rests on the sudden onset of the apoplectic symptoms, and on the later symptoms (if there be any) of impairment of the cerebral functions. The diagnosis can scarcely ever be made with absolute certainty, for cerebral embolism may exhibit almost identical phenomena: the differential diagnosis between the two will be given in the following chapter. Occasionally there may be danger of mistaking other cerebral affections for a hæmorrhage, such as meningitis and tumors. The same may be said of a suddenly developed uræmia, and of constitutional sepsis. In these cases the rapid onset of grave cerebral symptoms of a general nature, such as unconsciousness, simulates the apoplectic coma.

**Prognosis.**—The first question is, whether the patient will survive the initial shock. The answer depends upon the severity of the early symptoms. The deeper and more persistent the unconsciousness, the more deficient the respiration and pulse, the less the prospect of recovery; but we can never decide absolutely. If the patient have withstood the first onset and be hemiplegic, then the possibility of improvement hinges on the question whether the paralysis is a direct or an indirect focal symptom. Inasmuch as there are no means of knowing about this at first, we must speak very guardedly. It should never be forgotten that the hæmorrhage may recur. The predisposing disease of the blood-vessels renders individuals who have had one stroke liable to be visited, sooner or later, by another.

**Treatment.**—The treatment of the apoplectic shock demands, first of all, rest in bed, with the head and shoulders elevated. To avoid bedsores it is very important to maintain cleanliness, and to watch attentively that portion of the skin which is pressed against the bed by the weight of the body. An ice-bag should be put upon the head, and particularly over that side on which the hæmorrhage is supposed to be. Bleeding was formerly universally practiced, but of late its usefulness is doubted. It is not indicated unless the deep congestion of the face, the violent pulsation of the carotids, and the full, slow pulse show increased arterial tension. In such a case, if the patient seem otherwise robust, we may bleed at the commencement of an attack, in the hope of checking the flow of blood by lowering the intra-arterial pressure. In similar conditions experience shows that the local abstraction of blood from the temples is sometimes advantageous. The bowels should be well emptied by enemata, and later on by drastic purgatives. If the respiration and pulse fail, we may try stimulants (ether, camphor), but very likely they will be without success.

[Horsley and Spencer have found, by experiments on animals, that if the internal carotid be tied the bleeding from the divided lenticulo-striate artery is checked. Horsley therefore suggests that in the very earliest stage of cerebral

hæmorrhage ligature or compression of the internal carotid may check the bleeding, and prevent the formation of a large clot and extensive destruction of the brain. This procedure has not yet been tried upon the human subject.

Where there is much difficulty in respiration during the period of coma, relief may sometimes be obtained by turning the patient upon the side.—K.)

When the patient is safely over the shock, our resources for aiding him in the further stages of his trouble are very limited. As long as headache and symptoms of fever persist, the application of ice to the head should be kept up, and other disturbances should be treated symptomatically. For uneasiness and wakefulness, small doses of morphine or chloral are given. Treatment of the hemiplegia must be deferred for the first three or four weeks, until all the initiatory symptoms of irritation are over. Then electricity plays the chief rôle. Local galvanization should be tried, the current being made to pass transversely through the head, with as much regard as possible to the position of the hæmorrhagic focus; the current should be feeble, and the application should occupy two or three minutes. With this may be combined galvanization of the sympathetic nerve on the side of the hæmorrhage. Nor should galvanization (stroking with the cathode) and faradization of the paralyzed muscles and nerves be neglected. If favorable changes take place, it is, however, uncertain how much should be ascribed to treatment; since, as has already been stated, there is often improvement without treatment.

Passive movements and massage of the paralyzed limbs are very important as a prophylaxis against contractures. They should be commenced promptly, and be methodically continued. Massage, and later on systematic and appropriate gymnastic exercises, may contribute much to the restoration of voluntary motions. The same object is also promoted by rubbing with spirits of camphor, chloroform liniment, etc.

Internally, potassic iodide is frequently given, out of regard for its "absorbent" properties. We may also try the effect of strychnine; it is most adapted for cases of some duration.

As to baths, they should not be too warm—that is, not over 90°–93° (26°–27° R.). Moderately warm baths, medicated with common salt if it seems desirable, and employed three or four times a week, seem to be beneficial. If it be thought best to send the patient to a regular bathing-place, Wildbad, Ragatz, Teplitz, Wiesbaden, or Rehme may be chosen. At the first-mentioned places none but the cooler springs should be used.

Hemiplegic paralysis often lasts so long that the physician must repeatedly change the details of treatment, so as to support the courage and patience of the sufferer. Particular care should be given to regimen, in order that any recurrence of the hæmorrhage may, if possible, be avoided. The diet should be simple; any large amount of alcohol should be forbidden; and there should be no severe bodily exertion or mental excitement.

#### CHAPTER IV.

#### CEREBRAL EMBOLISM AND THROMBOSIS.

*(Softening of the Brain from Embolism or Thrombosis.)*

**Ætiology and Pathology.**—Occlusion of the cerebral arteries is one of the most frequent injuries inflicted by embolism. Usually the emboli originate in the left side of the heart, from thrombi in the left auricle, or from the thrombotic deposits which form in chronic endocarditis (mitral or aortic disease) upon the valves of

the left ventricle. Chronic arterio-sclerosis may also lead to thrombosis in the larger arteries, particularly the aorta; and in case the cerebral arteries themselves are extensively atheromatous, the larger vessels at the base of the brain may furnish material for embolism of the smaller cerebral arteries.

Thrombosis of the arteries of the brain is always due to primary disease of the blood-vessels, the most common cause being the chronic arterio-sclerosis just mentioned. Wherever the atheroma has altered the normal structure of the intima, deposits of fibrine may take place. Their development is further promoted by the subnormal elasticity of the arteries, and by the occasional narrowing of their lumen; for thus the flow of blood is rendered slow, if not even completely checked. It is easy to understand that thrombosis and embolism may each give rise to the other. From every thrombus an embolus may be detached; and every firmly lodged embolus may form a nucleus for thrombosis.

Next to arterio-sclerosis, the most frequent cause of a cerebral thrombus is syphilitic endarteritis. In the chapter on cerebral syphilis this subject will be minutely considered. Whether thrombi ever form here independently of disease of the vessels is doubtful. An apparently spontaneous thrombosis is now and then seen in patients who are cachectic or severely ill (cancer, grave typhoid or typhus fever, pneumonia); in such instances the cardiac weakness, and possibly also an abnormal tendency of the blood to coagulate, are regarded as either the causes, or at least the predisposing factors, of the thrombosis.

In whatever part of the arterial system complete occlusion has been produced by an embolus or thrombus, the results depend upon the possibility or impossibility of blood reaching by collateral channels the region thus deprived of its ordinary supply. If the collateral circulation prove efficient, no harm is done; if not, the tissues must perish and undergo "softening." It is thus a matter of the greatest practical import that the perforating arteries of the brain-stem, and particularly the branches of the middle cerebral artery in the fissure of Sylvius, which supply the great central ganglia and internal capsule, are all "terminal," in Cohnheim's sense—that is, they form few anastomoses with neighboring vessels. Now, the middle cerebral artery and its branches are known from experience to be peculiarly liable to embolism, above other cerebral arteries. Hence we see why the region they supply suffers so severely and so very frequently from emboli. It is noteworthy that the left middle cerebral artery is more frequently plugged by emboli than is the right. In the centrum ovale and cortex there is more opportunity for collateral compensation than in the central ganglia; but even here the supply of blood often proves insufficient, as is shown by the not infrequent occurrence of spots of softening in the cortex and the white substance of the cerebrum. On the other hand, embolic foci are much rarer in the crura cerebri, pons, and cerebellum.

The various steps in the process which begins with embolic or thrombotic occlusion and ends in softening of the brain-substance are essentially the same as occur in other organs (compare chapter on pulmonary embolism, page 247). The tissues which are deprived of their arterial blood perish, become disintegrated, and are transformed into a soft homogeneous mass. Into the empty portion of the artery, beyond the embolus, blood flows in the reversed direction from the veins, and, if the anatomical relations permit, from the minute arteries in the neighborhood; but the supply is not sufficient to nourish the tissues. The walls of the blood-vessels become abnormally permeable and delicate, so that some red globules invade the disintegrating region by diapedesis, and others in the way of minute but genuine ecchymoses. Actual infarctions are, however, never formed in the brain, perhaps because, as Weigert suggests, the nervous structures swell so much as to exclude any large amount of blood; but the little punctiform ecchy-

moses are in many instances so abundant that the whole softened spot seems distinctly reddish or yellowish. This red or yellow softening is also due in part to the tissues being stained by the dissolved pigment of disintegrated blood-globules. If the discoloration be not very striking, then we speak of a white softening.

Fresh foci of softening are seen through the microscope to be composed of drops of myeline, bits of swollen nerve-fibers, numerous fatty granular cells, and free fat globules. The minimum time required for these changes is one or two days. If within that period a compensatory collateral circulation is set up, the nervous structures may be restored and resume their functional activity. If not, the tissues perish and become disintegrated. The white blood-corpuscles and leucocytes (and possibly also the endothelial cells of the blood-vessels, and the neuroglia and ganglion-cells) absorb the fatty detritus thus made, and come to form the fatty granular cells above mentioned. If the patient live, the dead and disintegrated tissue is gradually absorbed, and it may even finally be replaced by a cyst not different in appearance from those which occur after cerebral hæmorrhage. A minute focus of softening may sometimes also be replaced by indurated cicatricial tissue. If portions of the surface of the brain become softened, quite a deep depression often results. This is filled up in part with serous fluid and in part by hyperplasia of the pia mater. Sometimes the convolutions are still recognizable in places; but they are atrophied, of a yellowish color, and of a greatly increased consistence, due to the growth of cicatricial tissue.

**Clinical History.**—The occurrence of cerebral embolism is attended with almost precisely the same sort of shock as is cerebral hæmorrhage. We do not need to enter into the particulars again here, but will refer to the preceding chapter (*vide* page 727). In embolism, also, the intensity of the shock varies; it ranges between extreme mildness, when it occasions only transitory confusion of intellect or slight vertigo, to the greatest severity, when there is deep and persistent coma. One chief factor in determining the nature of the case is the size of the occluded artery; another is its position, according as the embolism has taken place in the hemispheres or toward the base of the brain. In general, the shock of embolism is not often so severe and long continued as that of hæmorrhage; and embolism does not so frequently give rise to symptoms of cerebral compression, including slowing of the pulse. On the other hand, epileptiform convulsions are seen more often in embolism than in hæmorrhage. Embolism again may have a rather slow onset, where there is at first a small embolus and this becomes the nucleus of a gradually formed thrombus.

It is not easy to explain why there should be a shock at all in case of embolism. Perhaps the main reason is the diminution of pressure which the embolism occasions in the region directly affected and in its neighborhood. The portion of the artery beyond the plug becoming empty, not only causes a draught upon the blood and lymph, but subjects all the soft surrounding structures to a diminution of tension and to a certain amount of strain (Wernicke). It is not impossible, however, that the disturbance of circulation occasioned in the surrounding blood-vessels by sudden embolism of a good-sized artery is of itself enough to account for the symptoms of shock.

With regard, also, to the persistent symptoms of embolism we may be equally brief, inasmuch as they very closely resemble those which follow a cerebral hæmorrhage. As has been said, it is only when a compensatory collateral circulation is developed within the first forty-eight hours that the early symptoms of focal disturbance can entirely vanish. After this period, the tissues which have been deprived of their normal blood-supply must undergo necrosis; although there is still room for hope that some of the symptoms will prove indirect, and

therefore capable of improvement, so that embolic hemiplegia, like that from hæmorrhage, may improve decidedly in the course of the first few weeks.

Inasmuch as the middle cerebral artery is by far the most frequent seat of cerebral embolism, and inasmuch as this artery supplies the internal capsule as well as the great central ganglia, the most frequent focal symptom of embolism of the brain is ordinary cerebral hemiplegia, all the features of which have been depicted in the preceding chapter. Aphasia is associated with it with comparative frequency, for, as already mentioned, the left middle cerebral artery is especially apt to suffer. Less frequent is paralysis of a single member, due to cortical embolism, or an occipital lesion with hemiopia.

Where softening is the result of thrombosis, the symptoms are but seldom abrupt in their onset. Usually the focal symptoms and the more general ones (such as unconsciousness) are developed rather gradually. This is most often seen in so-called senile softening of the brain, a disorder almost always caused by sclerosis of the cerebral arteries. The various symptoms generally come on under cover of repeated relapses and fresh aggravations of the disease. A severe initial shock seldom occurs; but almost invariably there is a gradual and progressive dementia.

The further course and the final termination of cerebral softening vary as do those of cerebral hæmorrhage. Embolism of a larger artery may cause speedy death. If, however, the first shock passes away, the impairment of function which may be left behind may last for years without seriously affecting the general health. There is always danger of a recurrence when the source of the embolism continues unchanged, as in cardiac disease or atheroma.

**Diagnosis.**—Both the onset and the persistent focal symptoms are so much alike in hæmorrhage and embolism that in many cases it is utterly impossible to decide which caused the apoplexy and hemiplegia. The following are factors in making a differential diagnosis, if one can be made: 1. It is very important whether there be any source for an embolus. Thus, if the patient have valvular cardiac disease (particularly mitral), embolism is more probable than hæmorrhage. 2. A young person is, on the whole, more apt to have embolism than hæmorrhage. At a later period of life one is about as probable as the other. 3. When the shock is severe and persistent, with red face, strong pulsation of the carotids, and signs of cerebral compression (slow pulse), we would think of hæmorrhage rather than embolism, in which latter the initial symptoms are sometimes comparatively slight (*vide supra*). 4. Finally, it is sometimes possible to obtain support for a diagnosis of cerebral embolism by demonstrating embolism elsewhere, as in the fundus oculi, by means of the ophthalmoscope.

In rare instances, also, tumors of the brain, into the substance of which hæmorrhage takes place, may induce symptoms closely simulating a primary apoplectic shock, as may also abscesses which have been previously latent, and then suddenly burst into a ventricle. In such cases a correct diagnosis is seldom possible.

Softening due to a thrombus is the most readily diagnosticated in those cases where there is cerebral syphilis (*q. v.*). Senile softening is inferred from the age of the patient, the signs of general arterio-sclerosis, the abrupt advances of the disease from mildness toward severity, and the developing dementia.

For the prognosis and treatment of cerebral embolism we may refer simply to what was said in the preceding chapter.

---

## CHAPTER V.

## INFLAMMATION OF THE BRAIN.

*(Acute and Chronic Encephalitis.)*

## 1. ABSCESS OF THE BRAIN (SUPPURATIVE ENCEPHALITIS).

**Ætiology.**—In most cases of cerebral abscess it is possible to demonstrate with certainty that infectious material capable of exciting suppuration has penetrated to the encephalon. This is particularly true of those not very rare abscesses which follow injuries of the scalp, cranium, or brain (traumatic abscess of the brain). Here the wound is almost always an open one, affording free ingress to the virus. It is not essential that the bones should be injured, for experience shows that, even where the soft parts alone are wounded, suppuration may extend to the brain. The manner in which this extension takes place determines the question whether a suppurative meningitis (*q. v.*) or an abscess shall be developed. Not infrequently we find the two combined. Another source of traumatic cerebral abscess is foreign bodies which penetrate into the brain (for instance, through the orbit), and thus carry septic matter into the very substance of the organ. Some exceptional cases have been reported of traumatic cerebral abscess without any open wound; as yet they are beyond our comprehension. Possibly there is even in these some minute wound invariably present but overlooked.

Analogous to the above causes is suppuration in neighboring parts, which may, by direct extension, occasion cerebral abscess. The same processes are prominent in this connection which we have already found to excite purulent meningitis (*vide* page 698)—particularly suppuration (caries) in the middle ear and in the petrous bone. In such a case the most frequent position of the abscess is naturally the temporal lobe or the cerebellum. Abscesses also occur in the anterior part of the brain, from suppurative processes in the nasal cavity and the ethmoid bone; but this mode of origin is much less frequent.

In yet a third class of cases the morbid agents are conveyed from foci of disease situated in distant parts of the body. These are metastatic or embolic abscesses. They occur, for instance, in pyæmia and ulcerative endocarditis. Abscesses of this sort, however, are usually small, and seldom are conspicuous in modifying the grave general disease. Of more importance are cerebral abscesses connected with certain suppurative affections of the lungs and pleura. These are not so very rare. They are oftenest associated with fetid bronchitis, pulmonary gangrene, and empyema. Purulent meningitis (*q. v.*) may occur in the same way. There can be no doubt that virus is in some way conveyed to the brain, but just how is not yet known.

In some few cases of cerebral abscess no certain ætiology can be made out. To these the term idiopathic is applied. We met with several of them just at the time of an epidemic of cerebro-spinal meningitis; and it therefore seems reasonable to suspect that possibly many apparently spontaneous cerebral abscesses are referable to the same poison as is epidemic meningitis.

**Pathology.**—The pathological anatomy of abscess of the brain is precisely the same as that of abscesses in other organs. The size varies from minute foci hardly as large as a lentil to great cavities occupying nearly the whole of one lobe. Not infrequently several abscesses appear simultaneously in different parts of the brain. The pus is usually greenish yellow. It may be odorless or offensive. Sometimes remnants of the destroyed ("melted") nervous tissue and red blood-globules are mixed with it. The walls of the abscess often bulge out irregularly. The cerebral parenchyma around the abscess for a greater or less distance

exhibits white softening. This is due partly to the pressure and partly to the spread of the inflammation. An abundance of granular cells is generally to be found in the tissues near the abscess.

If the abscess be very large and reach nearly to the surface of the brain, it may sometimes be recognized during life by a distinct bulging and fluctuation. The convolutions on the surface of the affected hemisphere are almost always flattened. If the abscess extend clear to the surface of the brain, purulent meningitis is excited. Abscesses which are centrally situated not infrequently burst into a lateral ventricle. An abscess of long standing may finally become encapsulated—that is, become incased in a smooth, firm layer of connective tissue, which prevents further extension of the process. The pus inside gradually becomes thick and cheesy. Apparently, however, it is very seldom entirely absorbed.

**Clinical History.**—Small abscesses, and even large ones, may for a long while have scarcely any symptoms. This is particularly true of idiopathic abscesses, and of those which develop very slowly and insidiously after apparently insignificant injuries of the head or in connection with chronic inflammation of the middle ear.

In cases following more extensive injuries, the symptoms are more violent from the start; which is also true of many abscesses which develop acutely and enlarge rapidly. The symptoms can hardly be distinguished from acute meningitis. The patient is dull, or grows delirious; he has violent headache and fever. Sometimes the temperature repeatedly rises to a high point. The loss of consciousness becomes more and more complete; and in a comparatively brief time (one or two weeks) there may be profound coma and death. Rarely the violent symptoms abate, and the acute passes into a chronic stage.

The symptoms of cerebral abscess, when it pursues a chronic course, may be divided into (1) the general symptoms and (2) the focal symptoms, resulting from the special position of the abscess. There is no other localized cerebral disorder in which the focal symptoms are so often absent, either for a long while or even throughout the illness. This is partly because the abscesses are often situated in parts of the brain, injury to which does not occasion any demonstrable focal symptoms. Such localities are the white matter of the frontal lobe, and the hemispheres of the cerebellum. A second reason is that an abscess seldom excites indirect focal symptoms by affecting the parts around it.

Among the general symptoms, the most important is a persistent, deeply situated, dull headache. For a long while it may be the only symptom, especially when the abscess is gradually developed after an injury to the head or after aural disease of long standing. The pain is referred mainly to the seat of the abscess; but the exceptions to this rule are not infrequent. Another frequent symptom is vertigo; and in many cases there is vomiting, either after meals or entirely independently of food. Another valuable symptom in diagnosis is the irregular fever, sometimes slight, and sometimes exhibiting great elevations with intervals between them; but in many cases also, particularly where the abscess is encapsulated, there may be no fever whatever. An important negative point is that choked disk is much rarer in cerebral abscess than in case of tumors (*q. v.*).

The general health may be but slightly disturbed. Usually, however, there is decided indisposition. The patient is pale, has no appetite, and loses flesh.

As to the focal symptoms, little need here be added to what is contained in Chapter II of this section. Abscesses involving the motor region of the cortex have been repeatedly found to cause limited epileptiform attacks and paralysis of some one limb. It is particularly characteristic that, as the abscess grows, one symptom of paralysis is added to another, and that often the advance of the

paralysis is ushered in by epileptiform convulsions. Abscesses in the occipital lobe have repeatedly been observed to cause hemiopia, and abscesses in the temporal lobe word deafness; and these facts have been used in making a diagnosis of the location of abscesses. Abscesses in the cerebellum may remain unsuspected for a long while; or the above-mentioned general symptoms may occur in especial severity in such cases.

The duration of chronic cerebral abscess varies greatly. In most cases it lasts for months; and sometimes it has certainly lasted for years. Particularly where the abscess gives rise to no symptoms, or merely to slight and indefinite ones referable to the head, it may last a very long while. It is quite often the case that there are separate attacks of the severe symptoms, such as headache, vomiting, and fever, and that in the intervals of variable duration between these paroxysms the patient feels pretty well.

The final termination of cerebral abscess is almost always fatal. Recovery is not impossible, but it has been seen with certainty in only a very few instances. Death either comes on gradually, where, as the abscess grows larger, all the symptoms become correspondingly aggravated; or it may happen quite suddenly. Sometimes it is brought about by the abscess bursting into a lateral ventricle, or by the supervention of meningitis. Often a cerebral abscess terminates in a sudden and unexpected death, where no immediate cause for the event can be found.

**Diagnosis.**—Although it is often possible to make a correct diagnosis of cerebral abscess, yet there is usually a good deal of difficulty in arriving at such a conclusion, and entire certainty is seldom attainable. The most important points in diagnosis are: (1) The demonstration of some cause such as trauma, chronic otitis, fetid pulmonary diseases, or empyema. (2) The presence of general cerebral symptoms, such as headache, vertigo, and vomiting; and the fact that these are sometimes better and sometimes worse. To aid in excluding tumor, we have (3) the febrile symptoms frequently caused by abscess, but rare in case of tumor; and (4) the extreme rarity of choked disk, which is very frequently occasioned by tumors. The focal symptoms, if there be any, are not characteristic. They grow worse by fits and starts in tumor just as in abscess. One fact, however, is of value, namely, that while tumors (*vide infra*) frequently cause disturbances in the area of distribution of the nerves at the base of the brain (such as paralysis of the motor oculi), an abscess does this only exceptionally. It is often quite impossible to make a differential diagnosis between acute abscess and purulent meningitis, unless focal symptoms are developed. These can be caused by a circumscribed lesion alone, and therefore point to abscess.

**Treatment.**—The only possible way in which to cure an abscess is by operation: the skull is trephined and the abscess laid open. It can be readily seen that such a procedure is feasible in but few instances. We need to be certain that there is an abscess and where it is located, and, finally, that it is so located as to render operation permissible. Under the present antiseptic modes of procedure, the dangers of an operation need not be over-estimated. For particulars we must refer to works on surgery.

If operation be not justifiable, nothing but purely symptomatic treatment is left us. Ice to the head, narcotics, potassic bromide, electricity, and sometimes also the local abstraction of blood, are the main remedies beyond general hygienic measures.

## 2. ACUTE AND CHRONIC NON-SUPPURATIVE ENCEPHALITIS.

While the spinal cord is quite frequently affected by idiopathic circumscribed inflammation (transverse myelitis), analogous cerebral disease is much more

exceptional. The scanty information which we possess upon the subject is as follows:

1. **Idiopathic (Inflammatory) Softening of the Brain.**—In rare instances there are found in the brain quite extensive foci of softening, the pathological anatomy of which is almost identical with that of embolic softening, and yet the afferent blood-vessels do not furnish any explanation of the condition. They have accordingly been termed "foci of inflammatory softening." The mode of their production is unknown. The symptoms resemble closely those of softening from thrombus.

2. **Curable Form of Encephalitis.**—In certain cases pronounced symptoms of focal disease exist for a time, and suggest a tumor or the like; but after some months, or even a still longer time, the symptoms gradually abate, and finally there is complete recovery. Such cases undoubtedly occur. They are usually explained by assuming that there has been a localized inflammation, followed by a restoration to the normal state. The nature of the symptoms, as we have observed them, would seem to imply that the lesion is generally in the neighborhood of the cortex, for there is usually paresis of some one part of the body, often associated with certain symptoms of irritation and impairment of speech. Possibly the recovery of these cases may be assisted by electricity and potassic iodide; but we should never venture upon an absolutely favorable prognosis.

3. **Diffuse Cerebral Sclerosis.**—Diffuse sclerosis of the brain is a peculiar disease, which is usually classed as a chronic inflammation. The whole brain may be involved, or the disease may be confined chiefly to a large part of one hemisphere. There is a very marked increase in the consistency of the brain-substance, so that it cuts like a tough piece of leather. The microscope reveals in many cases, but not in all, diffuse hyperplasia of the neuroglia. In a case which we recently examined there was a decided atrophy of the nervous fibers lying in the white substance of the brain. The disease is rare, and its characteristic symptoms can not yet be stated absolutely. They are developed slowly. The most constant among them seem to be hemiplegia without much change in sensation; symptoms of motor irritation, such as epileptiform convulsions (sometimes general and sometimes unilateral), or single twitchings, which may be rhythmical or like those of chorea; and, lastly, dementia. Where both hemispheres are involved, there are usually marked spastic symptoms in the lower limbs.

The disease has been observed in children and in elderly people. Possibly chronic alcoholism sometimes acts as an ætiological factor. Treatment can be only symptomatic.

Multiple sclerosis of the brain is almost always associated with the same affection of the spinal cord. We have, therefore, already described the disease in the preceding section (page 627).

4. **The Acute Encephalitis of Children.** (*Cerebral Paralysis of Children. Spastic Infantile Hemiplegia of Benedikt.*)—Children not infrequently suffer from a definite form of hemiplegia, which deserves a brief special description.

The patient is usually between one and four years old. The commencement of the symptoms is almost always acute. Having been previously healthy, the child is suddenly attacked with malaise and fever. Very often there is nausea and vomiting, speedily or at once followed by grave cerebral symptoms. There is stupor, and convulsions are particularly frequent. This condition may last but one or two days; or it may continue, perhaps with unabated severity, for two or three weeks. Then the acute symptoms abate, and the child recovers comparatively fast; but it is noticed by the parents to be paralyzed; and this paralysis seldom entirely disappears, although it may diminish.

If such children come under observation after the paralysis has lasted some

time, as is usually the case, their condition is generally as follows: The cranial nerves, as a rule, are but little affected. The main change is in the extremities of one side; and the arm is almost always worse than the leg. The affected parts betray an arrest of development, more or less impairment of motion, in many cases a marked exaggeration of the tendon reflexes, and almost invariably contractures of more or less severity. The muscles, although generally somewhat atrophied, never exhibit the reaction of degeneration. Sensation, as a rule, is unimpaired. Motor symptoms of irritation are found upon the affected side with striking frequency; the commonest are movements like athetosis or chorea (hemi-athetosis, hemichorea); and associated movements are also not infrequent. The constant movements of the fingers resulting from the athetosis sometimes render the articulations so lax that it is possible to make the fingers assume an angle of ninety degrees or even less with the back of the hand, at the metacarpo-phalangeal joint. The child may keep making motions with its paretic arm while walking. It is not very rare for epilepsy to be developed later. There are convulsive attacks, which usually begin on the paralyzed side, but which may later affect the whole body. The intellectual development of many such children is tolerably normal. Others, however, are more or less demented, or betray defective moral sense.

The whole course of the disease suggests very strongly an acute encephalitis. The process is probably in most cases more or less completely limited to the motor region of the cortex, and has hence been called "polioencephalitis."\* It reminds one forcibly of the acute poliomyelitis of children, with a difference merely in the localization of the disturbance. It is not impossible that the two diseases have a very similar, if not identical, ætiology. They can hardly be differentiated in their initial stage; but when further developed they can not be confounded, because the cerebral disease causes unilateral paralysis, leaves the electrical reaction unimpaired, and frequently causes exaggeration of the tendon reflex. It deserves mention that precisely similar phenomena may be presented by children during recovery from measles, scarlet fever, and other acute infectious diseases.

The pathological conditions of the early stage have not yet been studied. Long after the process has run its course, the affected portion of the cerebrum presents marked atrophy with cicatricial contraction. If the surface of the brain has been affected, a corresponding depression is to be noticed ("porencephalia"). At these places the pia is thickened. Sometimes limited cystic formations are found. The pyramidal tract exhibits a secondary descending degeneration. It is thus evident that the process is, from an anatomical point of view, precisely like the atrophy of the anterior cornua occasioned by poliomyelitis.

Of course not all the hemiplegias arising in childhood are due to an encephalitis, for in not a few cases infantile hemiplegia may be due to embolic softening, and perhaps sometimes to hæmorrhage; but in most cases acute encephalitis is distinguished from these by the peculiarity of its initial stage. (There is really no pathological evidence of acute polioencephalitis in children. Sachs and Osler, from the study of a large number of cases, find that the cause of the paralysis is almost always hæmorrhage or embolic softening.—K.)

The treatment at first is to be governed by the same rules as in the initial period of acute poliomyelitis (*q. v.*). The hemiplegic symptoms which persist after the first few months will never improve much. The most we can do will be by means of electricity, massage, and cold baths with friction ("cold rubbing").

[\* This name, however, has been previously applied by Wernicke to that form of external ophthalmoplegia due to changes in the nerve nuclei in the pons (*vide* page 690).—Транс.]

For the epileptic attacks large doses of bromide of potassium are decidedly beneficial.

Only a very few cases of primary acute non-purulent encephalitis of adults are recorded. A short time ago we saw such a case in a young man. Death occurred after a few days' illness marked by very severe cerebral symptoms and at the autopsy one cerebral hemisphere was found studded with many little hæmorrhagic-encephalitic foci.

## CHAPTER VI.

### INSOLATION. SUNSTROKE. HEAT PROSTRATION. THERMIC FEVER.

[**Ætiology and Pathology.**—Under exposure to undue heat, either in the direct rays of the sun, or, during hot weather, in engine-rooms, laundries, and the like, marked effects may be produced on the human organism, manifesting themselves in a widely different manner in different cases. The liability to these effects is much greater with us than in most portions of Europe or in Great Britain, and is enhanced by a moist atmosphere which tends to prevent evaporation from the surface of the body. Attacks may come on at night and under cover as well as by day. While excessive heat is the sole and sufficient exciting cause of the changes and symptoms to be described, exhaustion due to muscular exertion or other cause plays a very important secondary rôle. A vigorous person, however, of regular and temperate habits, can stand much greater heat and exertion than an individual who is debilitated or addicted to the use of stimulants. The frequency of attacks after a full meal has been noted. Those newly arrived in the country are, other things being equal, more likely to succumb than natives or those who have become accustomed to the climate. That high temperature due to solar or artificial heat, or a combination of the two, is the prime causative condition, has been clearly shown by experiments on animals. There is practically nothing to add to the researches of H. C. Wood.

[**Pathological Anatomy.**—In cases of sudden death from shock there are no constant and peculiar lesions. The blood is dark, imperfectly coagulated, and collected in the veins; ecchymoses are frequently found.

After death, due chiefly to abnormally high temperature—that is to say, in cases of thermic fever—the heart, and especially the left ventricle, is firmly contracted from post-mortem coagulation of its myosin; the lungs are apt to be much engorged with dark fluid blood, and may be the seat of hæmorrhage; extravasation of blood under the skin is more or less marked, and hæmorrhage into and about the cervical sympathetic ganglia has also been observed. The membranes of the brain and cord are often greatly congested, and there may be evidences of commencing meningitis. The blood-corpuscles are crenated and show a diminished tendency to the formation of *rouleaux*. Rigor mortis is marked and early in the voluntary muscles as well as in the heart, and is attributable to the same cause. Parenchymatous degeneration of the organs is sometimes found.

[**Symptoms and Course.**—The onset of the attack is usually sudden, though there may be slight premonitions, such as dizziness, pain, or uncomfortable sensations in the head.

It will, perhaps, add to clearness to distinguish three leading forms of attack, it being understood that Nature does not always classify cases as sharply as is done here. The first of these comprises cases of heat prostration, denoted by faintness, syncope, nausea, and sometimes vomiting, with marked muscular and general weakness. The surface of the body is cool, the pulse rapid and feeble. The

great majority of these cases are mild, and the symptoms pass away more or less quickly on placing the patient in the recumbent posture in a relatively cool and quiet place with free ventilation. After a few hours the patient can be removed to his home, and in a day or two has recovered perfectly, except for some sensitiveness to heat or the sun's rays. There may be transient insensibility, or, on the other hand, the case may terminate fatally very soon from general exhaustion and cardiac failure.

The second form includes cases with respiratory as well as circulatory failure, due especially to the exhaustion of the nerve centers presiding over these functions. Under this head come cases of true sunstroke—patients suddenly losing consciousness while exposed to the sun. The skin is cold and the pulse is feeble; death may quickly ensue or recovery may follow, especially if prompt and suitable treatment be instituted. The after-effects of the attack may be very slow to pass away, and may never disappear entirely.

The most striking characteristic of the third form is the great increase in the temperature—a symptom which has given rise to the term thermic fever. In this form premonitions are more common than in the others. The thermometer may register 110° or even more; the skin is burning hot and generally dry; the pulse is slow and full, or quick and jerking; the respiration is quickened, sighing, or even stertorous; the pupils at first are usually contracted; there may be great restlessness; coma and convulsions sometimes occur; vomiting is common; and, toward the close of life, the sphincters are sometimes relaxed. A fatal result is due to apnoea and asthenia combined. What was said with regard to recovery from the second form holds good also for the third.

**Diagnosis.**—This is seldom difficult. The circumstances under which the attack comes on are generally patent; and the hyperpyrexia, if present, is distinctive. Acute alcoholism and meningitis are the chief affections which might lead to error.

**Prognosis.**—The mortality rate of the severer forms of the disease is very high, but the prognosis depends much on the possibilities of securing prompt and skillful treatment. Under this many a case recovers from a seemingly desperate condition. The tediousness and imperfection of recovery have been already alluded to. For long periods in some cases the mental and physical powers are much impaired, and great care has to be exercised as regards exertion, high temperature, and the sun's rays. Insanity is sometimes a sequel.

**Treatment.**—In the first place, much may be done by preventive measures to obviate the necessity for any treatment. A regular and temperate life will do much; and special precautions of an obvious nature should be taken during hot weather by those whose occupations involve a liability to exhaustion and exposure to unusual heat. It would be well if it were generally known that there is comparatively little danger of sunstroke so long as perspiration is free. Many an attack might be averted by noting the activity of the skin and seeking rest and shelter as sweating diminishes. A considerable responsibility rests upon militia surgeons and others in similar positions during hot weather.

Mild cases of heat prostration seldom require other measures than those already indicated in describing the symptoms. If there be nausea, and it seem desirable to give stimulants, they are better given under the skin or by the rectum. The clothing should be loosened; the cold douche and other refrigerating measures are not indicated unless there is fever, and they should then be used with caution.

For true sunstroke, treatment should be active and energetic, the indications being to reduce the temperature of the overheated centers and to stimulate their activity. If a cool or shady spot be near at hand, the patient should be removed to

it and largely stripped of clothing; if not, no time should be lost before resorting to the cold douche on the head and body while stimulants are administered by enema or subcutaneously. External stimulation by mustard or flagellation, and purgative enemata, are said to be sometimes useful. The use of cold externally should not be prolonged in these cases unless there is fever. Nervous exhaustion is the prominent symptom, and all depressing measures are out of place.

The case is widely different with the third form of the attack. Here the immediate danger is from the hyperpyrexia, which must be combated by rubbing the patient with ice, placing him in a tub of water with lumps of ice, or similar measures, until the temperature in the rectum is reduced nearly but not quite to the normal point. In the application of the refrigerating measures the head must not be neglected. The sole indication at first is the reduction of the temperature. Antipyrine subcutaneously has been given in a few cases in the Boston City Hospital, and also in Brooklyn, with good results. After a reduction of the temperature, any symptoms of collapse or exhaustion demand stimulants.

With regard to the employment of bloodletting there is considerable difference of opinion. That cases occur in which this procedure is indicated is undoubtedly true, but they are exceptional; they are characterized by the evidences of great cerebral congestion without hyperpyrexia.

The subsequent management of convalescents from any form of sunstroke is often very important. Prolonged rest, and sometimes change of climate, may be demanded. A symptomatic and common-sense treatment is in place. It has seemed to the editor that quinine, especially in solution with a moderate excess of sulphuric acid, is distinctly useful in those suffering from mild or moderate after-effects of undue heat.]

## CHAPTER VII.

### TUMORS OF THE BRAIN.

**Ætiology.**—The precise causes which lead to the development of tumors in the brain are no more certainly known than in regard to other organs. In most cases the new growths are formed insidiously and gradually in persons previously healthy, without ascertainable cause. A circumstance which deserves mention is that sometimes the first symptoms come on immediately or a short time after some injury to the head; but whether this is a matter of cause and effect, or of coincidence, can very seldom be determined.

The sufferer from cerebral tumor is usually in middle life. Certain forms of tumor, however, particularly solitary tubercles, are comparatively frequent in children. Sex seems to exert a decided influence: men are much oftener attacked than women.

**Varieties of Cerebral Tumor.\***—The most important forms of tumor seen in the brain are as follows:

1. **GLIOMA.**—Glioma is a kind of tumor peculiar to the central nervous system, but seen much oftener in the brain than in the spinal cord (*vide* page 676). Apparently the new growth always originates in the neuroglia, which is the connective-tissue framework of the true nervous matter. As seen under the microscope, a glioma is made up of fibers and cells, the latter being precisely like the

\* From a clinical standpoint, the term "cerebral tumor" usually is meant to include also such tumors as originate in the neighborhood of the brain (as in the base of the skull), if they finally involve the brain itself.

normal cells of the neuroglia, while the fibers seem to consist mainly of the numerous cell-processes. Klebs maintained that the ganglion-cells also take an active part in the new growth; but this has not yet been proven. It is characteristic of gliomata that they are seldom sharply defined, but shade off gradually into the healthy tissue. The affected portion of the brain is usually enlarged, but yet maintains pretty nearly its original shape. On cross-section, the glioma presents a gray or reddish-gray surface. It is usually rather soft, and almost always is very vascular. This great vascularity is not without clinical importance, for variations in the fullness of the blood-vessels, and, above all, sudden hæmorrhages into the interior of the new growth, which not infrequently occur, may produce marked symptoms.

Gliomata are most frequent in the white substance of the cerebral hemispheres, but they are also found in the central ganglia, cerebellum, and elsewhere. They are usually single, seldom multiple.

2. SARCOMA.—It is very seldom that any form of sarcoma originates in the brain-substance. It usually commences in the connective tissue of neighboring parts, in the dura mater, the periosteum of the cranium, or the cranium itself (osteosarcoma). The sarcoma is most often found at the base of the skull, in the form of a circumscribed tumor of varying consistency, and by pressing upon neighboring parts, or by involving them in the diseased process, it may cause the gravest disturbances. Histologically, we have here such varieties as round-celled, spindle-celled, fibrosarcoma, etc.

3. GUMMA AND SOLITARY TUBERCLE.—Both gumma and solitary tubercle are very prone to attack the brain. We shall revert to gumma in the chapter on cerebral syphilis. Solitary tubercles may grow to the size of a cherry or larger. They may be single or multiple, and may occupy any part of the brain. They are most often found in the cortex, and in the cerebellum and pons.

Solitary tubercles and gummata, upon cross-section, have a yellowish, cheesy appearance, and are usually distinctly defined. Histologically, they are composed of granulation tissue. It was formerly no easy matter to distinguish gumma from tubercle in all cases; but now complete certainty is attainable by determining the presence or absence of tubercle bacilli (and likewise of syphilis bacilli).

4. CARCINOMA.—Carcinoma completes the list of such cerebral tumors as have much clinical importance. They are here almost always secondary. It has been our experience that secondary cancer of the brain is principally associated with primary cancer of the breast, or of the lungs and pleura; which fact bears a remarkable analogy to the occurrence of secondary cerebral abscess after primary empyema, pulmonary gangrene, etc.

5. Among the rarer varieties of tumor are *psammoma*, which usually starts from the meninges, is hard, generally comparatively small, and therefore often harmless, and contains calcareous matter, so that it grates under the knife; *cholesteatoma*, a rare tumor which has the brilliancy of mother of pearl; *lipoma*; and *angioma*.

**The General Symptoms of Cerebral Tumors.**—As is the case with all focal diseases of the brain, some of the symptoms of cerebral tumors are connected with the special localization of the new growth. There are definite focal symptoms, varying with the part destroyed, or at any rate functionally impaired, and it is from these symptoms alone that we are enabled to determine the position of the tumor. But, in addition to these focal symptoms, there are certain general symptoms common to almost all cerebral tumors of any size. They are in large part referable to the general compression of the brain due to the enlargement of the new growth. In the first place, numerous clinical facts, which will be immediately enumerated, indicate that whenever there is a tumor of any great size, a large part of the

entire encephalon is subjected to pressure; and, secondly, the anatomical appearances of almost every brain affected by a large-sized tumor lead to the same conclusion. The convolutions are flattened and obliterated, the dura mater is crowded against the cranium, and perhaps thinned or even perforated because of the persistent pressure, or, on the other hand, thickened as a result of chronic inflammation. Now and then the effects of pressure are visible even in the bones of the skull: they are worn thin, or even perforated, or their sutures are loosened. Another result of the general intracranial tension, through its effect upon the venous trunks of the brain, is serous effusion into the ventricles (internal hydrocephalus), which occurs very frequently. The largest effusions are caused by tumors in the posterior cerebral fossa, which directly compress the *vena Galeni*.

The symptoms of cerebral tumors, referable to the effects of general compression, are as follows:

1. Headache is one of the earliest and most constant symptoms. It is usually persistent, although subject to temporary exacerbations and intermissions. The patient describes it as dull, deeply seated, and stupefying. Although it affects the whole head, it is sometimes (not invariably) referred mainly to the neighborhood of the tumor. It is particularly true of persistent occipital headache that it indicates a new growth in the posterior fossa. Sometimes also it is possible, by tapping upon the skull, to find a hyperæsthetic region. Considerable caution, however, should be used in drawing diagnostic conclusions from such observations. The headache usually lasts to the close of the disease, and, even after the patient has become completely comatose, the persistence of the pain is still evident, from his low groans and the way in which his hand seeks his head.

2. Next in frequency to headache are intellectual and mental disturbances. Even the facial expression may be somewhat characteristic, being peculiarly languid, apathetic, and dull. The patient talks slowly, often having to think a long while before knowing what to say. Memory becomes impaired, especially with regard to the most recent events. The interest of the patient in those about him, and the things he used to care for, grows less and less. He has a sleepy, dazed look, and grows careless and untidy. Of course, individual cases present various deviations from this outline; but in general, cases are a good deal alike, although the degree of mental disturbance may vary from a slight dullness to complete dementia.

If unusual fullness of the blood-vessels, a hæmorrhage into the new growth, or some similar cause, induce a sudden temporary increase of tension, there may be such marked symptoms as syncope or an apoplectic shock.

3. Other general cerebral symptoms are vertigo, slowing of the pulse, and vomiting. If, however, vertigo be a very prominent symptom, it implies that the cerebellum is especially encroached upon by the tumor. The retardation of the pulse is a frequent symptom, and not without diagnostic value. It has already been mentioned as one result of general compression of the brain, in connection with cerebral hæmorrhage. The rate may be put at about 50 to 60, or even lower. The pulse is also sometimes slightly irregular. Cerebral vomiting may be one of the earliest and most troublesome symptoms. It frequently occurs independently of the ingestion of food, especially in the morning, and is not infrequently associated with dizziness.

4. Epileptiform convulsions are sometimes excited by cerebral tumors, although many patients are free from them. Such attacks in all probability originate invariably in the cortex of the cerebrum, and it is therefore natural that they should be seen most frequently (as they are) in connection with tumors in the cerebral hemispheres. This rule, however, is not without exceptions. If the convulsions are not general, but are unilateral or confined to distinct portions of

the body, they are to be regarded rather as focal than as general symptoms, and may be utilized for the approximate localization of the lesion (*vide* page 711). A certain amount of information in the same direction may also be got from those attacks which begin unilaterally or in one particular limb, and then quickly involve the entire body.

5. Choked disk is one of the most important general objective symptoms of cerebral tumor. We should never omit to make an ophthalmoscopic examination of the fundus oculi in a case of chronic cerebral disease. Some differences of opinion yet exist in regard to the special pathology of choked disk; but we may regard it as extremely probable that the main factor in its production is the purely mechanical one of general compression of the brain. The original view of Von Graefe was that the increased intracranial pressure obstructs the venous return through the vena centralis retinae into the cavernous sinus. The opinion which prevails at present is that advanced by Schmidt and Manz—namely, that the increased tension forces the cerebro-spinal fluid into the lymph-sheaf of the optic nerve (Schwalbe), and that the "*hydrops vaginae nervi optici*" thus produced compresses the nerve and the blood-vessels which traverse it. [Leber and Deutschmann have shown pretty conclusively that the increased pressure is not the chief cause of optic neuritis. It favors its production, but probably there must be the presence of some irritant as well, in order to produce the inflammation.—K.] At any rate, choked disk is not a focal symptom. The tumor occasioning it may have any position, if only it gives rise to general compression of the brain.

Disturbances of vision may or may not be entailed by choked disk; the patient may have amblyopia, defects in the field of vision, or even total blindness. In some few instances, amblyopia has been one of the earliest symptoms of cerebral tumor, insomuch that the patient has applied first of all to an oculist. Usually the sight is preserved for quite a long while, in spite of the abundant objective evidences of choked disk. The latter consist of swelling of the disk, marked distention and tortuosity of the veins, possibly hæmorrhages (from passive congestion), and cloudiness of the disk, although the retina still exhibits its normal transparency. It is not until the long-continued congestion impairs nutrition to such an extent as to cause atrophy of the optic nerve that vision is much impaired.

6. The last general symptom to be mentioned is general loss of flesh and strength. This often appears comparatively early. It is in large part due to the small amount of food taken, vomiting, and wakefulness; but it is not impossible that the grave cerebral disorder itself exerts a direct and unfavorable influence upon all the processes of nutrition. There is in most cases, also, a tendency to obstinate constipation.

**Tumors in the Different Parts of the Brain—their Focal Symptoms.**—The symptoms above discussed indicate the existence of a tumor, but not its particular location. Other phenomena are necessary to enable us to localize the disease, but it is not exceptional to have none but the general symptoms. Tumors in the white matter of the frontal lobe, or such as affect the corpus striatum, as well as others, may run their course without any focal symptoms; but most cases afford evidence which points with more or less certainty to the exact position of the tumor. Almost all of these focal symptoms have already been fully discussed in Chapter II of this section, and their interpretation follows the rules for all focal lesions of the brain. We may therefore be brief here. It is necessary only to emphasize the fact that with regard to cerebral tumors, as well as other lesions, focal symptoms should be divided into the direct and the indirect. Direct focal symptoms are the immediate result of the destruction of nervous tissue by the new growth, while the indirect are excited by the pressure exerted by the tumor

upon the parts closely surrounding it. This pressure varies with the amount of blood in the vessels of the new growth, and therefore the indirect symptoms may undergo temporary exacerbations and remissions. An intermediate position is occupied by those focal symptoms which occur in many cases as the result of certain anatomical changes secondary to the new growth. Not infrequently there is white softening of the substance of the brain around the tumor proper. Probably this condition is generally the result of a compression of the minute blood-vessels surrounding the new growth, but sometimes it is the sequel of an obliterative endarteritis (Friedländer). The latter cause is especially operative where the tumor is a gumma or a solitary tubercle.

1. Tumors of the cerebral hemispheres generally lead to the gradual development of hemiplegia—a focal symptom which is to be regarded as partly direct and partly indirect. Since the new growth is often situated near the cortex, symptoms referable to that region are especially frequent with tumors of the cerebrum. It is therefore not infrequently the case that the hemiplegia is the result of the successive paralysis of single portions of the affected side; for instance, first there is only facial paralysis, then, in addition, paralysis of an arm, then of the lower limb. Very often the extension of the paralysis is accompanied by convulsions, which either are confined to one limb or one side of the body, or are universal. There may be still other focal symptoms, varying with the exact location of the tumor. Thus, there is hemianæsthesia, if the parietal region or the posterior part of the internal capsule be affected; hemiopia, if an occipital lobe suffer; aphasia, if the neighborhood of the left island of Reil be involved, and so on.

2. *Tumors at the Base of the Brain.*—The base of the brain is a very favorite place for new growths. The symptoms are in a majority of cases quite characteristic. Some of the tumors spring from the base of the skull; among these are many sarcomata and syphilitic growths ("gummatous periostitis"). Other tumors originate in the meninges, especially the dura; and still others from the brain itself. Of these last, it is remarkable that some spring from the pituitary gland. The exact starting point is very seldom of much clinical importance, for all the parts mentioned are in such close proximity to one another that there is no great difference in the symptoms produced. We can only decide that there is a tumor in this or that place at the base of the brain.

Tumors at the base of the brain owe their characteristic clinical stamp to the frequency with which the cranial nerves at the base are involved. The anatomical relations are such that these nervous trunks are often compressed by the new growth or actually incorporated in it. Of the symptoms thus occasioned, the most frequent is paralysis of the *motores oculi* (oculomotor and abducens). This is at first usually unilateral, but it may later affect both sides. If one of the optic tracts be involved, hemiopia may result, and pressure upon one optic nerve may produce unilateral choked disk with unilateral disturbance of vision. Tumors of the pituitary gland are especially prone to cause symptoms referable to the optic nerve at an early period. Lesions of the trigeminus not infrequently cause disturbances of sensation in the face, and occasionally also paralysis of the muscles of mastication. The trunk of the facial often suffers. The facial paralysis thus occasioned throws considerable light upon the diagnosis, for there is usually to be found in the paralyzed muscles the reaction of degeneration, showing that the paralysis is peripheral. We have therefore reason to assume that the lesion is situated at the base of the cranium, rather than central. Another factor is almost always present to support the idea of a peripheral lesion—namely, the frontal muscles are involved (*vide* pages 561 and 731). Peripheral paralysis of the hypoglossal nerve may also be produced by tumors at the base of the brain; but this is much rarer than facial paralysis. Whether other nerves of special

sense besides the optic are disordered is a question about which we possess little information as yet, but probably careful examination will not infrequently reveal changes in them.

As might naturally be expected, various degrees and forms of paralysis in the extremities are often found in combination with the above disturbances of the cranial nerves. Such conditions are most frequent where the crus cerebri, with its pyramidal tract, is affected. There is no need of enumerating all the possible varieties of symptoms. We must consider them all carefully in each individual case, and then, by bearing in mind the anatomy of the parts, we shall, in a majority of instances, be enabled to determine with some approach to accuracy the place at the base of the brain where the new growth must be. Sometimes, but not often, we may be led into error by tumors which, though situated in the brain-substance and at a comparative distance, yet by their pressure give rise to indirect symptoms referable to the cranial nerves at the base.

3. *Tumors of the Cerebellum.*—We shall refrain from describing the symptoms which may be excited by tumors in other parts of the brain, with a single exception. Tumors of the cerebellum are comparatively rather common, and deserve a brief notice. The direct focal symptoms of cerebellar lesions, such as the peculiar pitching gait and the vertigo, have been discussed at page 723. But cerebellar tumors generally occasion also very strongly pronounced general symptoms—namely, headache, mainly occipital; sometimes a spasmodic and persistent stiffness of the neck; vomiting; and visual disturbances, mainly due to the frequent existence of choked disk. Analogous to this last symptom would seem to be disturbances in other nerves of special sense. Thus, where the general intracranial pressure is elevated, the acoustic or olfactory nerves seem liable to passive congestion. Tumors in the posterior fossa have several times been found to occasion bilateral anosmia and deafness; and they should always be considered where such a condition is found.

(In view of the increasing importance of the focal diagnosis of tumors of the brain, it has seemed advisable to insert the following brief summary of the focal symptoms of tumors in different parts of the brain:

*Prefrontal Region.*—Marked mental impairment; symptoms of invasion of the central region (Jacksonian epilepsy, aphasia); disturbances of smell.

*Central Region.*—Jacksonian epilepsy; monoplegia; partial anæsthesia; motor aphasia.

*Posterior Parietal Region.*—Word-blindness; disturbance of muscular sense (?); homonymous hemianopsia.

*Occipital Region.*—Homonymous hemianopsia; soul-blindness.

*Temporo-Sphenoidal Region.*—Latent region. Word-deafness; disturbances of taste, smell, and hearing (?).

*Corpus Callosum.*—Latent region. Progressive hemiplegia, often bilateral from invasion.

*Optico-striate Region.*—Hemiplegia; contracture. In posterior part, hemi-anæsthesia, homonymous hemianopsia, post-paralytic chorea, athetosis.

*Crus Cerebri.*—Crossed paralyses of oculomotor nerve and limbs.

*Corpora Quadrigemina.*—Oculomotor paralyses; reeling gait; blindness (?); deafness (?).

*Pons and Medulla.*—Crossed paralyses of face and limbs, or tongue and limbs. Other cranial nerve lesions.

*Cerebellum.*—Marked cerebellar ataxia; marked vomiting. Often a latent region.

*Base, Anterior Fossa.*—Mental impairment; disturbances of smell and vision; exophthalmus.

*Base, Middle Fossa.*—Disturbance of vision; oculomotor disturbances; hemiplegia.

*Base, Posterior Fossa.*—Trigeminal neuralgia; neuro-paralytic ophthalmia; paralyses of face and tongue; disturbance of hearing; crossed paralyses.

*Hypophysis.*—Disturbance of vision; oculomotor disturbances.

It also is of importance, in cases which may come to operation, to determine whether the growth be cortical or subcortical. Seguin has given certain rules which, however, are not absolute. "In favor of a strictly cortical or epicortical lesion are these symptoms, none of them having specific or independent value: localized clonic spasm, epileptic attacks beginning by local spasm, followed by paralysis; early appearance of local cranial pain and tenderness; increased local cranial temperature. In favor of subcortical location of a tumor: local or hemiparesis followed by spasm; predominance of tonic spasm; absence, small degree, or very late appearance of local headache and of tenderness on percussion; normal cranial temperature."—K.]

**General Course of Cerebral Tumors.**—The symptoms of these growths almost always cover a long period of time. Exceptionally a tumor remains latent till a hæmorrhage or some similar event takes place in it, giving rise to sudden and grave symptoms, and possibly to an equally sudden termination. The rule is, however, for the phenomena to develop gradually. According to the location of a new growth, either the general or the focal symptoms may come first into prominence. They generally occur in the order named. First of all is an ill-defined, deeply seated headache, and by degrees all the other general and focal symptoms follow after. The symptoms may vary repeatedly and greatly in severity, a fact due mainly to the varying pressure of the tumor on neighboring parts. Repeated mention has already been made of the sudden exacerbations which may come on, especially in case of the vascular gliomata.

The entire duration of the disease is usually at least some months, and may be one or two years or more. The termination is almost invariably unfavorable. Death may be rather sudden, or it may not come till after a long period of wretchedness. Fortunately, however, the lameness, blindness, and marasmus are frequently made less terrible to the patient because of his mental debility. Recovery is possible only where the growth is syphilitic. It is indeed possible that solitary tubercles may also end favorably, but the matter is still in doubt.

**Diagnosis.**—The main points in support of a diagnosis of cerebral tumor would be the gradual onset and continuous slow increase of the general symptoms above detailed—namely, headache, vertigo, vomiting, convulsions, dementia, etc. The most constant of these symptoms is the headache. They all indicate the development of some chronic brain trouble, a tumor being the most probable if there be no definite ætiology to suggest some other process, such as traumatism resulting in abscess, or syphilis. Much stress may also be laid on the choked disk, which is much less often seen in case of abscess or softening than of tumor.

The general symptoms indicate that a tumor of the brain exists; but, in order to learn the position of that tumor, we have to rely mainly upon the focal symptoms. Their gradual development and the way in which one new symptom is slowly added to another, also give further ground for the opinion that some continuously progressive disease exists, and most likely a cerebral tumor. Of diseases with a similar course, abscess is recognized by the absence of choked disk (an important point), frequently by febrile symptoms, and by its ætiology (trauma). Inflammatory and thrombotic softening, if they come on slowly, usually produce less general disturbance than do tumors; they seldom cause a choked disk, and (unless of syphilitic origin) are much rarer before middle age than tumors of the brain. Sclerosis sometimes simulates cerebral tumor; but

here also there is no choked disk; the disease lasts much longer (five or ten years, or more), and, inasmuch as the sclerosis is usually multiple, there is frequently too great a complexity of symptoms to warrant the assumption of one solitary lesion.

[We must, however, bear in mind that, in about one seventh of the cases, tumors are multiple.—K.]

Certain rare cases of chronic circumscribed meningitis can not be differentiated from a tumor. They generally occur at the base, lead to a considerable thickening of the tissues, and they may simulate all the symptoms of a new growth in this region. Occasionally, also, chronic hydrocephalus is confounded with tumor of the brain. We met with a case of dropsy of the fourth ventricle which presented during life a perfect picture of tumor of the cerebellum.

As to the nature of a new growth, we can not go beyond surmises. If the focal symptoms indicate that the tumor is in the substance of the brain itself, our first thought would be of a glioma, because it is by far the commonest sort of growth in that situation; and, as has been stated, certain peculiarities in the course of the disease (especially if new symptoms add themselves abruptly) would make glioma probable. If, on the other hand, the tumor be at the base, it is most apt to be sarcoma, which is the most frequent form of new growths here. When symptoms referable to the optic nerve occur noticeably early, a tumor of the pituitary gland is to be thought of. In all cases, and especially in tumors at the base of the brain, we should bear in mind the possibility of syphilis. The previous history and the entire body of the patient should be closely searched with this point in mind; its therapeutic importance need not be dwelt on.

One special form of tumor deserves a brief mention here—namely, large cerebral tubercles. The growth may be single or solitary, or it may be multiple. It is seen chiefly in childhood, and any chronic cerebral disorder in a child should suggest the possibility of such a growth. It is rendered all the more probable by the co-existence of the signs of tuberculosis elsewhere, as in the lymph-glands, lungs, or bones. The symptoms are analogous to those produced by other tumors. Among the most frequent phenomena are headache and convulsions. The latter are often unilateral. There may also be all sorts of focal symptoms, according to the locality of the lesion.

**Prognosis.**—Except gummata, all tumors of the brain have a very unfavorable prognosis. It is said that in very rare instances tubercular growths have been arrested or cured; but in practice we can never rely upon any such result. In all other cases recovery is next to impossible. The time intervening between the appearance of the first symptoms and death varies greatly, as has been said. We should therefore be very cautious in predicting the duration of the illness. It seldom, however, exceeds one or two years, and sudden death without any warning may occur at any time.

[Tubercular growths are occasionally found at autopsies, which have become encapsulated, and have apparently existed for years without causing symptoms. In some cases, especially with tubercular growths in children, the symptoms diminish and the patient may live for years, suffering only from the blindness, etc., caused by the growth. Other cases may present only mild symptoms, and the patient may lead a fairly comfortable life for years.—K.]

**Treatment.**—Inasmuch as the nature of the tumor can not be determined with absolute certainty in any instance, antisyphilitic treatment should always be tried. Forty to seventy-five grains of mercurial ointment (grm. 3-5) should be used by inunction, and thirty to seventy-five grains (grm. 2-5) of potassic iodide should be given internally each day. If the new growth be syphilitic, much benefit may be done in this way. It must be confessed that the treatment is generally of little

avail, because the tumors are not of a syphilitic character; although it may be that iodide of potassium sometimes has a temporary good effect upon other forms. A long-continued course of arsenic has also been recommended, in order to check the growth of the tumor. This remedy particularly deserves a trial where there is a suspicion of solitary tubercle.

Beyond what has just been indicated, treatment must be symptomatic. The headache is combated with ice-bags and narcotics; the convulsions require bromide of potassium or the inhalation of chloroform; the vomiting is lessened by rest in bed, opium, and bits of ice. The general care and nursing of the patient are very important, so that bedsores and the like may be avoided if possible.

[Within the last few years it has been demonstrated that tumors of the brain may be successfully removed by surgical interference. Out of forty-six such operations, thirty recovered from the operation, although in some cases the growth recurred. Hence the propriety of such an operation should be considered in every case, but unfortunately the growth must be in an accessible region and the focal diagnosis must be tolerably certain, so that an operation is indicated in less than ten per cent. of the cases. In cases with intense headache, where removal is impossible, relief may be obtained by removing a portion of the skull and tapping the lateral ventricles, and thus taking off pressure. Such an operation will relieve the pain, but it causes cerebral hernia, and probably hastens death.—K.]

## APPENDIX.

### HYDATIDS OF THE BRAIN.

It was stated on page 441, that the *cysticercus cellulosæ*, which originates from the *tænia solium*, may occur in great numbers in the brain. The *cysticerci* most frequently occupy the pia mater, but generally project downward into the cortex of the brain. The meninges not infrequently exhibit signs of chronic inflammation, and may present hæmorrhages, which are not always minute. If there are numerous *cysticerci* in the neighborhood of the ventricles, a varying degree of internal hydrocephalus usually develops. The individual *cysticerci* are usually enveloped in a capsule of connective tissue, but may be entirely devoid of such a covering.

No characteristic clinical sketch of hydatids in the brain can be drawn, because the symptomatology of each case differs according to the number and position of the parasites. Sometimes *cysticerci* produce absolutely no symptoms, and are discovered incidentally at the autopsy. In other instances they cause a long and tedious illness. Epileptiform convulsions seem to be the most frequent symptom, and must be due to the position of the *cysticerci* in the cortex of the brain. These may, like true epileptic attacks, come on only at certain times when the general condition is otherwise good; or permanent general cerebral symptoms may also appear, such as persistent headache, vertigo, and mental disorder. Focal symptoms are likewise possible, but on the whole are rare.

The diagnosis can never be made with absolute certainty. The presence of *cysticerci* in the brain may be suspected when the above-mentioned symptoms occur in a butcher or other person who is from his calling especially exposed to infection, or who is known to have had or still to have a tapeworm, or in whom *cysticerci* have been demonstrated in some other part of the body, such as the skin.

We know of no remedy capable of destroying the *cysticerci*. Treatment, therefore, can be only symptomatic. [In a few cases, chiefly in Australia, the *cysticerci* have been successfully removed by surgical operations.—K.]

## CHAPTER VIII.

## CEREBRAL SYPHILIS.

**Ætiology.**—The importance of syphilis as an ætiological factor in many chronic diseases of the nervous centers has been repeatedly adverted to in preceding chapters. Although with regard to its influence upon the spinal cord in exciting tabes dorsalis and certain forms of myelitis there is still some obscurity, the brain presents with comparative frequency disorders unmistakably referable to constitutional syphilis.

Cerebral syphilis is almost always a tertiary symptom. It is only in exceptional instances that cerebral symptoms are produced by the end of a year from the date of the initial lesion. Usually the interval is several years, and it may be ten or even twenty.

Liability to the disease does not seem to be essentially influenced by age or sex. Even hereditary syphilis has been proved to cause diseases of the nervous system. But it can not be denied that a predisposition to cerebral syphilitic disease is often engendered by those influences which are apt to promote cerebral disease in general. Just as the position of syphilitic cutaneous lesions is often determined by external irritation at some one place on the skin, so the disease seems more liable to attack a brain which is exposed to certain unfavorable conditions than one which is perfectly normal and vigorous. Such conditions are inherited tendency to nervous diseases, various injurious mental influences, poisons, in a broad sense, and traumatism. It need hardly be said that even a previously sound brain does not enjoy immunity from the affection.

**Pathology.**—As far as has yet been ascertained, there are two chief forms assumed by syphilis in this organ: (1) a circumscribed syphilitic tumor, the gumma, and (2) a disease of the arteries of the brain, which is usually quite extensive. There is no essential difference underlying these two varieties. They may also occur in combination with each other. The disease of the blood-vessels is really a syphilitic new growth affecting the walls of the arteries.

The circumscribed syphilitic tumors are yellowish or grayish-red, and frequently cheesy in the center. Their most frequent seat is the dura mater or the subarachnoid spaces, whence they spread to the brain-substance; but exceptionally they may originate in the substance of the brain itself. Histologically they are made up of granulation tissue of varying degrees of vascularity, and presenting yellow spots usually visible to the naked eye. These spots are of firmer consistency than the rest of the growth, and have undergone coagulation-necrosis (have become cheesy). Circumscribed gummata in the brain which have become cheesy do not differ essentially in microscopic appearance from a collection of tubercles (see preceding chapter). The new growth sometimes takes on a more diffuse form in the meninges, particularly at the base (gummatous meningitis). Often the originally delicate granulations become transformed into a firm connective tissue, forming extensive cicatricial induration.

The syphilitic disease of the arteries was first fully appreciated by Heubner, who has described it accurately. It is usually most pronounced in the arteries of the base of the brain, and especially in the middle cerebral artery and its branches. Even the unaided eye detects a grayish opacity in the arteries. They feel firm and stiff, and on cross-section their walls are found to be thickened, either uniformly or in some places more than in others. This causes no inconsiderable narrowing of the lumen, or even its obliteration, particularly if the last gap be closed by the formation of a thrombus. The microscope shows that the new growth originates chiefly in the intima of the vessel, where there is a hyperplasia of the

endothelium, and a gradual transformation of it into a firm connective tissue. But the adventitia also undergoes a gradual thickening of considerable extent. Syphilitic endarteritis presents no distinctive histological characteristics. Entire certainty that the inflammation is due to syphilis can be attained only by discovering other evidences of syphilis, whether in the brain or elsewhere, or from the personal history and the previous course of the disease.

The great clinical importance of syphilitic endarteritis is due to its cutting off the normal supply of blood from the regions supplied by the diseased arteries. If the occlusion be complete, cerebral softening is inevitable, as in ordinary embolism and thrombosis of cerebral arteries; and, inasmuch as the middle cerebral artery is particularly liable to the disease, syphilitic softening is most often found in the region supplied by this vessel.

**Clinical History.**—The variety of the pathological processes and of their location produces a corresponding variety in the symptoms of cerebral syphilis. We shall therefore be obliged to limit ourselves to a brief description of some few types of the disease which are oftenest met with (Heubner).

1. The group of symptoms may be mainly those of a cerebral tumor. Here there is a circumscribed new growth, situated either at the base, or upon the convexity of the brain (and in the meninges). If at the base, the symptoms are analogous to those discussed on page 752. The focal symptoms are often preceded for a certain length of time by general cerebral symptoms, such as persistent headache, worse at night, wakefulness, mental depression, and impairment of memory. Then paralysis of the nerves at the base of the brain comes on: the nerves controlling the motions of the eyeball suffer the most frequently, but the facial and other nerves may also be affected.

In the second subdivision, where the syphilitic new growth is mainly upon the convexity of the brain, the picture is a tolerably characteristic one. Often in this case, also, prodromata similar to those just enumerated precede the severer symptoms. Then appear violent epileptiform convulsions. These often come on very suddenly, and may recur at considerable intervals or in quick succession. There are usually still other symptoms of cortical disturbance, especially paresis of one limb or even of one half the body; very frequently slight disturbance of speech (stumbling over syllables), referable to the cortex, and indications of mental impairment. Many of these cases reach a fatal termination comparatively early. The epileptiform convulsions become more and more frequent, and unconsciousness increases into a deep coma ending in death. But it is in cases of just this sort that prompt and energetic treatment may accomplish a great deal.

2. Another common and important variety of cerebral syphilis is characterized chiefly by syphilitic arteritis. Not infrequently there is a prodromal stage; then, as a result of the occlusion of some vessel, which often occurs quite suddenly, there is a pronounced apoplectic attack, followed in most cases by hemiplegia. The intensity of the initial shock may vary greatly; sometimes there is only a slight dizziness, sometimes there is a coma that lasts for days. Sometimes the shock is succeeded by a peculiar condition of mental confusion and dullness, which may persist for weeks. In severe cases, death is speedy, and is usually ushered in by a great rise of temperature. Other patients improve more or less rapidly, especially under proper treatment.

Apoplectic attacks of this sort may recur after temporary improvement has taken place, and may be associated with all sorts of nervous symptoms.

3. In a third class of cases, cerebral syphilis assumes the form of a diffuse chronic disease of the brain, closely resembling multiple sclerosis or certain types of progressive general paralysis of the insane. Perhaps it would be more correct to say that certain cases of cerebral syphilis are identical with general paralysis.

There are gradual impairment of memory and of speech, and various motor symptoms (tremor, ataxia, paralysis of single members). The intellectual powers grow less and less, and, after passing years as a physical and mental wreck, the patient at last dies, unless indeed he has the good fortune to be carried off earlier, in some apoplectic or epileptiform attack. In such cases the autopsy sometimes also shows specific syphilitic changes, especially in the smaller vessels; but we find chiefly atrophic and degenerative processes in the nerve-fibers, which, in our opinion, should be separated from the special syphilitic new formations under the name of "post-syphilitic changes."

**Diagnosis.**—While some few of the phenomena produced by cerebral syphilis are rather characteristic—we refer, for instance, to the intense prodromal headache, the epileptiform convulsions, and the apoplexy—still these symptoms alone are never sufficient to establish the diagnosis, for they may be precisely simulated in cases of tumor, softening, hemorrhage, multiple sclerosis, and other cerebral diseases. The most important diagnostic criterion is in every case the demonstration of the etiology—that is, a previous infection with syphilis. We can not here describe in detail the methods of determining this fact. The history of the patient, as well as previous specific affections—such as, in women, miscarriages, abortions, etc.—and the objective signs on other parts of the body, are the two sources of information. There may be scars on the skin or mucous membranes, enlarged glands, ulcers, tibial periostitis, or changes in the testicles. Age is also important: thus an apoplectic attack in a young person would suggest syphilis, because the other causes of such an attack operate chiefly upon the aged. The results of treatment often throw considerable light upon the diagnosis. As there is nothing to lose and much perhaps to gain, we should always give specific remedies in doubtful cases. If they prove successful, the diagnosis of syphilis receives strong confirmation.

**Prognosis and Treatment.**—There are few severe and dangerous diseases where timely and appropriate treatment is attended with so much success as that achieved in many cases of cerebral syphilis. In order, however, both to understand the favorable results and not to be misled by the failures, we need to gain a clear idea of the way in which antisyphilitic remedies can be of benefit. They can accomplish this only by causing the dissipation and absorption of the new growth—that is, the gumma or the swelling of the intima. If this be effected, the surrounding parts are of course relieved from pressure, and the circulation becomes unimpeded. If the tissues still retain functional power, they resume their duties and all symptoms of disease vanish. But when the tissue has already been considerably impaired by the compression, or by the scanty blood-supply, the results are quite different. Even then the nervous trunks at the base of the brain may gradually become regenerated; but such parts of the true cerebral parenchyma as have undergone softening have lost their functional capacity forever. In this case, antisyphilitic treatment is unavailing.

It is therefore obvious that the first essential of success is to begin treatment as early as possible. The sooner a correct diagnosis is reached, the sooner will existing symptoms be relieved, and further danger be averted. The method of treatment which will probably accomplish all that can be accomplished, and in the shortest possible time, is energetic mercurial inunction. At least a drachm (grm. 3-5) of mercurial ointment must be rubbed in every day at first, according to the ordinary method. We should not venture to restrict the diet unless the patient be well nourished and "full blooded." If he be anæmic and feeble, a generous regimen is demanded. Usually the internal administration of iodide of potassium is combined with the inunctions; we should give thirty to forty-five grains (grm. 2-3), or, in severer cases, even a drachm or a drachm and a half (grm. 4-6), daily.

[In this country iodide of potassium is given much more freely. In cases where syphilis is suspected, we may safely begin with doses of thirty grains (grm. 2) three times a day. If the symptoms be urgent, the dose should be rapidly increased until the patient takes three or even four drachms (grm. 10-15) three times a day. If the patient have syphilis, the danger of iodism seems less. The drug must be given in large amounts of water, and it is better borne if given in Vichy or Giess-hubler water. Sometimes the stomach will not tolerate the extreme doses.—K.] The same remedy should also be given afterward, for a long time, in smaller doses. Where there is no benefit at all after twenty or thirty inunctions, there is little prospect of any appreciable improvement. In favorable cases, the mercury often begins to produce some effect after the fifth or sixth inunction; and it may cause astonishingly rapid improvement. Potassic iodide alone is sufficient for the milder cases only, where there is merely headache, trigeminal neuralgia, or paralysis confined to the *motores oculi*.

In many cases some symptomatic treatment is also required. Narcotics, applications to the head, electricity, baths, etc., are employed, as in other chronic cerebral diseases, and they often supplement very efficiently the specific remedies.

## CHAPTER IX.

### PROGRESSIVE GENERAL PARALYSIS OF THE INSANE.

(*Paralytic Dementia, Parotic Dementia, General Paresis.*)

**Preliminary Remarks.**—Although the description of mental diseases is not properly a part of the plan of this book, we must nevertheless make an exception of one disease of the sort, namely, the so-called progressive general paralysis of the insane, or paralytic dementia, which in medical parlance is often abbreviated into "general paralysis." We consider it advisable to make this exception, because a great part at least of the symptoms of general paralysis are purely of a physical nature, and also because a knowledge of this disease, which is so common and so fatal in its results, is of the greatest importance for the general practitioner.

We must thank the French alienists Boyle (1822) and Calmeil (1826) for the first clinical descriptions of general paralysis, by which it was more sharply differentiated than previously from other diseases which run a like course. A more accurate knowledge of the different symptoms, and the anatomical changes to which the morbid symptoms must be referred, has, however, only of late years been rendered possible by the introduction of better methods of investigation. Accordingly, we must now say that general paralysis is a disease which may attack the most diverse portions of the whole central nervous system\*—the brain and spinal cord—at the same time or successively, but in which, of course, we can make out certain rules as to the predisposition of individual portions to disease, and as to the order of the symptoms. General paralysis begins most frequently in those regions of the cerebrum which have an immediate relation to the regular course of the psychical and certain psycho-motor processes. Mental and motor symptoms accordingly form the introductory features of the disease in most cases. More extensive regions of the central nervous system are gradually in-

\* At present hardly anything is known in regard to a primary implication of the peripheral nerves in the whole process of general paralysis. No theoretical objection can be raised to the supposition of such an implication.

volved in the morbid process, which goes hand in hand with a progressive degeneration of all the higher intellectual faculties, while at the same time many physical disturbances dependent upon nervous changes constantly increase.

**Etiology.**—General paralysis is a common disease, and apparently demands a heavier quota from the better and more highly educated classes than from the lower classes. We may assume that, on the average, one tenth of all patients committed to the insane asylums are general paralytics. In most patients the beginning of the disease falls in the period between the thirtieth and fiftieth year. The disease is much rarer in advanced life. In young people under twenty it has hardly ever been observed. There is no doubt that the male sex is much more frequently affected than the female, but the number of cases of general paralysis among women is not very small.

What is the special cause of general paralysis? A generally acceptable answer can not be given; but the theory is constantly gaining ground, and we agree to it, from our own experience, that by far the most important causal factor is a previous syphilitic infection. Such an infection can be made out in at least seventy-five per cent. of all cases. In this regard precisely the same conditions exist, and, of course, the same difficulties in the interpretation of this relation are to be considered, as we have previously mentioned in the account of the dependence of tabes dorsalis on syphilis (see page 632), a circumstance which again is not without significance, since intimate points of connection are to be found between tabes and general paralysis (*vide infra*). If we consider that general paralysis depends upon a previous syphilis, we have an easy explanation of most of the other peculiarities in the onset of the disease, especially the above-mentioned influence of age and sex, the decidedly common occurrence of the disease in persons in certain callings—such as artists and officers—the frequency of the disease in large cities in distinction from its rarer occurrence in the country, etc.

Besides the etiological factors named, which, in our opinion, are the most important, all other "causes" of general paralysis may well be regarded as merely predisposing. Mental overexertion has the greatest significance, especially if it be associated with psychical irritation. In merchants, civil officers, etc., who suffer from general paralysis, such a previous overexertion can often be made out. In some cases injury to the head or insolation is claimed to be the cause. Hereditary predisposition to nervous diseases plays perhaps a certain part in the origin of general paralysis, but by no means a very large one.

**Clinical History.**—General paralysis usually begins so slowly and gradually that a definite period for its beginning can hardly ever be given. In addition, it is often clear, at a period when the disease is already fully developed, that certain early symptoms, whose nature was at first not correctly recognized, ought to have been regarded as the initial symptoms.

The first symptoms of the disease in the psychical domain usually consist of the gradual appearance of a change in the whole nature and in the mental individuality of the patient; wherein, however, the mental disturbance usually shows from the start the character of weakness—that is, of a lessened capability of psychical exertion. The patient's ordinary mental work no longer goes on as easily as before. His memory is uncertain, and there are marked forgetfulness and inattentiveness, which were previously quite impossible for him to exhibit. The patient is often disorderly in his dress, and violates the ordinary social rules of decency and morality. Since his judgment as to the value and significance of things is uncertain, he commits purposeless actions, wastes money, commits crimes, is dissolute, etc. In these respects, too, the increasing mental dullness often ap-

pears, since the patient becomes incapable of any higher intellectual, æsthetic enjoyment, and since the nobler sway of feeling finally becomes dulled, and can no longer exert any lasting influence upon his actions. Besides all these signs of beginning mental weakness, we often notice, on the other hand, an abnormal irritability. The patient easily becomes agitated, or gets angry; but these humors rapidly pass away without leaving a lasting impression. We easily understand how this change in the whole personality of the patient must distress and alarm his family, since the relatives at first can not understand at all why the patient is now "so different from what he was."

In the first period of the disease a subjective feeling of illness is frequently present. The patient himself notices that his mental capacity, especially his memory, is diminished, and he very often becomes extremely anxious on this account. It frequently happens that certain subjective sensations are also noticed, a feeling of confusion in the head, pressure in the head, dizziness, rheumatoid pains, etc. The sleep is disturbed, as a rule, and also the appetite and the digestion. If such a patient comes to the physician with his complaints, it unfortunately only too often happens that he is in the beginning regarded as "neurasthenic," and is treated accordingly.

Careful observation, however, may even now usually discover the disease with certainty. The beginning mental disturbance is usually more apparent to the family than to the physician, who has not known the patient before and who sees him only cursorily, but it can usually easily be confirmed on a somewhat more searching examination of the patient. We generally succeed best by making the patient reckon; he often makes the greatest mistakes in simple examples in multiplication; especially does he forget to add numbers carried in the mind, etc.

Certain motor symptoms, however, which usually come on in the early stages of the disease, are of the greatest diagnostic significance, especially peculiar disturbances of speech and handwriting. The paralytic disturbance of speech shows itself first in the form of stumbling over syllables (*Silberstolpern*), or literal ataxia. The individual sound (in distinction from bulbar paralysis) can be pronounced quite correctly, but the combination of different sounds in the whole word causes increasing difficulties. It is a good plan, in order to recognize the first beginnings of this difficulty, to have the patient pronounce a few difficult words, such as "third riding artillery brigade," "representative government," "initiative," "electricity," etc. We often hear "artralleriry" instead of "artillery," and like blunders. In the later stages of the disease the speech is sometimes almost wholly incomprehensible. We also observe other more complicated aphasic disturbances, such as paraphasia, persistent repetition of the same word, etc. In such cases the patients are sometimes no longer able to read any sentence correctly. They at times put in entirely different words, so as to make utter nonsense; but they do not notice it themselves. The abnormal associated movements of the facial muscles on speaking are also often to be observed, and are very characteristic. The voice of general paralytics often loses its power of modulation and becomes weak and rough—symptoms which depend upon a defective innervation of the vocal cords. The change in the handwriting, to be observed in general paralytics, is even more characteristic than the disturbance of speech (see Fig. 106). This is at first purely of a motor nature; the letters are uncertain, irregular, and tremulous. A psychical factor, however, also shows itself; single letters are omitted, the dot on the *i* and the marks of punctuation are forgotten, the patient ceases to keep on the lines, or leave a free margin, etc. As the disease advances, the disturbance in the handwriting gradually increases, so that the writing may finally become wholly illegible, and may consist merely of senseless scratches.

Besides the changes in the speech and the handwriting, which we have just briefly described, other physical disturbances are often quite early symptoms, and prove in how many parts of the nervous system at once the disease may begin its work of destruction. The condition of the pupils especially is of importance in diagnosis. They are often unequal, and also show a reflex immobility (see page 642) in a large number of cases, especially in those in which other tabetic symptoms develop (*vide infra*). Transitory ocular paralyses are at times early symptoms. Not infrequently we find quite early changes in the tendon reflexes, either

FIG. 106.—Examples of handwriting in general paralysis. Attempts made by patients in the Danvers Lunatic Hospital to write "God save the Commonwealth of Massachusetts." Besides the motor disturbance, the frequent omission of certain letters will be noticed, e. g., "Massachusetts" for "Massachusetts." In 3 and 4 the handwriting is almost wholly illegible.

absence of the patellar reflex (a tabetic symptom) or an increase (beginning spastic paralysis of the legs). The association of reflex immobility of the pupils with an increase of the patellar reflex is not uncommon. In the distribution of the sensory nerves we may mention as repeatedly observed symptoms, neuralgia, attacks of migraine, and finally optic atrophy, the latter usually as one symptom of a co-existing tabes.

We can not give a generally applicable account of the further course of general paralysis, since it may differ decidedly in this respect. In what follows we can point out only the main features of the different types of the disease, and, in particular, we will sketch only very briefly the groups of mental symptoms.

We often say that those cases belong to the "classical form" of general paralysis where an initial "stage of depression" with a melancholy tendency is followed by a second stage of "maniacal exaltation." This is the stage where the delusions, which are already quite pronounced, assume more and more the character of "grand ideas," and thus exhibit the "delusions of grandeur" which have for a long time been generally regarded as ominous. The first signs are often found in the patient's statements that he is now much better, that he is "very well," that he

feels "very strong," etc. These delusions, however, often assume gradually a more exaggerated form; the patient considers himself enormously rich, he owns thousands of palaces, millions of dollars, has made the greatest inventions, considers himself the Emperor Napoleon, Christ, a "higher God," etc. Any judgment as to the absurdity of these ideas, and as to the sad contrast between his claims and the reality, has already become impossible to him; but, of course, there are even now occasional remissions in this condition, when the patient is clearer and recognizes temporarily the morbid character of his delusions.

We must not think, however, by any means, that the delusion of grandeur is necessarily an invariable symptom in general paralysis. In many cases (the so-called "depressive" form of general paralysis) the initial melancholic-hypochondriacal condition continues. The delusions that appear possess the same coloring; the patient claims that he can no longer eat, that he is poisoned, that he no longer has a head or an arm, that he is very small ("*delire micromaniaque*"), etc. Sometimes acute and severe conditions of anxiety come on. In other cases, again (the agitated or maniacal form of general paralysis), there are states of violent excitement, in which the patient raves loudly, cries, and tries to destroy whatever falls in his way. Such states sometimes alternate with delusions of grandeur. Finally, we not infrequently see cases which, in their mental relations, present simply the symptoms of a mental enfeeblement gradually increasing to complete dementia, without ever showing, in any notable form, states of excitement, the development of delusions, etc.

While the intellectual life steadily goes to utter ruin in the ways just stated, the physical disturbances of the disease, as a rule, gradually advance in a more severe degree. In many cases ataxia of the extremities develops, and also loss of sensibility and vesical disturbances—in short, the symptoms of tabes. In these cases the tendon reflexes are almost always lost, and the pupils are often immobile. In other rarer cases, however, there is actual paralysis first in the lower and then in the upper extremities. In these cases the tendon reflexes are often increased, so that the picture of "spastic paralysis" develops. Again, in other cases bulbar symptoms appear, such as disturbances in swallowing or masticatory paralysis, and also ocular paralyses, usually as a part of the tabetic symptom-complex, etc.

Peculiar attacks, which are among the commonest and most characteristic symptoms of general paralysis, are, however, of special interest, and sometimes even of marked importance in diagnosis. These "paralytic attacks" in their milder degrees sometimes appear even in comparatively early stages of the disease. Then they usually consist of attacks of vertigo, an obscuring of consciousness, or even a loss of consciousness, coming on quite suddenly, and lasting from a few minutes to half an hour or more, and they are very often associated with mild hemiplegic or monoplegic symptoms. We very often see, besides the vertigo, a temporary feeling of weakness in the right arm, associated with a marked aphasic disturbance of speech. To this there is often added some slight twitching in the affected extremities or in the face. In the further course of the disease the attacks usually increase, and are termed apoplecticiform or epileptiform paralytic attacks, according as the conditions of paralysis or spasm predominate. The epileptiform attacks may often be repeated with great frequency—thirty or forty attacks a day or more—during which time the patient remains in an unconscious state. If the patients gradually return to consciousness, sometimes only after a week or two, we very often see, as a result of such severe attacks, a permanent impairment of the general condition, an increase of the dementia, etc.

The other organs, apart from the nervous system, are only secondarily implicated in the morbid process. It may be mentioned briefly here that formerly, for a long time, stress was laid upon certain changes in the pulse, the *pulsus tardus*

especially being thought to be characteristic: but the numerous investigations of the pulse have so far not given us any significant or sure results.

The temperature as a rule is approximately normal, or often somewhat sub-normal, but very marked changes in the temperature occur in connection with the paralytic attacks—sometimes elevations and sometimes very deep declines.

The whole duration of the disease is in some cases only a few months (the "galloping" form of general paralysis), usually it is two or three years, and sometimes much more. The most rapidly fatal form is that in which there is very soon a marked emaciation and a rapid loss of strength as a result of the sleeplessness, the constant unrest, and the refusal of food. In other cases death ensues from the gradual and general loss of strength, or in a paralytic attack; or, finally, as is frequently the case, from the onset of secondary conditions, such as severe bedsores, pyelo-cystitis, tuberculosis, intestinal diseases, etc.

**Pathological Anatomy and Nature of the Disease.**—Considering the great difficulty of an accurate microscopic examination of the brain, it is not strange that our knowledge of the pathological anatomy of general paralysis is still very defective. If we except occasional immaterial changes in the skull, such as hyperostoses and the like, or in the meninges, such as hæmatoma of the dura or secondary thickening of the pia over atrophied portions of the brain, the first striking and at any rate most important anomaly seems to be the atrophy of the brain which affects chiefly the anterior half, especially the frontal lobes. In this region the convolutions are very much diminished, and the fissures are wider; the weight of the anterior portion of the brain may be reduced to one fourth or one third of the normal. If we examine the convolutions microscopically we find that the diminution of the whole organ depends chiefly upon a loss of nervous elements. The cortex usually shows the greatest changes. In fresh cases we sometimes see the signs of a mild "inflammation"—that is, we find vascular dilatation and little disseminated foci of round cells about the vessels, but the changes in the nervous elements themselves are far more important, and consist essentially in a degenerative atrophy. We must mention especially that in the cortex of the frontal lobes, especially marked in the straight convolution and in the island of Reil, and also in other portions, we can make out with certainty, by the aid of good methods of examination, a very considerable loss of the fine medullary nerve-fibers, mainly those which run parallel with the surface, and hence are termed "association-fibers" (Tuczek); but signs of degeneration and atrophy are very often to be seen in the ganglion-cells themselves. The destruction of the nervous elements is regarded by many investigators as secondary, since they lay the chief stress upon the marked changes in the interstitial tissue, such as increase of the connective tissue, numerous spider-cells, or thickening of the vascular walls, which are almost always to be found in old cases, and hence they speak of an interstitial encephalitis (Mendel). We ourselves, with Tuczek, Wernicke, and others, are much more inclined to the theory that we have to do mainly with a primary process of degenerative atrophy of the nerve-fibers and nerve-cells, to which the increase of the connective tissue is only a secondary addition.

The anatomical affection in general paralysis, moreover, is by no means limited to the cerebral cortex. We can often make out the loss of fibers in the deeper parts also, in the white substance, and the central ganglia. The co-existing changes in the spinal cord, first accurately described by Westphal, and since then recognized as almost constant, are of especial interest. They usually consist of fascicular systemic degeneration of the lateral columns (the pyramidal tract), or the posterior columns. A large part of the physical disturbances of general paralysis, such as tabetic symptoms or spastic paralysis (*vide supra*), are certainly due not to the cerebral disease, but to these accompanying changes in the spinal cord.

Accordingly, we believe that, according to our present knowledge, we can best conceive the nature of general paralysis in the following way: By the action of certain injurious influences, which usually seem to stand in some connection with syphilis (see page 632), there is a gradually progressive destruction of nerve-tissue in the most diverse portions of the nervous system. The clinical symptoms must naturally differ according to the significance and function of the affected fibers or cells. As a rule, certain cortical regions of the cerebrum are first diseased. The disturbances of speech are probably dependent upon the loss of fibers in the left island of Reil, the disturbances of intelligence upon the destruction of fibers in the frontal lobes. We may also make out corresponding anatomical changes, either cerebral or spinal, as an explanation of the later motor, tabetic, and other symptoms; but in many cases the order in which the different sections are affected varies considerably. We have seen in a previous section (see page 645) that the whole process may begin with a spinal disease, especially tabes dorsalis, to which the paralysis is "added" later; but we must understand that the two conditions are wholly analogous to and co-ordinate with each other. Both are parts of the same degenerative process, which can accomplish its work of destruction in the most diverse regions of the nervous system.

No coarse anatomical lesions can be made out, as a rule, to explain the paralytic attacks, but it is very probable that they depend, at least in great part, upon the changes in the motor central convolutions.

**Diagnosis.**—Since the diagnosis of beginning general paralysis is of the greatest practical importance, we will once more mention briefly all those symptoms which are especially to be considered in diagnosis: Striking alteration in the behavior, rapid and motiveless change in the disposition, disturbances of memory, loss of intelligence (failures in reckoning, etc.), the characteristic changes in the speech and handwriting, and finally the somatic symptoms which often co-exist: difference in the pupils, immobility of the pupils, loss, or, more rarely, increase of the tendon reflexes, and mild paralytic attacks, such as vertigo, disturbance of speech, temporary disturbance of motion in one arm, etc.

We would also mention, as especially common and disastrous mistakes, that the symptoms of general paralysis are often misunderstood at first, and are regarded as the signs of immorality, the failure of the sense of duty, etc. It also frequently happens that general paralysis is at first regarded as simple neurasthenia or hypochondriasis, and treated accordingly.

As a rule, general paralysis can be certainly distinguished from other organic nervous diseases by careful attention; but of course we must add that in some cases cerebral tumors, syphilis of the cerebral arteries, and especially certain cases of multiple sclerosis, may show a type of disease very like general paralysis.

**Prognosis.**—The prognosis of general paralysis, like that of all chronic degenerative conditions of the central nervous system, is very unfavorable. At present we know of only a small and decreasing number of actual recoveries, but there are many cases where there is a temporary improvement in the condition, a "remission," sometimes of a considerable degree and lasting a long time. The earlier the patient comes under proper care and treatment the sooner may we hope for such a favorable turn. Of course, as we have said, relapses of the disease almost always come on later. Those cases especially are to be regarded as unfavorable in which frequent paralytic attacks come on early, in which other physical symptoms, especially of a spinal nature, soon set in, and in which the whole nutrition of the body rapidly suffers.

**Treatment.**—As soon as the disease is recognized, the first and imperatively necessary injunction must be to remove the patient from all physical and intellectual exertion as well as from all mental excitement. The patient must there-

fore, if possible, withdraw from business, which up to that time he may have tried to carry on. His methods of life and his diet must be regulated, and every excess must be forbidden. For the cases which even at first are associated with states of great mental excitement, the commitment to a proper asylum is often most urgently to be recommended, while for cases that during their course show simple mental weakness, care at home is often sufficient.

In regard to the treatment of the disease itself, we should advise inunction with mercurial ointment, especially if we can discover a previous syphilitic infection. As a rule, we ought not to expect much success from this any more than in *tabes* (see page 647), but we may perhaps check the advance of the disease. We should therefore try the antisiphilitic treatment chiefly in the initial stages of the disease. We may combine the internal use of iodide of potassium with the inunction.

Furthermore, we should try tepid baths, with cool sponging, and also a cautious application of electricity (galvanization of the head and spinal cord), and, of internal remedies, ergotine especially. We need not go more fully here into the numerous symptomatic details.

## CHAPTER X.

### CHRONIC HYDROCEPHALUS.

**Ætiology and Pathology.**—Repeated mention has been made in preceding chapters of the occurrence of dropsy in the ventricles as a sequel to other cerebral diseases, such as meningitis and tumors. Besides this "secondary hydrocephalus," a collection of fluid in the ventricles may be a symptom of an apparently idiopathic primary disease. This is observed most of all in the newborn, or at least in young children.

Little is known with certainty about the causes of chronic hydrocephalus. The assumption is very frequently made that the condition is the result of an inflammation of the ependyma of the ventricle, which itself occurs either before birth or very soon after, but the autopsy often fails to support this idea. There is equally slight objective evidence that there is a stasis due to mechanical obstruction. Syphilis and dipsomania have been regarded as predisposing causes; whether justly or not, is uncertain. It has been repeatedly observed that the disease has attacked several children of a single family.

The most important physical sign of hydrocephalus in children is enlargement of the head. The circumference of the skull may even in the first year of life be sixty to eighty centimetres. Usually the frontal bones and the parietal eminences are especially prominent. The cranium becomes gradually almost as thin and translucent as paper. The fontanelles and sutures gape widely. The brain is flattened out, so as to seem almost like a bag, filled with the hydrocephalic fluid. In well-marked cases the entire thickness of the hemispheres is frequently not more than an inch. The space within, containing the serous effusion, represents the enormously distended ventricles, particularly the lateral ventricles, although the third and fourth ventricles are quite often distended also. The walls of the ventricles are often strewn with minute granulations, or they present a reticular hypertrophy. The hydrocephalic fluid usually has the appearance of colorless serum, and contains a very slight amount of albumen, if any. The specific gravity is about 1004 to 1006. The amount of fluid may be a quart or more; but, of course, there is great variation in this respect in different cases.

Congenital hydrocephalus is often associated with other peculiarities or defects in the structure of the brain, which we can not mention here.

**Clinical History.**—Sometimes a child is born with hydrocephalus so far developed as to occasion dystocia. Usually, however, the parents notice nothing peculiar about the child for some weeks. Then they are alarmed by the gradual swelling of the head. As a basis for determining abnormal size, we may mention that under normal conditions the circumference of the head at birth is about forty centimetres, at the end of a year about forty-five centimetres, and from that age to puberty there is a gradual approach to a circumference of about fifty centimetres. The possible dimensions in chronic hydrocephalus have been already stated. The increase in circumference is often quite rapid, amounting in a fortnight or three weeks to one or two centimetres. Usually the swelling is tolerably symmetrical; but sometimes the greater increase is in the antero-posterior diameter, making the skull dolichocephalic. At times the rate of expansion may be particularly rapid, and then at other times it may seem to be suspended. That the fontanelles and sutures remain widely open has already been mentioned; sometimes it is even possible to get fluctuation through them. An intravascular murmur can now and then be heard in the head, but it has no great importance with regard to diagnosis. The veins are often so greatly distended as to form a bluish network underneath the scalp. The face remains small, in striking contrast with the great, heavy cranial portion of the head. The head almost always hangs over forward from its weight. The eyes generally look down, partly because the roof of the orbit is depressed, and partly because of impairment of the nervous supply to the *motores oculi*.

A very important symptom is the defective intellectual development of hydrocephalic children. They can not learn to talk well, if at all. If they play, it is in a silly manner. They can not concentrate their attention upon anything, and they are heedless and dirty. It must, however, be mentioned that sometimes, in spite of considerable hydrocephalus, the patient now and then evinces an unexpected activity of mind—thus, he gradually becomes able to distinguish the different objects and individuals about him.

There is almost invariably motor disturbance also. The legs, more rarely the arms, are decidedly paretic, or there may be even complete paraplegia. There are usually spastic symptoms and increased tendon reflexes. Few patients learn to walk or stand alone. The arms seldom present any great paresis, but their movements often betray an awkwardness and uncertainty suggestive of ataxia. It is noteworthy that sensation almost always remains intact. At least the patient reacts vigorously to the prick of a pin, etc. Of the special senses, sight is most frequently affected; choked disk and atrophy of the optic nerve have been observed repeatedly. Symptoms of motor irritation are of very frequent occurrence, such as general convulsions and spasm of the glottis. General nutrition is pretty well maintained in many cases, but, as a rule, hydrocephalic children are atrophic and ill developed.

The chronic hydrocephalus of children almost always terminates unfavorably. Only a few patients survive the fifth year, although now and then striking exceptions occur. Death is generally the result of marasmus; or a convulsive seizure may prove fatal. The possibility of recovery has not yet been demonstrated. The progress of the disease may, however, be arrested, and the child continue for years *in statu quo*.

Hydrocephalus in adults is a very rare, chronic, and apparently idiopathic disease. Its cause again is assumed to be a chronic inflammation of the ventricular ependyma. The symptoms are sometimes very like those of a tumor of the brain, and sometimes there is a remarkable absence of characteristic cerebral disturbance, except that spastic paralysis of the extremities (compare page 663) is gradually developed.

**Diagnosis.**—A pronounced case of congenital hydrocephalus can be recognized without difficulty, inasmuch as the excessive size of the head betrays the disease upon the first glance. Less extreme cases may indeed be somewhat obscure, and

we have especially to avoid confounding the condition in question with rachitic enlargement of the skull. We should always, therefore, take into consideration the intellectual powers, the presence or absence of motor disturbances, and other similar symptoms, as well as the cranial peculiarities. In the hydrocephalus of adults there is often no enlargement whatever, so that a diagnosis can hardly ever be declared positively.

**Treatment.**—Thus far, no remedy has been applied with success in chronic hydrocephalus. The following may be tried: Applications of mercurial ointment and of tincture of iodine to the scalp, methodical compression of the skull, and iodide of potassium internally. The hydrocephalic fluid has often been drawn off, to a certain extent, by tapping, but with merely temporary benefit, if any.

Hence we confine ourselves chiefly to hygienic and symptomatic treatment.

## CHAPTER XI.

### MÉNIÈRE'S DISEASE.

(*Vertigo ab aure laza. Labyrinthine Vertigo.*)

IN 1861, Ménière, a French physician, first called attention to a peculiar affection which sometimes results from chronic aural disease and is characterized mainly by excessive vertigo and loud tinnitus aurium. At first the symptoms appear in distinct paroxysms. These are ushered in by a shrill ringing in the ears, which is often compared to the whistling of a locomotive, and which is perceived in but one ear. At the same time, or shortly after, comes on a very pronounced dizziness, of a unique sort. The patient has a feeling as if his whole body were moving, as if he were falling forward or were whirling around. Consciousness is unimpaired, but the patient feels very bad, the skin is pale and cool, and the face is bathed in cold perspiration. Frequently there is vomiting toward the close of the attack. The first paroxysms are of brief duration.

As the disease progresses the attacks become more and more frequent, and at last the vertigo may be constant, being extremely annoying to the patient and perhaps confining him to bed. Even now there are occasional paroxysmal exacerbations of the disorder, usually ushered in by the shrill tinnitus. The tokens of chronic aural disease on one side, or less frequently on both sides, also persist. Sometimes there is purulent otorrhœa; often the aural speculum reveals lesions of the drum or of the middle ear; and almost invariably there is more or less deafness on the affected side. This condition may persist for years, until finally it ceases of its own accord, after the deafness on that side becomes complete.

We possess scanty information as to the origin of these subjective phenomena. That they are due to a disease of the internal ear (labyrinth) can scarcely be doubted; and it is further probable that in every case the semicircular canals are involved. Numerous experimental investigations have demonstrated that these last-named structures bear a part in maintaining the equilibrium of the body. Acquaintance with this variety of vertigo is valuable to a nervous specialist, inasmuch as Ménière's disease has been more than once confounded with epilepsy and disease of the cerebellum and other parts of the brain.

Treatment is not wholly unavailing. Charcot has discovered that the persistent use of quinine almost always gives great relief, and may even completely cure the disease. Eight to fifteen grains (grm. 0.5-1) of quinine should be given daily, in two or three doses, and continued for at least several weeks. The particulars of such special treatment of the ear as may be necessary must be sought elsewhere.

## VI.—Neuroses without known Anatomical Basis.

## CHAPTER I.

## EPILEPSY.

(Falling Sickness. *Morbus sacer.*)

**Etiology.**—Epilepsy is a peculiar disease of rather frequent occurrence, the main symptom of which is paroxysmal loss of consciousness. In typical cases the unconsciousness is associated with violent general convulsions; but there are many anomalous and rudimentary forms of epilepsy without any symptoms of motor irritation. "Genuine epilepsy" is a functional neurosis—that is, with our present means of investigation we can discover no constant objective lesion of the nervous system as its basis. It is, indeed, true that attacks similar to those of true epilepsy not infrequently occur in the course of tumor, syphilis, and other diseases which do present an anatomical lesion; but such attacks are merely symptomatic, and are therefore termed "epileptiform," in distinction from the genuine epileptic paroxysms. [Convulsions may also be due to lead encephalopathy (*vide infra*). —K.]

Of the actual causes of epilepsy we know nothing. We are acquainted only with certain factors which are favorable to the development of the disease, and are to be regarded, therefore, as predisposing or exciting causes. Heredity is decidedly the most important of these. About one third of all cases of epilepsy occur in persons who have inherited a nervous diathesis, and one or more of whose blood-relations have suffered from diseases of the nervous system. It should not be understood that we must find other cases of genuine epilepsy in the family, in order to establish the fact of congenital predisposition. The question is merely whether the ancestors have exhibited a general tendency to nervous disease. The more accurate and careful our investigations, the oftener shall we find among the relatives of the patient instances of nervous trouble—sometimes genuine epilepsy, sometimes insanity, hysteria, or general "nervousness." Of course these "nervous families" present, besides those that are actually ill, others who are more or less peculiar and odd, and yet others who have extraordinary talents, although frequently somewhat ill-balanced. It is said that the children of parents who are related to each other are somewhat predisposed to epilepsy, as well as to other nervous diseases; but certainly this factor is very rarely of importance. Perhaps dipsomania in the parents is somewhat more prejudicial in this regard. It is said to have been repeatedly observed that children begotten while the father was intoxicated became epileptic.

There are other influences which are assumed to have ætiological importance, but whether justly or not is difficult to decide. Alcoholic excesses can seldom act in this way (although epilepsy is said to attack absinthe-drinkers in France quite frequently). Venereal excesses probably have still less importance. It should also be borne in mind that not infrequently excesses in these directions are the result of neurotic tendencies already existing. Syphilis has no direct connection with genuine epilepsy. Epileptiform convulsions may, as we have seen, be symptomatic of syphilis, being due to the cerebral lesion caused (*vide* page 758) by the latter disease. Certain factors may determine the onset of epilepsy, although the

can not be said to cause the disease. Such are overexertion of mind or body, repeated emotional disturbance, certain general conditions of the system, such as anæmia or malnutrition, on the one hand, and plethora on the other; and, in particular, acute febrile diseases, such as scarlet fever, measles, and gastritis. [In some cases abnormal putrefactive processes in the small intestines seem to act as the exciting causes of the individual attacks.—K.] Another important point is that the first attack is sometimes brought on by great mental excitement, especially fright. But here, too, it is probable that the terror is merely the exciting cause, a tendency to the disease already pre-existing. We must also be on our guard against confounding genuine epilepsy with the convulsive form of hysteria (*q. v.*), which very frequently develops after fright.

In some instances there is an evident connection between epilepsy and a previous injury to the head, as from a fall, blow, or cut. At a certain interval after the trauma, attacks begin which seem precisely like those of genuine epilepsy. This is known as "traumatic epilepsy." But these are not cases of genuine epilepsy, inasmuch as there is really some anatomical lesion of the cortex cerebri which, in some way as yet unknown, causes irritation of the motor centers of the cortex (*vide infra*). It is often the case that this sort of epileptiform attacks is peculiar in that the convulsions are at first unilateral, or confined to a single limb, corresponding to the seat of the injury in the opposite cerebral hemisphere.

"Reflex epilepsy" remains to be mentioned. This name is applied to cases where each convulsive attack seems to be excited by reflex influence originating in some one part of the body. Most cases have followed traumatic injury of peripheral nervous trunks (retained splinters, or scars), and have ceased upon removal of the exciting cause. Other causes are new growths in the nerves, foreign bodies in the ear, otitis, intestinal parasites, and, apparently, diseases of the female sexual organs. But it seems probable that sufferers from these attacks have had a tendency to disease of the nervous system. We must hesitate to rank reflex epilepsy in the same class with the genuine form. In former treatises "reflex epilepsy" has certainly very often been confused with traumatic-hysterical spasms (*vide infra*, the chapter on traumatic neuroses).

Both the traumatic and the reflex varieties of epilepsy have repeatedly been the object of experimental investigation. Brown-Séquard has shown, by a great number of experiments, that epilepsy can be excited in rabbits by injuries to the medulla, the spinal cord, and the sciatic, as well as other peripheral nerves. A certain time after the operation the animals undergo spontaneous convulsive paroxysms. These occur at frequent intervals for a long time, and may be voluntarily excited at any time by irritation of a certain portion of the skin called the "epileptogenous zone." An interesting observation in this connection has been made by Brown-Séquard, which is that sometimes the progeny of these animals, who have been made epileptic, suffer from spontaneous epilepsy. Westphal induced epilepsy in guinea pigs by blows upon the skull. Immediately after the blow general convulsions occurred, but soon entirely ceased. Afterward, however, there were repeated epileptiform attacks. Westphal thought that the causative lesion in these instances was the minute hæmorrhages which were found in the upper part of the cervical division of the cord and in the medulla.

Further experiments bearing upon the same subject will be discussed later on.

**Clinical History.**—In describing the symptoms of epilepsy, we shall first consider the various forms of the epileptic paroxysm, and then describe the general course of the disease.

1. The typical epileptic paroxysm is usually described, for the sake of greater clearness, as made up of several stages. First is the prodromal stage, or, according to Galen's expression, still in vogue, the stage of the epileptic aura (*aura* =

breath). Not infrequently, however, there is no aura whatever, the convulsions coming on without warning. But in many cases the prodromata are well marked, and are repeated with remarkable regularity and similarity before each individual attack, although the different cases of epilepsy differ greatly as to the special phenomena of the aura occurring in each.

The best manner in which to distinguish the various forms of aura is according to the nature of the nervous phenomena, whether sensory, motor, vasomotor, or psychical. Of these the most frequent is, beyond a doubt, the sensory. Here we have peculiar paræsthesiæ, beginning in an arm or leg, or perhaps in the region of the heart or stomach, and thence usually "mounting to the head." It is seldom that the peculiar sensation is actually like a "breath" or puff of air. The aura which proceeds from the epigastrium is sometimes associated with a very disagreeable feeling of oppression and anxiety, and often also with nausea and vomiting. The aura may be referred to the nerves of special sense. In certain instances the patient perceives an unpleasant odor, which he likens to some familiar one. An aura of taste also occurs, but it is very rare. An optical aura is much more frequent, consisting in a subjective sensation of color or light (usually a sensation of red appears first), in an apparent increase or diminution of the size of surrounding objects, or finally in actual hallucinations of vision, such as beholding all sorts of human or brute shapes. An auditory aura is not very rare: it produces a sudden feeling of deafness in one ear, or various subjective sounds, like whistling, humming, or roaring.

The motor aura takes the form of mild premonitory contractions, affecting the head, face, arm, or leg. There may be aphasic disturbance at the same time; or we may observe symptoms of irritation of the unstriated muscles (strangling, or a desire to go to stool). Sometimes there are prodromal vasomotor phenomena, where the aura consists in a sensation of cold or warmth, often associated with excessive pallor or redness of the face or hands. An attack may be ushered in by chilliness, perspiration, or palpitation.

Finally, the name of psychical aura is applied to an initial impairment of consciousness, with vertigo, confusion of thought, etc. A particularly frequent form for this to assume is excessive mental uneasiness and excitement.

Various forms of aura are not infrequently seen in combination.

The aura lasts sometimes only a few seconds. It may persist long enough for the patient, who knows from experience what is coming, to lie down or take other precautionary measures (*vide infra*). In some few cases the aura may last hours, and even days. This is especially true of the psychical variety. Sometimes the aura passes away without being succeeded by any true epileptic fit; but it is usually followed by the second stage of the attack—the convulsive stage.

The convulsions almost invariably begin abruptly. Perhaps there is no aura, or only a very brief one, before the patient falls suddenly to the ground, usually on his face, although sometimes on the side or back. Consciousness is entirely suspended. Insensibility is complete, and often the patient sustains severe injury from his fall. Some patients utter a loud "epileptic cry" at the commencement of the attack, but they are already entirely unconscious.

The convulsive stage begins with a brief period of general-tonic spasm of the muscles. The head is usually strongly extended, the teeth are pressed firmly together, the trunk is curved backward in opisthotonos, the extremities are extended, and the fingers are clinched over the flexed thumb. Inasmuch as the respiratory muscles participate in the seizure, breathing stops, and the original pallor of the face soon gives place to deep cyanosis. This general tonic convulsion ordinarily is but brief, perhaps fifteen to thirty seconds. It is followed by the second period of the convulsive stage—that of the clonic convulsions. The facial

muscles now exhibit the most violent contortions; the eyeballs roll, or occasionally present a conjugate deviation toward one side; the tongue is thrust out and retracted convulsively; the head beats violently against the floor; and the muscles of the arms, legs, and trunk undergo the severest clonic spasms. The pupils are probably contracted for a short time at first, but during the convulsive stage they are widely dilated and do not react at all. The pulse is somewhat accelerated, but not greatly. The temperature is normal, or elevated a small fraction of a degree. The cutaneous reflexes are still suspended directly after an attack; but the tendon reflexes are generally somewhat exaggerated, although sometimes they also are diminished or absent. Not infrequently an involuntary dejection takes place during the fit, or the bladder is emptied; and in men there may be a seminal emission. During these violent convulsions the body is often severely injured. The tongue is frequently bitten. The venous stasis is so extreme that sometimes minute hæmorrhages occur into the conjunctiva, the skin of the face, and other parts.

The convulsive stage usually lasts several minutes. Then the contractions cease, often after a deep, long-drawn sigh; and the patient passes into the third stage, of post-epileptic coma. He lies unconscious, but his respiration grows quiet, and the cyanosis vanishes. Gradually the coma yields to slumber, which may persist for some hours; but some patients remain only a very brief time in this stage, and recover from their attack with surprising rapidity. It is, however, not infrequently the case that for some days after-pains are felt; there are headache, languor, and exhaustion, and mental despondency and irritability. For some time there may be severe pain in the muscles, particularly those of the trunk. There may be slight paresis of one limb or one side of the body after an attack, but this speedily vanishes again in cases of pure epilepsy. In the urine first passed after the seizure is often found a trace of albumen, and perhaps a few hyaline casts. Not infrequently there is also decided polyuria for some time subsequent to the fit.

2. *The Milder, Rudimentary Forms of Epileptic Seizure. Petit Mal.*—Besides these violent paroxysms just delineated ("*grand mal*"), there are very often witnessed in epilepsy milder attacks of so-called "*petit mal*." Sometimes there is only a transitory dizziness, or slight faintness, or perhaps a brief loss of consciousness, but without accompanying symptoms of motor irritation. These milder attacks may or may not be preceded by an aura. Cases have been seen repeatedly where the patient suddenly pauses in the midst of conversation, card-playing, piano-playing, or other occupation, stares absently for a moment, and then, with equal abruptness, goes on with what he was doing, as if nothing had happened. In other instances the patient pursues his occupation during this brief suspension of consciousness. For example, if seized while upon the street, he walks on mechanically, but takes the wrong turning, or goes into a strange house, when suddenly he comes to himself and wonders to find himself where he is. Cases of "sudden somnolence" are also almost all of them ascribable to epilepsy. There are all sorts of transitional forms between the slight attack of vertigo and the typical epileptic fit. Not infrequently the patient falls down unconscious, but he has only a slight twitching of the face or arm, and in a few minutes is entirely himself again.

[The medico-legal bearings of epilepsy, in its mild as well as in its severe form, are very important, but they can be only alluded to here.]

3. *Epileptoid Conditions.*—Cases of *petit mal* are generally rudimentary forms of the typical epileptic paroxysm, and consist merely of a simple impairment of consciousness, possibly associated with slight motor symptoms; but in the *epileptoid* state the character of the typical epileptic attack is almost indisti-

The disturbance is paroxysmal, and it can often be shown to be connected with genuine epileptic seizures, else its undoubted relation to epilepsy would never have been recognized. The greatest practical importance attaches to Samt's "psychical equivalents of epilepsy." These are attacks of mental disturbance, which either immediately succeed a typical epileptic fit ("post-epileptic insanity") or occur independently. The patient is completely deranged, and may do the strangest things—may strip himself, steal, jump into the water, or commit incendiarism. Here the mind may be said to be only clouded, as compared with other instances where there is violent psychical excitement, associated with terror, frightful hallucinations, and resultant maniacal excitement. Not infrequently the patient is led to acts of violence against those about him. In the young the attack may take a peculiar form: the child runs about in a peevish way, collects all sorts of things together, makes strange motions, etc. Almost always the patient, on recovering consciousness, remembers nothing, or almost nothing, of what has happened. Numerous and valuable particulars upon this subject, and a consideration of its great medico-legal importance, must be sought in text-books on insanity.

Another form of epileptoid attack is the epileptoid sweating of Emminghaus a spontaneous outbreak of excessive perspiration in epileptics, which may or may not be associated with impairment of consciousness.

**General Course of the Disease.**—In a large majority of cases epilepsy begins before the thirtieth year. Often the disease appears in early youth, and sometimes in even the earliest years. Many a child has "convulsions from teething," which later on are seen to have been epileptic. It is only in rare instances that the first appearance of trouble occurs in advanced life.

It is impossible to give any general rule as to the frequency of the paroxysms. Different cases differ very much. There are persons who during their whole life have no more than three or four seizures, at intervals of ten or fifteen years, while in most cases there is an attack every two to eight weeks. In severe types the fits may even recur daily. One very often sees certain variations in the course of the disease: at some periods the intervals between the attacks will be longer, and at others shorter. In severe cases the patient may have for several days very frequent seizures, so that he does not regain consciousness at all between them. This is termed the epileptic state (*état de mal*, *status epilepticus*). The condition is quite rare. It is often fatal, death being ushered in by a great rise of temperature.

External influences sometimes affect the frequency of epileptic attacks. Alcoholic or sexual excess, mental excitement, and physical overexertion almost always exert a malign influence. An opposite effect is often experienced where a quiet life is led, with every attention paid to hygiene and pure air. In women, the appearance of the catamenia is not infrequently the signal for the occurrence of an attack. In many instances the disease begins with the first establishment of menstruation. Sometimes, however, epileptic girls grow better when they arrive at puberty. Pregnancy sometimes increases and sometimes diminishes the frequency of the paroxysms. Intercurrent diseases seem frequently to exert a beneficial influence upon the frequency of the attacks.

There is a practical distinction between diurnal and nocturnal epilepsy. Many patients have attacks only during the day, while others again have them only at night. A case of purely nocturnal epilepsy may go on for a long while unsuspected, particularly if the patient sleep alone. He seldom has, on the next morning, the slightest recollection of his attack during the night. He usually perceives, however, from a confused feeling in his head, or from certain injuries such as a bitten tongue, or from the disordered state of the bed, that something must have happened to him during the night. In some cases of nocturnal

epilepsy the patient wakes up out of sleep before he enters into the epileptic state of unconsciousness. Probably he is aroused by the aura. Besides cases where the fits occur during the day or the night only, mixed forms are frequently seen.

With regard to the occurrence of the different varieties of epileptic seizure, all sorts of combinations are possible. Many cases never have any but the typical convulsions; but in many others there are also a greater or less number of attacks of petit mal. The latter may even be for a long period the sole indication of the disease. Often there are no epileptoid conditions whatever, while in other instances the "psychical equivalents" are the most prominent feature of the disorder.

During the interval between the individual attacks many epileptics seem perfectly well, both physically and mentally. They are not infrequently, to be sure, somewhat peculiar and nervously excitable, or again dull and lethargic; but this does not by any means apply to them all. Many epileptics, and particularly such as have comparatively infrequent paroxysms, are very capable; and history furnishes numerous examples of eminent men who suffered from this disease—for instance, Caesar, Mahomet, Rousseau, and Napoleon I.

Much effort has been devoted to the discovery of "signs of physical degeneracy" in epileptics. Relying upon numerous measurements, Benedikt believes that a majority of epileptics exhibit craniometric anomalies, such as asymmetry of the cranium, macrocephalia, or steepness of the vertex. It is also not unusual to meet with anomalies of the auricles, teeth, or hands\* in such cases. And, indeed, all peculiarities of this sort are, in general, more frequently observed in neuropathic families than in healthy ones.

When the disease has lasted some time, and particularly if the attacks come at very short intervals, the general condition of the patient often undergoes a gradual but marked change. This rule is by no means invariable. The mind becomes more and more affected; the intellect grows feeble; memory grows weaker, and occasionally there is at last dementia. In such cases the body also suffers. There are emaciation, paresis, tremor, and other persistent disturbances of cerebral origin.

**Duration.**—Epilepsy must be termed a life-long disease. To be sure, it is no rare thing for the paroxysms to cease and not return for years. But one can never rest satisfied that all trouble is at an end; some cause or other may excite another attack after a long interval. In general, an epileptic has a shorter life-expectancy than healthy persons, especially as he may be carried off by chronic pulmonary or other intercurrent disease.

The prognosis is obvious from what has been already said. The individual seizure is only exceptionally dangerous of itself. Often the so-called "*status epilepticus*" ends fatally, as above stated. In general, those cases may be called the most favorable where the separate paroxysms are infrequent and mild; but even here the disease may suddenly assume an aggravated form. With regard to the distinction between nocturnal and diurnal epilepsy, the nocturnal is, in our opinion, the milder of the two.

**Pathology.**—The very fact that in the intervals between attacks the patient often betrays no sign of disease, shows that epilepsy can not be due to any persistent macroscopic lesion of the tissues. Indeed, in many cases nothing is found at the autopsy, or, at most, changes which can not be regarded as essential, such as osteosclerosis of the cranium or thickening of the cerebral meninges. Epileptic subjects who were during life decidedly demented usually present atrophy of the hemispheres. Meynert states that changes in the pes hippocampi major are

\* We have lately seen an epileptic

persons on each hand.

noticeably frequent in epilepsy; but these changes are not at all constant, and their significance remains to be established.

We must therefore, for the present, be content to assume that the cause of the epileptic seizure is an intermittent functional condition of irritation. A natural question is, Where shall we locate this irritation, and what may be its nature? The opinion was long current that the medulla oblongata must be regarded as the true seat of the disease. Schröder van der Kolk was the first to express this opinion. It afterward received support from the experimental investigations of Nothnagel, who demonstrated that irritation of a particular spot ("convulsive center") in the pons, in rabbits, invariably excites general convulsions. Nevertheless, most pathologists have now abandoned this view, because experiment and clinical observation indicate with increasing distinctness that the origin of epileptic convulsions is to be sought in the cortex cerebri. The clinical evidence is the invariable combination of convulsions and impairment of consciousness; the circumstance that the milder and the masked forms of epilepsy, now known to be intimately related to the true epileptic convulsions, also, almost without exception, indicate psychical disturbance; that attacks, the symptoms of which are perfectly analogous with those of epilepsy, are often found to be the result of anatomical lesions of the cerebral cortex; and, finally, that these convulsions in man and the convulsions of "cortical epilepsy" (*vide infra*), experimentally produced in animals, extend over the different groups of muscles in a way which corresponds precisely with the anatomical position of the different motor centers in the cortex (Hughlings Jackson). For example, if the convulsion begins in the distribution of the facial nerve, it extends from this point to the arm before it affects the leg.

There is also experimental evidence that epileptic paroxysms are of cortical origin. A great number of observers (Hitzig, Ferrier, Albertoni, Luciani, Franck, and Pitres) have proved that electrical irritation of the motor regions of the cortex in animals will produce epileptiform convulsions. Unverricht has made some of the latest and most thorough investigations in regard to this point upon dogs. He found that when a motor center is stimulated the convulsions spread from the corresponding group of muscles to others in a way which corresponds precisely to the anatomical position of the separate centers. If one of the centers in the cortex be destroyed, the convulsions of the corresponding muscles cease at once. This proves that the motor centers must be intact in order to render the occurrence of epileptic seizures possible. Just how the stimulation extends from one center to another we have as yet no certain information. Probably it travels horizontally through the cortex.

We see, therefore, that in all probability the seizures in man also originate in the cortex of the brain. The phenomena of the aura are likewise referable to some stimulation of the cortex, probably of the sensory region in most cases, as in the optical aura. The starting point of the irritation is probably usually in the motor cortex, but it does not seem impossible that an irritation developing in the posterior cortical regions may extend secondarily to the anterior motor portion of the cortex (Unverricht). The manner in which the irritation is created is as yet entirely conjectural. Kussmaul and Tenner proved that epileptiform convulsions can be excited by a general cerebral anæmia; and this fact was the main foundation for the assumption that the genuine epileptic convulsions are also due to a temporary cerebral anæmia, caused, it may be, by local vasomotor constriction. Definite proof has not yet been furnished on this point. In the artificial epilepsy which Unverricht produced, and that also which Magnan excited by absinthe, the cortex of the brain was not strikingly anæmic.

**Diagnosis.**—Most cases of epilepsy are easily recognizable. It needs only to be

borne in mind that epileptiform convulsions may also occur as a symptom of cerebral diseases which do have an anatomical basis, such as tumor, abscess, multiple sclerosis, and hydatids. As a rule, however, such diseases are readily distinguished by the state of the patient between the seizures, or by the further course of the illness. It should also be understood that unilateral convulsions, or such as are confined to a single member (Jacksonian epilepsy, *vide supra*, page 714), are usually not true epilepsy, but symptoms of some circumscribed affection of the cortex. The differentiation from hysterical convulsions (*q. v.*) is seldom difficult. Weight should be laid on the general character of the attack, the complete loss of consciousness in epilepsy, the dilatation of the pupils, which do not react to light, the initial pallor not infrequently observed, and the late cyanosis of the face. It is mainly the same factors which will enable us to detect simulated epilepsy. Here, also, there is an absence of those bodily injuries, such as a bitten tongue, which are often so characteristic of the genuine disease.

**Treatment.**—Although no remedy is capable of working a certain and permanent cure of epilepsy, yet a favorable influence can be exerted upon the disease in many ways, so as to lessen the frequency and severity of the paroxysms, and to avert many of their evil results.

In the first place, regimen is of great importance. Any excessive exertion of mind or body must be forbidden. Temperance must be exercised in eating and drinking. Alcohol, strong coffee, and tea, can be used only moderately; nor is too much smoking permissible. The diet should be simple and unirritating, and vegetable rather than animal. It is said that in some cases decided improvement has been brought about by confining the patient to milk and vegetables. In summer the patient should live quietly in the country or the mountains. We have also the individual constitution to consider: a weak and anæmic person must have iron and abundant nourishment; and a full-blooded, corpulent individual should drink the natural aperient waters, and live abstemiously.

Proceeding to the treatment of the disease itself, we shall rarely find any cause to remove; although, in a few cases of reflex epilepsy, the excision of old scars, the extraction of foreign bodies, or trephining the skull, where the disease has followed an injury, have brought about permanent recovery. In genuine typical epilepsy we have no such indications to fulfill, and we must have recourse to such treatment as experience shows can influence favorably the outward manifestations of the disease. [In Jacksonian epilepsy the cortical center of the initial spasm of the convulsion has been excised a number of times, even when, after trephining, it appeared healthy. The center should be carefully determined, after the brain is exposed, by faradic stimulation of the cortex. In some cases relief has been obtained, and the convulsions have ceased for a considerable period. It is too early to speak of the ultimate results, but in some cases the attacks have finally recurred in equal severity.—K.]

Among symptomatic remedies, potassic bromide has an undisputed right to the first place. It was first recommended by Locock in the year 1853. It should be the first thing tried in any severe case. Apparently it acts by directly lowering the sensitiveness of the motor centers of the cortex to irritation. Rather large doses are requisite. Beginning with about one drachm (grm. 4-5) a day, we may find it advisable to increase up to two or two and one half drachms (grm. 8-10). It may be prescribed in water (1 to 10 or 15), or in powders which the patient himself is to dissolve in water, sweetened if desired. The remedy in almost all cases needs to be used for months and years, and it is therefore often advisable for the patient to buy a half pound or a pound and weigh it out himself into the proper doses. It should always be taken in a good deal of water, say half a tumbler or more, to avoid irritating the stomach. The total amount for the day

is usually divided into two or three portions; but the whole may be dissolved in a large amount of water and drunk gradually through the day. The bromides of sodium and ammonium are also frequently employed. They have the advantage of disturbing the stomach less than does the potassium salt. It is a good way to combine the different bromides—for instance, bromide of sodium and bromide of ammonium, of each 10 parts; distilled water, 200 parts: three tablespoonfuls a day in water. It is well to combine the various bromides. Erlenmeyer strongly recommends a mixture of two parts of potassic bromide with one each of sodic and of ammonic bromide.

In using the bromides, persistence is necessary for at least months, and often, with occasional interruptions, for years, if benefit is to be obtained. In case there are unpleasant symptoms due to the remedy, such as excessive acne, muscular lassitude and tremor, cardiac weakness, dyspepsia, impotence, or melancholy, we must diminish the dose, or even omit the medicine for a time. Many patients are greatly annoyed by pustules due to the bromide; this can sometimes be avoided by giving Fowler's solution at the same time. If the attacks are decidedly abated, the dose may be gradually diminished, to be increased again, however, if there be any tendency to a relapse.

Recourse to other remedies is seldom had, unless potassic bromide fails, or for some cause must be discontinued. We may then try valerian in powder, 8-30 gr. (grm. 0.5-2) several times a day, or as an infusion. It is a very good plan to give patients who are taking bromide a cup or two of valerian tea at bedtime. Belladonna may also be exhibited, or a pill of atropine, gr.  $\frac{1}{16}$  (grm. 0.0005), three to five times a day; or zinc oxide in the dose of one to three grains (grm. 0.05-0.20), perhaps combined with a grain of extract of belladonna, and fifteen grains of valerian, as a powder, three times a day. There are also many other remedies of doubtful efficacy: curare, hyoscyne, the root of *artemisia vulgaris*, ammonio-cupric sulphate, nitrate of silver, and arsenic.

Electricity is apparently beneficial in occasional instances, and may be tried in connection with other remedies. The galvanic current should be cautiously applied to the head and the sympathetic nerves. Still greater benefit is sometimes obtained from a carefully conducted cold-water cure. Cold sponging with friction at night helps most cases, and it is sometimes very advisable to send the patient in summer to some appropriate establishment for cold-water treatment.

*Treatment during the Paroxysm.*—In most cases we can do little during the seizure except to take such precautionary measures as common sense suggests. We possess no means of suppressing an attack when once under way; nor, indeed, is it often dangerous. In individual instances the patient finds out from experience some method to cut short the paroxysm during the aura. For instance, there are cases where tightly bandaging or vigorously rubbing the part in which the aura originates will avert the convulsions. A number of cases have also been known where the ingestion of a generous quantity of common salt during the aura (usually in these instances starting from the epigastrium) has had the same effect. A patient of our own, whose attacks began with a feeling of rectal tenesmus, maintained that she could almost invariably suppress the convulsions by promptly going to stool, if she had time and opportunity. It was formerly a frequent manœuvre to seek to ward off the attack by compressing the carotids; but this usually fails. Berger recommends the inhalation of nitrite of amyl at the commencement of the fit, having repeatedly seen benefit follow its use.

In the "status epilepticus," narcotics are the most deserving of trial, and in particular chloroform or ether given by inhalation. Amyl nitrite may also be of service.

[It is sometimes desirable to withhold the knowledge that he is an epileptic

from the patient, whose ordinary life should be interfered with as little as is possible.

Especially in cases characterized by headache and heat in the head, Brown-Séquard finds the application of ice directly to the back of the neck and between the shoulders useful.]

## APPENDIX.

### INFANTILE CONVULSIONS (ECLAMPSIA INFANTUM).

Convulsions in childhood are of such frequency and importance as to justify brief special mention here.

Every practitioner learns from experience that the young are especially predisposed to convulsions. Probably this is partly due to excessive reflex excitability of the brain in childhood. Thus children not infrequently undergo convulsions under circumstances in which adults would very rarely have them. They sometimes are seen in children in the beginning of acute febrile diseases, such as pneumonia, scarlet fever, and measles. They also occur from indigestion, particularly when the stomach has been overloaded; sometimes on account of teething; or because of intestinal worms. Here they are in all probability of reflex origin.

Convulsions may occur in very early life without ascertainable cause. In many cases they are really the commencement of epilepsy, as is seen afterward. Again, they may be due to some actual lesion in the brain. For example, if one recalls the initial stage of the acute poliomyelitis and acute encephalitis of children (*vide* pages 668 and 744), it will not seem unlikely that many rapidly fatal cases of "convulsions" are really instances of the diseases mentioned. This point has not yet been at all satisfactorily investigated by pathologists. At any rate, it does not seem satisfactory to us to regard the "œdema of the meninges" found in such cases as an independent disease and the sufficient cause of death. Often convulsions occur suddenly in children and then cease, never to recur, without our being able to find any explanation of the attack. Experience shows that rachitic children are especially liable to suffer from eclampsia—possibly because of cranial rachitic changes (?).

The symptoms of the eclamptic attacks are on the whole analogous with those of epileptic paroxysms. The child's eyes become staring and fixed, and there are tonic and clonic spasms of the face, trunk, and extremities. Such seizures may continue for days with brief intermissions. In such cases the prognosis is dubious, particularly if the child be weakly, but it is by no means absolutely bad. The cause and the significance of the convulsions can seldom be determined immediately.

Symptomatic treatment consists in applying cold to the head, wet packs, sinapisms on the chest and the calves of the legs, and perhaps an enema (to which vinegar may be added). These measures generally answer for mild cases. If the fits are very frequent and violent, we may allow even small children to inhale chloroform, often with great advantage. A dessertspoonful is to be poured upon a handkerchief and administered cautiously.

Of course, we must also try to discover and remove the cause. The attacks due to overloading the stomach usually occur in not very young children, and are apt to be greatly benefited by a prompt emetic or purge.

[A bath at a temperature of 90°-95°, while cool water is applied to the head seems often to be of service; if the child be exhausted by diarrhoea, a head should be omitted. In a teething child it can do no harm.]

has a very marked beneficial effect to lance the gums thoroughly. Enemas containing chloral with or without bromide of potash are more used in this country than is chloroform by inhalation.

A drop of nitrite of amyl by inhalation is said by Eustace Smith to exert a controlling effect on the muscular movements.]

## CHAPTER II.

### CHOREA.

(*Chorea Minor. St. Vitus's Dance.*)

**Ætiology.**—Centuries ago the name *chorea* (dance) was applied mainly to those strange states of "dancing mania" which were endemic in certain places, being due to excessive mental excitement and to the innate propensity to imitation. The specific for this condition was held to be a pilgrimage to some shrine of St. Vitus. At the present time, however, chorea is used to designate a perfectly definite disease, of which the characteristic symptom is the appearance of certain peculiar motor phenomena due to irritation of the nervous centers. It is sometimes called *chorea minor*, in contradistinction from what was formerly termed *chorea major* or *magna*. This latter is, however, not a genuine, independent disease, but a manifestation of hysteria (*q. v.*), or apparently in many instances of epilepsy.

Chorea proper is mainly a disease of children. It occurs most often between the fifth and fifteenth years, although it may be seen both earlier and later. There is a slightly greater liability to it in girls than in boys. Hereditary neuropathic tendencies are also a factor in its ætiology, but not a very important one.\*

As to causation, in many cases nothing definite can be made out. Mental excitement, as from fright, seems in some few instances to favor the onset of the trouble. It is also certain that the imitative impulse will often lead to choreic movements in healthy children who come in contact with choreic patients, but it is doubtful whether this "imitative chorea" can be regarded as true chorea. There is a very interesting connection between chorea and acute articular rheumatism. Although the statement of certain authors, that almost every case of acute articular rheumatism in children is followed by chorea, is far too strong, yet this sequence is comparatively frequent. Chorea is sometimes seen also in children who have a mild form of chronic rheumatism, or in such as have valvular cardiac disease, whether preceded by articular rheumatism or not. [Some observers claim that there is an increased amount of uric acid in the urine of patients with chorea, the acid diminishing as the chorea subsides.—K.] Here chorea is seen as a sequel to an infectious disease; perhaps this is a hint of the light in which we should view apparently idiopathic cases of chorea. [Lewis, having studied 1,383 attacks of chorea and 673 of acute articular rheumatism, finds that the fewest attacks of chorea occur in October and November, the greatest number in March and April. The greatest number of attacks of rheumatism occur in April, the smallest in the autumn. The frequency of attacks of both diseases seems related to the number of storm-centers which passed within four hundred miles of the localities studied, and to the mean actual barometer and mean relative humidity. Over-

\* The so-called hereditary or Huntington's chorea is a special disease. Choreic movements appear in many members of the same family in several generations, and at an advanced age, from thirty to forty. The disease is incurable, and often leads to mental deterioration.

study, acting with meteorological conditions, may be a predisposing but not an exciting cause of chorea.—K.]

Women are particularly liable to chorea during pregnancy. *Chorea gravidarum* is most frequent in youthful primiparæ.

**Clinical History.**—Chorea usually begins gradually, and without any special prodromata. Sometimes, however, there are prodromal symptoms, chiefly a certain mental depression and irritability, with indisposition to intellectual effort. There may be slight rheumatic pains or anorexia, and other evidences of constitutional disturbance.

Ordinarily, the peculiar motor disturbances are the first thing to attract the attention of the patient or its parents. There are involuntary and irrepressible movements in the most diverse groups of muscles. Both single contractions and also complicated movements occur, independently of the will, and in all parts of the body, now in one place, now in another, sometimes in a single member, and sometimes in several at once. The movements may be made in rapid succession, or may be separated by long intervals of quiet. The facial muscles may be involved, causing an occasional wrinkling of the brow or distortion of the mouth. The eyes or the eyelids may also exhibit involuntary movements. The pupils are frequently dilated. If the patient be asked to protrude his tongue and keep it quiet, it will often be involuntarily withdrawn into the mouth or thrust to one side. The tongue may even be sufficiently affected to impair speech. The laryngeal muscles have also been observed to make choreic movements. The arms are frequently the most affected of any part; they are twisted, flexed, elevated, put behind the back—in short, moved in every conceivable way. The trunk is generally but little disturbed in the milder cases, but in severe ones the whole body participates. The patient stands up, lies down again, turns upon his side, etc. The legs are seldom as much disturbed as the arms and face, but slight movements of the lower limbs are very frequent—the foot is thrust forward or extended, the knee is flexed, and so on. In general, it may be said to be characteristic of chorea that the abnormal motor irritation usually affects a considerable number of muscles simultaneously, thus exciting all sorts of combined movements; and, secondly, that choreic movements, for the most part, are not short twitches, but take place in a manner decidedly similar to that of voluntary movements.

The vigor of the movements varies greatly in different cases. At first they may be too slight for the unpracticed eye to catch. Many children in an incipient stage of chorea are unjustly punished at school because they write ill or do not sit quietly. Many cases are mild throughout, never having very severe disturbance. Others, though considerably annoyed, can nevertheless walk or stand alone. In the severest cases, however, the whole body is continually in active motion. The patient throws himself about in bed, and all the extremities exhibit constant violent and irregular movements. The ingestion of food is extremely difficult, sleep is disturbed, and the patient's flesh and strength are rapidly and greatly diminished.

Further, each individual case presents variations in severity at different times. If the patient be left quietly to himself, the contractions are comparatively very slight. As soon as he is conscious of being watched or as soon as any one speaks to him, his condition usually becomes much worse. During sleep the choreic movements cease altogether.

In many cases all the voluntary muscles are involved; but sometimes the disease is limited to certain groups of muscles. Very frequently the disturbance is mainly unilateral (hemichorea); the opposite side of the body then exhibits few involuntary movements, or, it may be, none. As already stated, the face and upper extremities are often more affected than the trunk and lower limbs.

These motor disturbances often constitute the sole or the predominant symptom of chorea. There is hardly ever muscular weakness or paralysis. It is remarkable how little feeling of fatigue there usually is, despite the incessant activity. In a few cases only, of genuine chorea, have we seen actual paresis, affecting, for instance, one arm, or in hemichorea the same half of the body. Sensation is unimpaired. The reflexes do not exhibit striking peculiarities. The tendon reflexes we have sometimes found to be noticeably diminished, although in other instances they were normal. There may be isolated spots in the spinal column tender on pressure, but this is not at all constant. That chorea may be complicated by arthritis and valvular cardiac disease has already been stated. Some caution should be exercised in making a diagnosis of cardiac lesion here, for experience shows that choreic patients are apt to have functional murmurs and slightly irregular cardiac action. [Osler has found that the endocarditis of chorea is very apt to lead to organic valvular disease. Of 110 choreic patients that he examined more than two years after the attack, 54 presented signs of organic heart disease.—K.] The temperature is not elevated, in spite of the constant muscular contractions, nor is the amount of urea excreted by the kidneys increased.

Slight mental disturbance is frequently observed. The patient is often rude, peevish, capricious, incapable of mental exertion, irritable, and inclined to tears; but any great or permanent impairment of intellect is very exceptional indeed.

The entire process generally occupies several months. In mild cases, however, recovery may ensue at the end of a few weeks, while, on the other hand, cases may last a year or even longer. Variations in the intensity of the chorea are often witnessed. These are sometimes spontaneous, and sometimes are due to outward influences. Even when the disease is apparently extinguished, we must be prepared for a possible relapse. The disease may appear repeatedly in the course of a few years, in such a way that it is not easy to determine whether the different attacks are relapses or new illnesses. The protracted cases are, as a rule, comparatively mild; and many cases that begin with great violence end comparatively early. In adults, however, we have met with some rather severe cases which were very chronic, and seemed at last to become stationary.

The termination of chorea, in the great majority of cases, is favorable. Now and then severe cases do occur which end in death. In these the choreic movements are extremely violent. The patient is tossed about in his bed, and can eat little and sleep none. We have ourselves observed three such cases, in girls fourteen to seventeen years of age, which proved fatal within the first two or three weeks. Two died from general exhaustion and collapse, and the third from gangrene affecting numerous cutaneous traumatic lesions, which had occurred despite every possible precaution.

**Nature of the Disease.**—All cases of genuine chorea thus far examined by pathologists have failed to furnish any lesions which can be regarded as essential. In the three cases above mentioned the autopsy revealed absolutely nothing abnormal in the central nervous system. We are at present, therefore, obliged to classify chorea as a "neurosis"—that is, as a disease that produces functional disturbances, for which latter there is no anatomical basis known to us. The symptoms themselves show that the disorder must affect principally some motor region of the nervous system; but just which motor region is involved can at present only be conjectured. It seems very probable, however, that the true seat of chorea is to be sought in the brain. In the first place, the frequent occurrence of hemichorea would indicate this; as would also the fact that slight mental anomalies are frequently combined with chorea: and, finally, "choreiform" movements may occur as the sole symptom of undoubted cerebral disease, as in post-hemiplegic

hemichorea. We have, however, no hint as to whether the motor regions involved are those located in the cortex, or others. The surmise has quite often been expressed that chorea is due to embolism of a mild type; but, in our opinion, this view lacks proof entirely, and is even improbable. As already said, it may be that the connection existing between chorea and acute articular rheumatism will throw some light upon the nature of the former disease.

[Money has produced choreic movements in dogs by the injection of starch into the carotids, thus causing embolism of minute cerebral vessels.]

**Diagnosis.**—The diagnosis is almost always easy, and it can often be made at a glance. The motor symptoms of athetosis, paralysis agitans, and of alcoholic, senile, saturnine, and mercurial tremor are so characteristic as to be readily distinguished from the movements of chorea. It is not difficult to perceive the difference between genuine idiopathic chorea and the symptomatic choreiform movements occasioned by some other cerebral lesion.

**Prognosis.**—As has been stated, the prognosis is almost invariably favorable, although the disease may prove very tedious. The possibility of relapses should be borne in mind. The prognosis is doubtful only in the worst cases of acute chorea, where there is great and rapid failure of the general health.

**Treatment.**—Even in mild cases the patient must be kept from school and at home, in order to avoid all unnecessary excitement from ridicule and the like. If the chorea be only moderately severe, it is not necessary that the child should be in bed; we may even allow moderate exercise in the open air. Where the motions are violent, we should seek to guard the patient from self-injury by means of pillows and cushions.

Among the remedies recommended for chorea, the chief place is occupied by arsenic and potassic bromide. Arsenic in particular seems often to be of value. We give Fowler's solution in water; beginning with five drops, two or three times a day, we gradually increase to eight or ten drops. [In severe cases much larger doses may be given. It should be pushed up to twenty drops or more, stopping for twenty-four hours if symptoms of poisoning appear, and beginning again at the same dose. It should be freely diluted.—K.] In children under six, the dose should be made somewhat smaller. If the child be anæmic, iron may be given in addition; or, if there be great restlessness and loss of sleep, narcotics may also be administered. Antipyrine, in doses of seven to fifteen grains (grm. 0.5-1.0) several times a day, is sometimes of distinct service in severe cases. We may also, especially if arsenic fail, try bromide of potassium in large doses, a drachm (grm. 3-5) a day. Numerous other drugs have been recommended: oxide of zinc, valerianate of zinc, nitrate of silver, and sulphate of copper. At present they are very rarely used; but Riess has lately recommended physostigmine, one sixth to one third of a grain a day (grm. 0.001-0.002), best subcutaneously. [Sulfonal, three to five grains (grm. 0.2-0.4) three times a day, acts well, as an adjuvant to arsenic, in cases where there is much excitement. Exalgine, two or three grains (grm. 0.1-0.2) three times a day, has recently been recommended.—K.] If the disease occur as a sequel of articular rheumatism, we may try salicylic acid. Narcotics should be employed very cautiously in chorea. Although chloral has been recently recommended for grave cases, there are instances known where this remedy has been followed by unfortunate results.

Hydrotherapeutics of a mild kind do good, and can easily be carried out in most instances. Thus, we may use lukewarm baths, a wet pack, or gentle sponging with water at 72°-82° (18°-22° R.) to great advantage.

Electricity may also be tried. A feeble current of galvanic electricity is applied to the head (in the region of the motor centers), or the spinal cord is galvanized. If there be points along the spinal column where pressure causes pain,

it is said to be an excellent plan to apply the anode to them; but the results of electrical treatment are seldom very brilliant.

In the chorea of pregnancy, which sometimes is a very violent disease, the same remedies may be employed. If they do no good, artificial delivery may be required; after which, as we have ourselves once observed, there may be a rapid abatement of all symptoms.

### CHAPTER III.

#### PARALYSIS AGITANS.

(*Shaking Palsy. Parkinson's Disease.*)

**Ætiology.**—In 1817 Parkinson described for the first time a disease which he named the "shaking palsy." It is not of very frequent occurrence, and as yet little has been ascertained with regard to its ætiology. In most cases it develops very gradually, without any demonstrable cause. It almost always attacks elderly persons, being very rare before the thirty-fifth year. Sex does not seem to exert any great predisposing influence. Hereditary neuropathic tendencies can indeed be traced in some instances, but are certainly of less potency in paralysis agitans than, for instance, in epilepsy. Special exciting causes have sometimes been observed, such as catching cold, violent emotional excitement, and traumatic influences, among the latter injury to the nerves, burns, etc. Berger reports two cases where the first symptoms appeared after an acute febrile disease (typhoid fever).

**Clinical History.**—Paralysis agitans has two characteristic symptoms, viz., (1) peculiar evidences of motor irritation, evinced by tremor, and (2) a condition of stiffness and persistent shortening of certain muscles, consequent upon which is a series of peculiar motor phenomena.

The trembling is generally the earliest symptom to attract the patient's attention. It usually begins in the hands, especially in the right hand, and then gradually involves the arm and leg on the same side, next the other arm and leg, and finally, in well-marked cases, the entire body. The form of tremor is very characteristic. There are rapid, uniform, oscillatory movements of varying extent. The tremor is usually greatest in the hands and arms. At the same time the thumbs and half-flexed fingers exhibit a movement which suggests spinning or pill-rolling. The forearm is generally flexed and extended in rapid alternation, but it is always very difficult to determine just what muscles contract. With regard to the trunk, it is often a question whether its tremor is of independent origin, or due merely to the motion of the extremities. Charcot states that the head and the facial muscles are never implicated, but there is doubt about this point. We ourselves, as well as other observers, have repeatedly seen independent tremor of the head. As to the face, the muscles about the chin seem to suffer chiefly.

The trembling of paralysis agitans is almost continuous. It may, indeed, cease for a moment in a limb, but only to recur immediately. The quieter the patient is, in mind and body, the less violent are the movements. If he is excited, or begins to speak, or is watched, the tremor at once becomes exaggerated, and may be violent enough to jar the whole body vehemently. Active motion does not intensify the tremor. On the contrary, it may often be observed that the trembling abates when the muscles undergo vigorous voluntary contraction, as when a weight is lifted, or the hand of another is firmly grasped.

The second symptom is almost more characteristic than the first. It consists of a peculiar rigidity of the muscles. We generally notice, even in the face, peculiar tension of the muscles. This often produces a stolidity of expression, so that the emotions are less clearly depicted than upon the countenance of a healthy person. The head gradually becomes more and more flexed. When the disease has lasted some years, the chin may even rest upon the sternum. The muscles of the trunk and extremities also stiffen gradually, and lead to peculiar and almost pathognomonic appearances. The body is bent over forward; the arms cling to the trunk, and are flexed at the elbow-joint; the fingers are flexed, especially at the metacarpo-phalangeal joint; the thumbs rest against the fingers, as if holding a pen, or else are flexed inward upon the palm; and the legs are somewhat bent at the knee. The accompanying picture (Fig. 107) is from the photograph of a patient who was for a long time under observation at the clinique in Leipsic, and gives a good representation of the characteristic posture.

The stiffness of the muscles also operates to impair motion in various ways. In particular all movements of the trunk are greatly impeded. In advanced cases the patient can not get upon his feet, if he is lying in bed, without help. Inasmuch, however, as the muscular strength usually remains good (*vide infra*), he requires to exert but a slight traction upon some helping hand in order to attain an erect posture. On the other hand, the patient is often utterly unable to turn in bed from one side to the other. In severe cases, therefore, it is often necessary to alter the patient's position several times in a night, especially as lying long in one attitude makes him feel very uneasy. If the patient is in a chair, he can not get up of himself, because it is impossible for him to bend his body forward in the necessary manner; but with just a little help he can stand up, and is then able to walk alone or even to run. Then, since the flexion of the trunk forward brings the center of gravity forward also, and the trunk can not be sufficiently bent backward, he is apt to "get a-going," so that he can not stop until he brings up against a post or a wall. If such a patient, with a considerable degree of anteflexion and rigidity of the trunk, is slightly pushed from behind, he will have to start into a run to avoid falling. This phenomenon is termed "propulsion." A push backward, which brings the center of gravity behind the point of support, is very likely to make such a patient fall, as he will seldom succeed in moving backward fast enough to recover his balance (retropulsion). Both propulsion and retropulsion are conceived by Charcot to be "forced movements" (see page 541) in the strict sense of the term. We are, however, convinced, as the result of numerous observations, that these phenomena can in every case be explained simply by the mechanical conditions arising from displacement of the center of gravity. Again, the reason why many patients are prone to keep their arms behind them as they walk is that such a position contributes slightly toward bringing the center of gravity farther backward.

The movements of the extremities but they often betray a certain slow

FIG. 107.—Characteristic position of the body in paralysis agitans.

ness of the trunk.  
The strength of

the muscles may be preserved for a long while, but often there is at last evident paresis. Even in the early stages of the disease the muscles may become easily fatigued. The impairment of facial expression has already been referred to. In many cases the muscles of the eye also seem to participate in the rigidity, making it difficult for the eye in reading to follow rapidly along each line, or to pass from the end of one line to the commencement of the next. [The voice is often affected; the patient talks in a high-pitched monotone.—K.]

The muscular rigidity is almost more characteristic of paralysis agitans than is the tremor. Indeed, there would seem to be cases, as we have ourselves observed, where, at least for a time, the posture of the patient is typical, and yet there is no trembling. Such cases might be called *paralysis agitans sine agitatione*. In uncomplicated cases all other nervous functions remain perfectly normal. Sensation is never impaired. Sometimes some pain is felt at the commencement of the disease, particularly in the shoulders. There is no striking disturbance of reflex action nor of the bladder. In a few cases of paralysis agitans, cerebral and mental symptoms have been observed; but they are so rare that it is impossible to say whether they belong to the disease or are merely accidental complications. It is also noteworthy that many patients complain of a subjective feeling of excessive warmth. The internal temperature is normal; but it is said that the temperature of the surface of the body is frequently somewhat elevated. Sometimes there is a tendency to excessive perspiration. [Mosse and Banal have found that the excretion of urea and the total excretion of phosphoric acid is increased in paralysis agitans, but that the excretion of imperfectly oxidized phosphoric acid is diminished, thus showing that there is increased combustion.—K.]

The disease runs a very chronic course, perhaps for twenty years or more. From the first, it keeps on slowly but gradually developing. The symptoms rarely exhibit marked alterations of mildness and severity, but for long periods the progress of the disease may be apparently arrested. Recovery has never yet been observed. The final and fatal termination is not brought about by the disease itself, but is due to some intercurrent affection or to general marasmus. The original of the above picture came to a pitiable end by tumbling face downward into a puddle of water. He could not get up, and was drowned.

**Nature of the Disease.**—The true nature of the disease is unknown. Inasmuch as the disorder is purely a motor one, the corresponding lesions must be sought somewhere in the motor system. As yet, however, post-mortem examinations of the nervous system, even with the microscope, have revealed no definite changes. We must, therefore, confess that we have even had a doubt whether it is justifiable to claim that paralysis agitans is an affection of the nervous system at all, or whether it may not possibly be of purely muscular origin. Certainly it would not be impossible for abnormal processes in the muscles to excite the tremor and tonic contraction. But, as has been said, there is at present no ground for deciding this question; we would merely suggest it.

[Borgherini has found, at the autopsy of a case of paralysis agitans, an increase in the nuclei of the vessels of the brain and cord, with changes in their caliber, and hyperplasia of the interstitial tissue affecting the nerve-elements, the hyperplasia being most marked in the motor tract. The gray axis and the white matter of the pons, medulla, and cord were affected. An increase of connective tissue was noted also in the muscles.—K.]

**Diagnosis.**—Any typical case of paralysis agitans can be easily and certainly recognized. The important factors are the peculiar tremor, the characteristic carriage, and the rigidity of the muscles of the trunk and extremities. It was formerly a difficult matter to distinguish between paralysis agitans and multiple sclerosis; but to-day the peculiarities of the two diseases are better known, and

confusion is seldom possible. The character of the tremor varies in the two. In paralysis agitans it persists even when the patient is quiet, and it is decidedly oscillatory. The motion in multiple sclerosis (*q. v.*) is almost always an intention tremor only; and, what is of still greater importance in distinguishing between them, the general appearances of the two diseases are essentially unlike.

**Treatment.**—As has already been implied above, we possess no means of controlling the disease. In most cases, therefore, the treatment is confined to general hygienic measures. Good may be done by lukewarm baths of considerable duration, and by gentle massage of the muscles. Among internal remedies Erb has lately recommended hyoscyne, as having the most palliative and soothing influence. It is best given subcutaneously, and we must always begin with very small doses, as otherwise unpleasant symptoms, such as vertigo, headache, etc., may arise. We inject a twentieth to a twelfth of a grain (mgr.  $\frac{1}{4}$ – $\frac{1}{2}$ ) in aqueous solution (solution of hyoscyne muriate, 1 to 1,000, seven to fifteen minims). If well borne we can cautiously increase the dose. [Atropine has recently shown good results, especially when given subcutaneously.—K.] Arsenic, ergotine, potassic bromide, physostigmine, and curare may also be tried. If electricity is to do any good at all, the case must be a recent one. It is said that in some instances stretching of the nerves has diminished the tremor considerably; but our own observations would not lead us to recommend the procedure in this disease.

#### CHAPTER IV.

##### ATHETOSIS.

IN 1871 the American neurologist Hammond described under the name of athetosis (*ἀθῆτος*, without fixed position) a peculiar symptom of irritation of the motor centers, differing in a characteristic manner from all other forms of involuntary movements, including the epileptiform and choreic. The movements of athetosis (see page 541) are often very complicated and peculiar. The part affected by them is in continuous unrest. If the facial muscles (usually those of the lower division of the facial nerve) and the muscles of mastication be attacked, the face and mouth are constantly being twisted and distorted. If the tongue suffer, as in one case which we saw, speech is difficult and indistinct. If the muscles of the back of the neck be implicated, the head is usually drawn backward or to one side, and is turned and twisted in all sorts of ways. Most characteristic of all, however, are the movements exhibited by the hand and fingers when affected. The fingers are incessantly being separated, extended, flexed, and intertwined, assuming the oddest positions. The accompanying pictures may serve to illustrate this (*vide* Fig. 108). The character of the movements reveals that the interosseous must be chiefly involved. It is a very frequent result of the unceasing stretching of the articular ligaments of the fingers that at last the articulations become relaxed to such a degree as to permit of hyperextension of the fingers, which it is impossible for a healthy person to imitate. The arms are generally less severely affected than the hands; and in the lower limbs the trouble is not often so severe as in the upper. The toes may, however, exhibit motions analogous to those of the fingers.

Although in general the movements are continuous, their vigor frequently varies. Thus they almost always are aggravated if the patient becomes excited. During sleep they generally cease, although in certain instances they have persisted even then, only being diminished. When voluntary motions are being

made they ordinarily grow feebler; but they may, on the contrary, become exaggerated, taking the form of sympathetic movements.

We must distinguish between genuine idiopathic athetosis and a symptomatic form, which also occurs.

Symptomatic athetosis is seen in various nervous diseases. The first observations reported by Hammond were, most of them, made in cases of epilepsy, or the severe psychoses, and the like. By far the most frequent source of the phenomenon, however, is hemiplegia, producing what is known as post-hemiplegic chorea, or better, post-hemiplegic hemi-athetosis. This is, to be sure, a very rare sequel to the ordinary hemiplegia of elderly persons, but follows rather infantile paralysis of cerebral origin (*vide* p. 744). Some traces of athetosis are seen in a majority of the cases of infantile hemiplegia.

Idiopathic athetosis is rare. Here the peculiar movements are the chief, if not the sole, symptom of disease. A few cases of this sort have been reported where the athetosis began without known cause, and usually was limited to some one region. It attacked elderly individuals who were previously healthy. Of especial importance is an apparently congenital form of athetosis, dating from the earliest infancy. Of this we have ourselves seen several instances, which closely resembled one another. The condition is a permanent one, not progressive, nor, on the other hand,

FIG. 108.—Example of the position of the fingers in the movements of athetosis (personal observation).

capable of any great amelioration. The movements are almost always most pronounced in the face, head, and fingers. There are no other nervous disturbances,

neither paralysis nor impairment of sensation. The intelligence of the patient may or may not be below par.

Of the nature of athetosis, or the locality or nature of the irritation, we possess no information as yet. It is extremely probable that the lesion is in every case a cerebral one. Perhaps it is in the cortex. In symptomatic athetosis we find post mortem the changes caused by the original trouble. In idiopathic athetosis no changes have thus far been reported. In a case of our own which came to autopsy, absolutely nothing abnormal was found in the brain. The patient was an elderly female, who displayed typical movements of the arm and hand.

It is not yet known whether recovery is possible. A certain amount of improvement sometimes follows the administration of Fowler's solution, bromide of potassium, or galvanism.

## CHAPTER V.

### TETANY.

(*Intermittent Tetanus. Tetanilla.*)

**Ætiology.**—Tetany, a name originating with Corvisart, is applied to a peculiar neurosis, characterized mainly by paroxysmal tonic convulsions in certain groups of muscles. The disease attacks by preference children and young adults between fifteen and thirty years of age. The physiological processes peculiar to the female sex seem to have an especial tendency to excite the disorder. It is comparatively so frequent in nursing women that Trousseau has called it "*contracture des nourrices*."

Among exciting causes, catching cold deserves particular mention. Hence the earlier observers describe the disease as "intermittent contracture of rheumatic origin." In other cases the disorder has appeared as a sequel to other acute diseases, such as typhus or typhoid fever, smallpox, and intestinal troubles. A very remarkable fact was pointed out by N. Weiss—namely, that tetany is apt to follow operative extirpation of goitre. No explanation of this has yet been discovered. Reports from various quarters give color to the idea that tetany may sometimes be, to a certain extent, epidemic. It must be confessed, however, that it is somewhat doubtful whether the attacks referred to were genuine tetany. We are also inclined to believe that endemic influences may promote its occurrence. At any rate, the published accounts would seem to indicate that tetany is much more frequent in Heidelberg (Erb, F. Schultze), Breslau (Berger), and Vienna (N. Weiss), than in Leipsic, for instance, where it is one of the very rarest nervous diseases.

**Clinical History.**—The paroxysm of tetany usually has certain prodromata, consisting of slight general discomfort and pain, and of a feeling of weakness and stiffness, most marked in the arms. These symptoms last some hours (at least) before the true convulsive stage begins. The upper extremities, and more particularly the fingers, almost always suffer first; and then, after the arms, the lower extremities become involved. The spasm usually affects the toes before it seizes upon the other parts of the leg. The symptoms are almost invariably bilateral and symmetrical. Exceptionally, the disturbance commences in a lower limb, or is confined to one side of the body. In most cases the flexor muscles are predominantly affected, giving rise to very characteristic postures. The fingers are in apposition with one another, and placed as if holding a pen, or, as Trousseau says, as if the hand were about to be thrust into the vagina, during labor.

The hands are flexed, the elbows are also slightly flexed, and the upper arm in severe cases is pressed against the chest. In the lower extremities, the toes are flexed, and the feet are in the posture of talipes equinus. The muscles of the thigh rarely suffer. The same is true of the trunk, face, and diaphragm. The main characters of a typical attack, such as has just been sketched, apply to all but a few cases.

The intensity of the tonic spasm is very great. The affected muscles feel as hard as a board, and are usually rather sensitive to pressure. The attack sometimes continues only a few minutes, but not infrequently it may occupy several hours or days. As a rule, there are no disturbances of sensation or other additional nervous phenomena. There is no impairment of consciousness. In a few instances slight œdematous swelling has been observed, and also profuse perspiration. The temperature is normal or slightly elevated, but the pulse is often quite rapid.

When the attack ceases, which it always does gradually, and never suddenly, the patient feels perfectly well, save for a slight pain and stiffness in the muscles. But even in the interval between the paroxysms there are usually some few objective symptoms, which have a most important bearing on the pathology of tetany. In the first place, the peripheral nerves are generally abnormally sensitive to electricity. The complete demonstration of this fact we owe to Erb. The weakest current will produce frequently violent contractions. In an analogous way, the nerves react to unusually slight mechanical stimulation. This is often peculiarly marked in the facial nerve, as Chvostek and N. Weiss have shown. Thus, if the face be vigorously stroked from above downward, almost all of the muscles contract energetically, one after the other. The direct mechanical excitability of the muscles, on the other hand, is not increased (F. Schultze).

Another very characteristic symptom was discovered by Trousseau—"Trousseau's sign." It is found in most cases, although not in all, and is this: a fresh paroxysm can at any time be artificially excited by pressure upon the larger arteries and nerves of the arm (particularly the median nerve and the brachial artery). It is not definitely known how compression accomplishes this. Berger found that mechanical or electrical irritation of certain painful points situated along the spinal column produces the same result.

The frequency of the attacks varies greatly in individual cases. As a rule, there are several paroxysms daily; but the intervals may last for days, or again may be almost inappreciable. The entire duration of the disease is generally several weeks. It is noteworthy that when the paroxysms grow less frequent and violent there is also a gradual diminution in the hypersensitiveness of the nerves and in the reaction to Trousseau's test. As long as these symptoms persist, spontaneous attacks are also possible.

The termination of tetany is almost always favorable. No essential anatomical lesions have yet been detected. The symptoms leave us in doubt whether the disease affects the peripheral nerves or the nervous centers.

**Diagnosis.**—The diagnosis is not difficult if we only consider carefully the symptoms presented, the nature of the paroxysms, and the other phenomena above enumerated. Similar conditions may result from ergotine-poisoning, or from certain occupations, as in "cobbler's cramp," but the differential diagnosis is usually easy. The peculiar tonic spasms of young children are not, in our opinion, to be regarded as tetany; they have already been described (*vide* page 576) under the name of arthrogryposis, and are characterized by persistent tonic contracture, not paroxysmal, and most pronounced in the distribution of the ulnar nerve on both sides; and in them there is no abnormal sensitiveness of the nerves to mechanical stimuli.

**Treatment.**—The main treatment, besides general hygienic measures, is electricity. The stable current is passed upward through the nerves affected; the galvanic current is also applied to the spinal cord, and the anode is applied to the various nerve-trunks, with the cathode on the sternum. This last procedure sometimes dissipates a spasm actually present. Internal remedies, such as bromide of potassium, arsenic, and belladonna, rarely produce brilliant results. Berger was successful in some cases with subcutaneous injections of curare. Tepid baths, and cold sponging with friction cautiously employed, and applied especially to the back, often aid treatment materially.

---

## CHAPTER VI.

### TETANUS.

(Lock-jaw.)

**Ætiology.**—There are two chief exciting causes of this disease, as are indicated by the names rheumatic tetanus and traumatic tetanus. The rheumatic variety results from catching cold, or getting a thorough wetting, or some similar mishap. The other occurs in persons who have some open wound, whether from injury or operation. There is no ground for establishing tetanus neonatorum as a third distinct form. Cases to which this name has been applied are invariably connected with the falling off of the cord, and are therefore instances of traumatic tetanus. In a few instances it is impossible to discover what has been the immediate occasion of the disease; such cases are classed as idiopathic tetanus.

With us tetanus is a comparatively rare disease. It is noteworthy that people who have to do with horses are quite often affected (Verneuil). In the tropics it is much more common. Negroes are well known to be peculiarly liable to it. Men are much oftener attacked than women. Tetanus has been seen as an endemic and also as an epidemic. This has been most frequent in times of war, and is in part due to the unfavorable influence of certain external circumstances, such as bad weather or bad hygienic surroundings. Traumatic tetanus comes on after injuries of the fingers, hands, and lower extremities.

All these facts must previously have led to the thought that tetanus was a specific infectious disease, but we have only recently succeeded in establishing an actual foundation for this suspicion. Rosenbach cultivated from the wound of a man who died of tetanus a special form of bacillus which Nicolaier had formerly found in garden earth. These bacilli are distinguished by a little head at one end (spur). If a small amount of these bacilli be injected under the skin of mice, the most violent tetanic spasms ensue in the animals thus treated. Since the development of the bacteria remains limited to the seat of the wound or the injection, it is *a priori* probable that the spasms are not excited immediately by the bacilli, but by a chemical poison produced by them during life. In fact, Brieger has lately succeeded in producing several alkaloid-like substances from tetanus-cultures, so-called toxins, which he terms tetanine, tetanotoxine, and spasmotoxine. All these substances are violent poisons, and, like strychnine, provoke the most violent tetanic spasms in the animals experimented on.

It is still uncertain whether the tetanus bacilli enter the body only through injuries of the skin, or in other ways.

**Clinical History.**—In rheumatic tetanus the symptoms usually begin soon after exposure to the exciting cause. There may be, however, an interval during which the patient feels perfectly well, or at most has only certain mild and indefinite

premonitory symptoms, such as languor and headache. Similar prodromata may occur in the apparently idiopathic cases.

Traumatic tetanus seldom begins immediately after the injury has been received. Several days or even weeks may intervene previous to the outbreak of the disease. Here, too, there may be mild prodromata for a brief period preceding the graver phenomena. The patient's wound presents no specific appearances. Tetanus may be associated with either slight or severe injuries, whether treated carelessly or kept aseptic.

The symptoms of the disease proper are the same in both rheumatic and traumatic tetanus. They usually begin gradually. Ordinarily, the first thing noticed is a feeling of rigidity and tension in the muscles of the face, lower jaw, and back of the neck. The stiffness spreads by degrees to the muscles of the back and abdomen. The disease is sometimes completely developed in a few hours, but sometimes not till after several days.

The persistent tension of the facial muscles gives the countenance a strange immobility. The brow is usually wrinkled, and the corners of the mouth are often drawn back in a "sardonic grin." Most prominent of all is the tonic spasm of the masseters, or trismus. The teeth are so firmly pressed together that it finally becomes impossible to open the mouth more than one or two millimetres. The eyes are staring, the pupils usually contracted. The muscles at the back of the neck draw the head somewhat backward, and it is immovable. The spinal column is bent forward, so that the trunk is convex anteriorly, permitting the hand to be passed between it and the bed—opisthotonos. The epigastrium and the anterior part of the abdomen are flat. The abdominal muscles are as hard as a board. The lower limbs may be rigidly extended, but the arms generally can be quite freely moved. Convulsive dysphagia, as seen in hydrophobia (*q. v.*), may occur, but it is rare (*vide infra*).

In many cases the continuous tonic spasm is occasionally interrupted by sudden and irregular paroxysms, during which all the affected muscles become still more tense. In severe cases this gives the whole body a violent shock, and makes the opisthotonos even more pronounced. In a very bad case the paroxysms are very frequent; in a mild case they are rare or almost indistinguishable. Sometimes they are apparently spontaneous, and sometimes they are evidently of reflex origin, being superinduced by external irritation. In severe cases the cause may be comparatively insignificant, such as a slight jar or noise.

If there are other nervous derangements, little is known about them—partly, no doubt, because it is seldom possible to make an extended examination of the patient. Sensation is said to have been impaired in some instances, but in others it is perfectly normal. The muscles affected by the spasms are usually the seat of severe pain. The cutaneous reflexes are almost always greatly exaggerated. In two cases which we saw very recently, the patellar reflex was much increased, and in one there was distinct ankle-clonus. Paralysis is extremely exceptional. There is often profuse perspiration. The intellect remains perfectly unclouded.

There is a special form of tetanus which must be briefly mentioned. It was first described by E. Rose, and is called "hydrophobic tetanus," or "cephalic tetanus." It occurs only in connection with injuries situated in the distribution of the cranial nerves—that is, in the face and head—and is characterized in most cases by violent spasm of the pharynx and œsophagus. This is in addition to the other ordinary phenomena of tetanus. The disease in many ways reminds one of hydrophobia. Another characteristic point is that in most cases there is facial paralysis on the injured side.

Tetanus seldom gives rise to disturbances referable to the internal viscera. In one case, however, in the Leipsic hospital, croupous pneumonia and acute nephri-

tis came on a few days before the end. Often there are dyspnoea and a most harassing sense of thoracic oppression—symptoms due mainly to the convulsive rigidity of the muscles, by which the thorax is constantly maintained in the position it normally assumes during inspiration. Expectoration is impeded; and, finally, there may be such an accumulation of secretions in the mouth and air-passages as to cause a secondary diffuse bronchitis, or an inhalation pneumonia. Another occasional source of extreme dyspnoea is spasm of the glottis.

The pulse often remains normal for a long while, but it is usually accelerated, not infrequently reaching 120 or 160 beats a minute in severe cases. Such a pulse is small, and may be somewhat irregular. The temperature is at first usually normal, or slightly elevated. Later it is almost sure to rise; and, as Wunderlich pointed out, it is often very high shortly before death—for instance,  $107^{\circ}$  to  $111^{\circ}$  ( $42^{\circ}$ – $44^{\circ}$  C.). It is not rare for the temperature to keep on rising for a short time after death. No explanation of this terminal elevation of temperature has yet been furnished. It can not be the result of the increased production of heat occasioned by the muscular spasm, for in earlier stages the most violent convulsions are unattended by any such change. Authorities are, therefore, inclined to assume that at the last there is a paralysis of the centers which regulate the warmth of the body, just as is seen in other severe nervous disorders, such as meningitis, injury to the cervical portion of the cord, and uræmia.

Interesting observations have been made with regard to tissue-metamorphosis during tetanus. The excretion of urea is not increased. This fact agrees well with Voit's view, that muscular activity has no connection with the breaking down of albuminoids. Senator failed to find any increase of kreatine and kreatinine in the urine. Probably the production of carbonic dioxide is abnormally large in tetanus. At least, physiological considerations would strongly indicate this, although it has not yet been actually demonstrated. Occasionally traces of albumen and sugar have been detected in the urine. There is usually obstinate constipation, probably due to the persistent rigidity of the abdominal muscles; and, indeed, micturition is not a little impeded from the same cause.

It may be said, in regard to the general course of the disease, that there are severe and mild forms of the disease. What has been said above applies mainly to the severe form. In this, all the symptoms reach their extreme violence in a few days, the paroxysms occur in quick succession, and death usually takes place within a week or two. The fatal result is brought about by the suspension of respiration and by cardiac failure. Of course, the extreme difficulty of taking an adequate amount of food has an unfavorable influence. The bad cases seldom outlast the first week. If they do, there is some slight hope of recovery; the paroxysms may gradually become less frequent and less severe, until they finally cease altogether. The severe form, however, so rarely ends favorably that the prognosis is always very grave. The mild form, on the contrary, usually runs a much more favorable course. In it, all the symptoms are from the first much less severe. Often there is only more or less trismus, accompanied by no marked spasm in the muscles of the trunk, if any at all. There is little constitutional disturbance. The temperature is normal; and the prognosis is rather favorable. The disease may sometimes drag on for some weeks, but it often ends in complete recovery. It must not be forgotten, however, that what at first seems a mild case may develop into the severe form.

The anatomical changes in the nervous system in fatal cases are almost wholly negative. Any small hemorrhages, etc., have, if they be present, only a secondary significance.

**Diagnosis.**—In most cases, tetanus can be easily recognized from the peculiar convulsions and the general aspect of the disease. It might be confounded with

acute meningitis, for this may cause rigidity of the neck and back; but here there are usually certain cerebral symptoms also present, such as headache and impairment of consciousness; and, on the other hand, in tetanus, trismus is an almost constant phenomenon, although exceptional in meningitis. Strychnine poisoning produces convulsions similar to those of tetanus, but they generally affect the extremities in a more marked degree. Hydrophobia is distinguished from tetanus by the ætiology, the absence of trismus, the predominance of the pharyngeal convulsions, and the greater distinctness of the individual paroxysms.

Where trismus is the only symptom, we must guard against mistaking for tetanus the symptomatic rigidity of the jaws which occurs with severe sore throat, diseases of the teeth, or inflammation of the maxillary articulation.

**Treatment.**—There is no specific method of treating tetanus. In accordance with the view above mentioned as to the nature of the disease, we have employed, repeatedly, large doses of salicylic acid. This seemed to work well in one case, but in others it did not. We must therefore rely mainly on symptomatic remedies, with the aim of preserving life until a spontaneous cure takes place. For this purpose, narcotics are apparently to be preferred; and among them the best are opium in large doses, and chloral, of which thirty grains (grm. 2) should be given two or three times a day, and the amount gradually increased. If deglutition be very difficult, the chloral may be given per anum. Bromide of potassium should also be mentioned (at least two and a half to four drachms, grm. 10-15, daily), and calabar-bean (a sixth of a grain of extract of physostigmine, grm. 0.01, three to five times a day). The above remedies diminish the irritability of the nervous centers. In curare we possess a means of lowering the excitability of the terminations of the motor nerves in the muscles. It has therefore been employed by many, but by few with success. It is difficult to say what the dose of curare is, inasmuch as the strength of different samples varies. The best way is to determine the strength of the solution to be employed by experimenting on some animal. Usually a one-per-cent. solution of curare in water is employed, and an amount equal to one quarter of the contents of a Pravaz's syringe is injected, the dose being gradually and cautiously increased. [Such a syringe contains about thirteen minims (0.8 grm.).]

It is very desirable to put the patient by himself in a darkened and quiet chamber. Nourishment should be liquid, and lukewarm stimulants, such as alcohol and camphor, should be given from the first. Protracted warm baths may be given cautiously. We know from personal observation that such baths are very grateful to some patients.

It need hardly be said that in traumatic tetanus the primary wound should receive careful attention. Since, according to recent investigations, the tetanus bacilli remain limited in their growth to the seat of the wound, it may be indicated in the beginning of tetanus, if possible, to amputate the wounded part or to excise the wound. Of course, from present experience we can not promise a successful result. Otherwise the treatment is the same as in rheumatic tetanus.

## CHAPTER VII.

## CONGENITAL MYOTONIA.

*(Thomsen's Disease.)*

IN 1876, Thomsen, a Sleswick physician, described a peculiar disease which up to that time had escaped observation. He had had experience of it in himself and numerous members of his own family. Thomsen called it "tonic convulsions of the voluntary muscles," an appropriate but somewhat clumsy name, for which we suggested instead "congenital myotonia." Apparently the disease is very infrequent; but a considerable number of cases have already been reported in Germany, France, and Italy.

The disease seems to be congenital; at least, the symptoms invariably date from the earliest infancy. It is very often hereditary; and males seem to suffer oftener, and also more severely, than do females. The essential symptom of myotonia is this: whenever any voluntary muscle has been inactive for a time and is then made to contract, it falls into a state of more or less persistent contraction, a mild sort of tetanus, so that it can not be immediately relaxed. It is obvious how this would interfere with any series of motions, and make voluntary movement difficult. The patient is not paralyzed at all, but he has a feeling of great resistance to be overcome in performing any act. Quick and accurate motions are often out of the question, so that, for instance, the patient can not perform military duty. It is noteworthy that the stiffness temporarily disappears after the patient has been moving his muscles for some time. On going upstairs, the first steps are often very stiff and laborious, while succeeding ones grow easier and easier. Mental excitement invariably exerts a very unfavorable influence, exaggerating the stiffness of the muscles.

Upon physical examination, the observer is usually struck by the extraordinary development of the muscles. The size of the extremities, in particular, almost deserves the term "genuine muscular hypertrophy," although the strength is not always proportionately great. It is a remarkable fact that, upon direct electrical irritation of the muscles, the contraction outlasts, in most cases, the passage of the current. This is also true, although less marked, when the electricity is applied to the motor nerves. Erb has also observed, during the stable application of the galvanic current, wavelike contractions starting from the cathode and passing one after another over the muscles toward the anode. The direct mechanical excitability of the muscles is sometimes normal, but sometimes increased. The idio-muscular contractions (*vide* page 546) are especially apt to be increased. The reflexes, sensation, and, indeed, all other nervous phenomena, are normal.

These facts render it very probable that the cause of the disease is to be sought in the muscle itself, and that myotonia is due to a congenital peculiarity of the muscular system. Erb reports that, upon microscopic examination of minute particles of muscular tissue which were excised, he found marked hypertrophy of individual muscular fibers, and an increase in the number of nuclei in the sarcolemma.\*

\* [In a recent treatise Erb admits only twenty-three typical cases known at present. His investigations show that on voluntary movement there are protracted contractions of the muscles lasting from five to thirty seconds; these he terms myotonic disturbances of motion. Mechanical excitability of the nerves is perhaps diminished; faradic excitability of the nerves is normal, but a sudden increase of the current may excite protracted contraction; galvanic excitability is nearly normal, but a succession of shocks may produce the tonic contraction. The mechanical excitability of the muscles is increased, a touch with the finger being enough to excite tonic contraction. Faradic excitability

The disease persists through life. The patient gradually becomes accustomed to it, and learns to conceal his misfortune as much as possible. There may be no constitutional disturbance. Sometimes there is melancholia. Therapeutic efforts have not yet been attended with much success. We might try cold sponging, with friction, gentle massage, and methodical exercise of the muscles.

[Ealenburg describes a congenital family affection, which he calls congenital paramyotone, allied to myotonia, where tonic spasm was produced by cold. Gowers has found the association of tonic spasm with ataxia—ataxic paramyotone.—K.]

## CHAPTER VIII.

### CATALEPSY.

FORMERLY catalepsy was regarded as a special form of disease, but at present the opinion is almost universally held that it is merely a symptom of several different diseases. As was mentioned on page 541, "cataleptic rigidity" is a term descriptive of that peculiar condition of the muscles in which the limbs maintain involuntarily any position which the observer puts them into. If we change the position of the members which are cataleptic, the patient does not make the slightest effort to alter the posture in which we leave them, however strange and awkward, and apparently insupportable, it may be. The limbs may be moved in this way almost like wax, and have therefore been said to exhibit a "waxy flexibility."

No real explanation of the cataleptic state has been given. We have not yet advanced beyond the study of the circumstances under which it appears, and of the associated phenomena. As has been said, the tonic muscular spasm of catalepsy is never very great, being little more than suffices to overcome gravity and maintain the limb in the posture given to it. This shows that there must, in every case, be a due proportion in the vigor of the contractions of antagonistic muscles; and this relative force must vary with every change of position. How this continuous and remarkable regulation of motor nervous energy takes place is an unanswered question. Perhaps reflex action has something to do with it. A further interesting point is, that changes of position induced by electrical stimulation of the nerves or muscles are not permanent; when the stimulus ceases to act, the limb falls back into its old place.

Catalepsy occurs oftenest as a symptom of hysteria. In this case it is usually associated with other disturbances, chief among which are impairment of consciousness and anæsthesia. The anæsthesia is especially marked in the muscles. For example, the patient will stand for an hour with arms extended, and yet experience not the slightest sensation of weariness. At last, however, the arms sink slowly down. Closely allied to hysterical catalepsy is hypnotic catalepsy, a condition which can be artificially produced by certain procedures (see the next chapter) in many hysterical subjects at will. Charcot has reported cases where

is very marked; the muscles are quickly relaxed after weak currents, but a sudden increase produces protracted contractions. Galvanic excitability is increased quantitatively, anodic and cathodic closure contractions appearing with currents of one or two milliamperes; qualitatively both poles react alike. The wavelike contractions mentioned above are very characteristic. Erb has given the name of myotonic reaction (MyR) to these electrical phenomena. Hereafter, he thinks, a tap with the percussion hammer and a few cathodic closure contractions will suffice to establish the diagnosis. Besides the anatomical changes above mentioned, Erb also finds that the cross-section of the individual muscular fiber is rounded instead of polygonal, like the normal fiber, and that the interstitial tissue is increased. In one case he found a striking vacuolization of the individual fibers.—TRANS.]

the lethargy of hypnotism could invariably be transformed into catalepsy by opening the previously closed eyes. These cases also presented, in addition to the catalepsy, the strange phenomenon called "suggestion." If the patient were put into any posture associated with some definite mental conception (such, for example, as the attitude of prayer, or that assumed in terror, or to express detestation), then the corresponding thoughts would come into the mind, as a hallucination, but with all the vividness of reality. Ample proof of this was visible in the expression of the face and in the whole bearing of the subject. An analogous fact has been observed by Duchenne, Lasègue, and ourselves—namely, that sometimes a hysterical person can be brought into the cataleptic state by artificial closure of the eyes (compare what is said in the next chapter about hysterical anaesthesia).

Catalepsy is also seen in many psychoses, particularly in certain grave forms of melancholia known as melancholia attonita and katatonia, and sometimes in progressive general paralysis. (For particulars see works on insanity.) The cataleptic state may also develop in connection with grave organic cerebral disease, as in meningitis and apoplectic coma. It may finally be mentioned in passing that quite well-marked catalepsy is sometimes observed in young children of one or two years when they are ill. Probably they fall into a sort of stupor; or often it seems that they are rendered hypnotic, as it were, by the presence of strangers.

Catalepsy has been regarded as a special disease in those very rare cases where otherwise healthy persons are liable to "cataleptic fits." The condition comes on suddenly, unprovoked, and passes off spontaneously after a variable length of time. It is, however, very probable that these cases are either hysterical or epileptoid, and deserve to be classed with genuine epilepsy.

**Prognosis and Treatment.**—Since catalepsy is a symptom of so many different diseases, it is impossible to make any general statements with regard to prognosis or therapeutics. The reader may gain some light from the remarks on the treatment of hysteria in the next chapter.

## CHAPTER IX.

### HYSTERIA.

**Ætiology and Definition.**—It is impossible to give a definition of hysteria that shall be at once brief and accurate, for the aspects of the disease are so manifold that there is no one symptom which can be called pathognomonic or even universally characteristic. Hysteria is therefore symptomatically not a well-rounded morbid unit, but the nature of all those pathological conditions which we term hysterical may very well be regarded from a single point of view. Hysteria thus has its peculiarities and its rules like any other disease. Only because its laws have been sought elsewhere than where they really are, has the claim often been made in the past that the morbid symptoms of hysteria were subject to no law.

The fundamental condition for a right understanding of hysteria seems to be that we should free ourselves from the old untenable idea that hysteria is a "general functional disease of the whole nervous system, where now this and now that portion of it may be disturbed in its functions." We regard hysteria as a disease which relates to the cerebral activity immediately associated with the psychical processes—that is, if you will, with a psychosis, but in the broader sense of the word; the disturbance affects not only the normal course of the psychical pro-

cesses, but also their association with the purely corporeal processes of innervation. The starting point of the disturbance, however, is always, in its final relation, in the psychical sphere, although, as we shall see later, the occasion of the psychical change is often to be sought in material processes.

Starting from this standpoint we may note the following characteristic marks of hysterical affections:

1. All hysterical disturbances, no matter how severe the functional nervous derangement attributable to them, are without visible anatomical basis. The best proof of this is the fact that any case, however alarming, may recover completely in a very short time.

2. The hysterical affection is very often intimately associated with exciting causes of a psychical nature. Not only is its appearance and incipency most closely linked with emotional excitement, but later on the mind is the main if not the only channel through which causes can operate to change the condition of the patient, whether favorably or unfavorably.

3. It is therefore evident that the origin of all hysterical disturbances must be sought in the most central portions of the nervous system—those regions which are most directly concerned in the mental processes. Hysterical phenomena are, however, exhibited in all parts of the nervous system, so far as these depend upon psychical processes or may be altered by them. The symptoms of hysteria are therefore more manifold than those of almost any other disease. Although so manifold, certain symptoms predominate with such frequency as to be characteristic of hysteria, and therefore to be regarded as especially valuable in diagnosis. Following Charcot, we term such symptoms "hysterical stigmata." These symptoms are most constantly present, and therefore they can easily be found at any time.

4. Besides the permanent symptoms—the "stigmata"—we see in many cases of hysteria peculiar nervous attacks. These are also highly characteristic of hysteria, since they come on in forms which are seen in no other disease; but there are also patients who suffer from hysteria who nevertheless are never visited by attacks. The possibility of the occurrence of an attack is, however, always present. Very often the attacks are provoked by easily discoverable psychical causes.

After this brief introduction, turning to the ætiology, psychical causes, as has been said, are of first importance. In numerous instances hysteria comes on as an immediate sequel to violent emotional excitement or to a "psychical trauma," if we may use such an expression. Hysterical convulsions or paralysis may be excited by great terror or violent anger or any unusual agitation. Here the efficient cause is often hidden by some attendant circumstance. If, for example, a woman falls into the water, or gets burned, or tumbles downstairs, and thereupon develops hysteria, the mistake is often made of ascribing the disease to catching cold, or to the injury received, although really it was the mental excitement which produced it. Only in severe traumatic concussion of the whole body may the partly physical symptoms of *commotio cerebri* and *commotio spinalis* be united with the psychical shock. There then develop peculiar morbid conditions which we term traumatic neuroses and which are closely related to hysteria. We will speak of them particularly in the last chapter of this section. Purely hysterical conditions, such as *anæsthesia*, *hyperæsthesia*, *contracture*, *paralysis*, etc., may also arise from slight local injuries. What is very remarkable in such cases is, that the special attendant circumstances at the time of the psychical disturbance often influence the localization of the hysterical phenomena: that part, to which attention was particularly directed at the time, not infrequently becomes, later on, the seat of the nervous disturbance. In hysterical joint-affections (page 528) the cause not infrequently proves to have been an injury to the particular

joint now suffering from hysteria. A young girl, who was awakened at night by the smoke of her burning mattress, and who had a severe laryngitis from inhaling the vapors, exhibited later an indubitably hysterical paralysis of the vocal cords. In the case of another girl, who in jumping from a carriage fell upon her side, we afterward saw hemianæsthesia of the same side. Many such instances could be cited.

Certain hysterical cases, therefore, have for their obvious cause a single occasion of mental agitation; but in many others the disease is not thus abruptly excited. As, in poisoning, we can distinguish between the sudden action of a large dose and chronic cases where minute amounts of poison are absorbed daily for a long period, so hysteria may come on not only after a single violent shock, but also as the final consequence of psychical influences insignificant of themselves, but potent because of their frequent repetition or persistency. It is in cases of this sort that the causes do not become evident to the physician until he has gained the entire confidence of his patient; for the root of the trouble is often entwined about the most private affairs. Anxiety, sorrow, disappointed expectations, abandoned hopes, and, in brief, everything which can depress and overwhelm the mind—these are factors which may at last excite the functional nervous derangements of hysteria.

Finally, we must state that hysteria may often develop without any specially noticeable cause. We see this particularly in young people with a marked hereditary nervous taint. Here the ordinary daily demands upon the central nervous system sometimes suffice to disturb in a measure its normal equilibrium.

There are still other causes. The blow which brings a feeble body to the ground rebounds without effect from a massive frame. Exactly the same may be said of the "blows" to which the nervous system is subjected. Few entirely escape these influences, but there are some "strong natures" who resist the psychical assault without wavering, while others have a feebly resistant nervous organization and are overpowered. We see, therefore, that the predisposition of different individuals to diseases of the nervous system varies. This fact is a very important one in the pathogenesis of all functional nervous disorders. In what this predisposition consists we do not know, being acquainted only with its results and with some of its causes.

In many cases this predisposition is hereditary. Hysteria is prominent among those neuroses which attack different members of a family—one suffering from one disease and another from another (*vide* page 770). It is also possible to acquire such a predisposition. At least it may be developed and fostered, on the one hand, or, on the other, checked and repressed. In these directions physical as well as psychical factors are of importance. Anything which weakens the constitution diminishes the resistant power of the nervous system. Among psychical influences, nothing favors the development of hysterical tendencies more efficiently than does a bad education. Hysteria is often ascribable to an irritability and feebleness of the nervous system thus engendered. The whims of the child are not controlled, its will is not strengthened, nor its energy developed; its imagination is unsuitably and excessively stimulated, or its intellectual powers are overtaxed and prematurely ripened.

It is well known that hysteria occurs more frequently in the "feebler" female sex than among men; but it is by no means a rare thing for men to exhibit hysterical convulsions, paralysis, contracture, or other well-marked disturbances. Most cases occur between puberty and the end of middle life. It is not very rare to see pronounced hysteria in children, especially such as are over eight or ten years old. The disease very frequently begins to develop a year or two previous to puberty. Nationality and race also seem to exert some influence—for instance,

the severer forms of hysteria are decidedly more frequent in France than in Germany; and the Jewish race are particularly subject to the disease.

One matter remains to be considered with regard to ætiology, to which a greatly exaggerated importance was formerly ascribed. It is the influence of disease of the sexual organs. The very name "hysteria" (*hystéria* = uterus) reveals what the old view was, namely, that hysteria invariably originated in disease of the female genitals. Not to speak of the fact that the disease occurs in men and children, an unprejudiced consideration of the matter will show that the above assumption is entirely groundless even in regard to women. A large number of hysterical women present no anomaly of their sexual organs; and even if the latter be diseased, we are not justified in at once assuming that the hysteria is secondary to the sexual disorder. In these cases, also, we usually find, on careful inquiry, that psychical causes have been at work; and these are incomparably more potent in exciting hysteria than is malposition of the uterus or constriction of the cervical canal. It is true, however, that disease of the genital organs may depress the spirits more than some other diseases would, and so indirectly promote hysterical disturbances. In the same indirect way, menstruation, pregnancy, and confinement exert an important influence upon the development and course of hysteria. Sexual excesses or total abstinence from sexual indulgence also produce their effects indirectly through the mind.

#### THE SYMPTOMS AND MANIFESTATIONS OF HYSTERIA.

Considering the great differences in the external morbid symptoms under which hysteria may manifest itself, it is not easy to give in a brief summary a superficial, intelligible, and yet accurate description of its clinical manifestations. We believe that we can best attain this end by speaking first of the most important and most frequent of the single symptoms of hysteria, by describing next the hysterical attacks, and finally by trying to evolve a general picture of the disease.

1. **The Hysterical Stigmata, especially the Sensory Anæsthesia and Hyperæsthesia.**—In every case where the diagnosis of hysteria has already been established or where it is to be confirmed, we must examine the patient for certain symptoms, which, as we have said, are so common in hysteria, and in part so peculiar to it, that by themselves they are often of decisive diagnostic significance. These symptoms are termed "hysterical stigmata." A knowledge of them is the more important for the physician in that we often detect them only by a special examination directed to that end. Patients only exceptionally inform us as to these symptoms. It is not at all unusual for patients to have no inkling of their existence until after an examination.

The most important, because the commonest, of these hysterical signs relate to sensibility. The more carefully we examine, the more rarely will we meet with a case of severe hysteria in which in some sensory region we do not find manifest disturbances, especially a diminution of sensibility. We must therefore test accurately not only the sensibility of the whole surface of the body, but also the functions of all the other senses (sight, hearing, smell, and taste).

The sensory disturbances of the skin must first be mentioned. Not infrequently we find a diminution of sensibility over the whole surface of the body, especially a more or less complete analgesia. In such cases we can stick a pin in deeply anywhere, or pierce a fold of skin with a pin, without the patient's complaining of pain. As is well known, it often happens that hysterical patients, in order to appear interesting or from some other reason, produce upon themselves deep injuries and wounds; this is almost always connected with the patient's analgesia. Very

often, however, the anæsthesia is not general, but it is limited to a definite region. We find complete anæsthesia of one arm or leg, or we find on the trunk or the extremities single areas of anæsthesia, in which the anæsthetic parts are bounded by the normally sensitive skin; these areas may take all possible forms, and may often be very peculiar. The sensibility to pain is almost always the most disturbed when the other forms of cutaneous sensibility may be quite unaffected, but changes in the sensibility to temperature, pressure, etc., may also occur. It may be added that in the severer forms of anæsthesia the deeper parts may also be insensitive, so that the so-called muscular sense is absent, and patients with their eyes shut have not the slightest idea of the position of the anæsthetic limbs.

Besides cutaneous anæsthesia, disturbances in the sensibility of the other sensory organs (other "sensory anæsthesias") are among the commonest signs of hysteria. Sometimes the patients say, when asked, that they see indistinctly and dimly. If we examine the eyes we often find a loss of visual acuteness and a rapidly induced fatigue on using them. A limitation of the visual field is the most characteristic sign—that is, an anæsthesia of the peripheral portions of the retina. The degree of this limitation sometimes shows manifest differences for the different colors. Hysterical achromatopsia is a common symptom—that is, a partial or complete loss of the color sense. According to Charcot, in the hysterical the perception of violet usually first disappears, then green, and lastly blue and yellow; but we must not hold too strictly to all these rules; for, although the French investigators are otherwise deserving of great praise in adding to our knowledge of hysteria, in this respect they seem decidedly too schematic, and to have generalized too rashly. Diminution of the auditory acuteness in one or both ears is also not uncommon. Anæsthesia of smell and taste is still more common. Salt, quinine, vinegar, sugar, etc., either excite no sensation of taste at all, or the tongue is anæsthetic for one or another of these substances. The same holds for the sense of smell. All these symptoms are especially important in diagnosis, because in organic diseases they are relatively much rarer in such a degree than in hysteria.

The sensory anæsthesias above described may of course be combined in various ways in different cases, but none of these combinations is so characteristic and individual as hysterical hemianæsthesia, a symptom-complex which occurs almost solely in hysteria, and is therefore of distinct diagnostic value.

Hysterical hemianæsthesia is one of the most common symptoms of profound hysteria. It must often be sought for, inasmuch as the patient herself frequently has no suspicion of its existence until her attention is called to it. It seems just as if one half of the body had been entirely lost to consciousness; the patient does not know whether it is or is not capable of feeling.

In a typical and fully developed case the hemianæsthesia does actually affect just one half of the body. There are rudimentary forms; but in these complete ones, the boundary between the anæsthetic parts and the parts retaining normal sensitiveness accurately corresponds to the median line of the body. The skin on the affected side is entirely insensible to the prick of a needle or to heat. Often it seems somewhat blanched, and its blood-vessels seem to be constricted; at least the skin very often bleeds surprisingly little if wounded. The mucous membranes upon the abnormal side are all equally anæsthetic, including the conjunctiva, that half of the buccal cavity and of the tongue. The deeper parts, such as the muscles and joints, are also almost invariably anæsthetic. The patient can no longer feel in what position the limbs of the affected side are; and if they are moved passively, no sensation is communicated to her. The organs of special sense are usually involved. Hearing is impaired upon the affected side; the corresponding half of the tongue can not taste; the corresponding nostril can not smell; and

sight upon that side is affected in a peculiar manner. There is no hemiopia, but a total amblyopia, or possibly amaurosis. If the amaurosis be not complete, we find at least a limitation of the visual field and the signs of the above-mentioned achromatopsia.

Apart from other hysterical symptoms with which hemianæsthesia as well as all the other sensory anæsthesias may be associated, we must mention here one symptom which is in close relation to anæsthesia, and which was first described by Duchenne under the name of "loss of muscular sense" (*perte de la conscience musculaire*). The patient, whose arm, for example, is anæsthetic, can not move it if she closes her eyes, although with open eyes she can move it as well as ever. When the eyes are shut the arm remains motionless in the position it has previously occupied. If its position be altered by passive motion, the new position is maintained with equal persistency. There is, with the eyes shut, pronounced catalepsy. Duchenne referred this peculiar symptom to the loss of a special sense which he termed "muscular sense" (*conscience musculaire*). According to our present conception of hysteria it would be more correct to regard the symptom as purely psychical.

The much-discussed and peculiar symptoms of transfer, as well as metalloscopy and allied symptoms, will be mentioned below.

Thus far we have spoken only of anæsthesia, but we very often find in the hysterical certain hyperæsthetic regions. These hyperæsthesias are so characteristic that we must reckon them among the hysterical stigmata, and must therefore look for them in every case. Sometimes the physician's attention is called to these places because they are the seat of constant slight or severe pain. In other cases the tenderness appears only upon pressure. The hyperæsthesia may be so great that the patient can scarcely bear the slightest touch. Of course, the hyperæsthesia is very closely connected with the condition of the patient's attention. If the thoughts be diverted, even firm pressure is often not at all noticed. We see clearly, then, that we usually have to do here with a "psychical hyperæsthesia."

The hyperæsthetic spots are either quite extensive or quite circumscribed, or even limited to one definite spot. They may lie near to or in the midst of anæsthetic areas. They are relatively rarest in the extremities and more common on the head and trunk, especially on the sternum, on the sides of the chest, under the mamme, etc. Most common, and therefore especially characteristic, is the hyperæsthesia of the vertebral column, and, in women, of the lower abdominal region ("ovarian pain," "ovaric"). The latter term is convenient but by no means correct, since really we have only a tenderness of the soft parts generally, which is at once noticeable on deep pressure, and we do not have solely or chiefly a tenderness of the ovary. We usually find "ovaric" only on one side, oftener on the left than on the right. Analogous symptoms in men—tenderness in the groins or the testicles—are less common. Hyperæsthesia of the vertebral column, hysterical "spinal irritation," is even more important for diagnosis than ovaric. The hyperæsthesia affects either the whole spine or merely single portions of it, often only single vertebræ. It may attain so high a degree that the slightest touch of the skin over the vertebræ, or somewhat deep pressure, may cause the liveliest outcries and shrinking. This symptom is almost pathognomonic of hysteria.

The relations which these hyperæsthetic regions have to the hysterical attacks are very important, and they have therefore procured for them the name of "hystero-genous zones." We will speak further on this point in describing the hysterical attacks.

Hyperæsthesia in other sensory regions—abnormal sensitiveness of the eye, ear, etc.—also occurs. Thus certain cases of hysterical blepharospasm seem to be due to an immoderate sensitiveness to light. Unusually sharp hearing is noted, espe-

cially during the hysterical attacks. Here, too, belongs the aversion of many patients to certain smells and tastes, and the like.

**2. Hysterical Paralysis.**—Hysterical paralysis is frequently an immediate sequel to some violent mental excitement (for example, "paralysis from fright"); but it may come on gradually. Hysterical paralysis is indubitably of central origin. It is a paralysis of the will. The patient has lost the power to will a contraction of the affected muscles. One always has the feeling that the patient could move the paralyzed limb perfectly well if she only desired to; but she can not bring the will to bear on it, and this inability is the real trouble. It also seems a remarkable circumstance that hysterical paralysis often, but of course not always, affects only certain combined movements. Many patients, for instance, can move their legs very well in bed, but they can not walk a step.\* We have seen a hysterical writing paralysis; the right arm was not paralyzed, but it utterly refused to make any attempt to write.

The extremities are most frequently paralyzed, particularly the lower limbs; but hemiplegia is not especially rare. A very common manifestation is loss of the power to walk. The patient lies in bed or on a sofa, and sometimes while thus reclining she can flex and extend the legs very well; but as soon as she is urged to stand up or walk, the knees double up, the patient begins to tremble, the respiration grows rapid and convulsive, and there is not the slightest effort made to move the legs. If only one leg be paralyzed, the gait is often very peculiar and characteristic. The sound limb makes long strides, while the paralyzed one is held perfectly rigid, and often is dragged along with a loud shuffling sound. The arms are much less often affected. The facial muscles are hardly ever paralyzed. We once saw hysterical diplopia.

In regard to the more precise form of the paralysis, both flaccid and spastic paralyzes occur in hysteria. In many cases of hysterical paralysis the tendon reflexes may be so exaggerated—nay, there may even be, as we have repeatedly seen, such a lively foot phenomenon—that one is at first disposed to think of actual spinal paralysis. In other cases, as in paralysis of an arm, the paralyzed limb hangs down completely flaccid. The paralyzed parts are often at the same time completely anæsthetic (a circumstance which may often be distinctive in diagnosis), but in other cases they are normally sensitive or even hyperæsthetic.

Hysterical paralysis of the vocal cords is seen very often. The voice is generally lost suddenly, and the patient can talk only in a whisper—hysterical aphonia. On laryngoscopic examination, we are often struck, at the outset, by the anæsthesia of the pharynx and its lack of reflex excitability. We find no trace of any anatomical lesion of the cords, but merely that they are parietic. The glottis can not be completely closed, and sometimes the vocal cords actually grow wider apart upon every effort at phonation. The patient then speaks exclusively in a whisper. Hysterical mutism quite rarely follows hysterical aphonia. The patients entirely lose voluntary control of their speech apparatus, and finally become completely dumb.

Hysterical paralysis of the pharynx and œsophagus is much less frequent. If there be dysphagia, it is often not an easy matter to determine whether it is due to paralysis or to spasm.

**3. Hysterical Contractures.**—Contractures may occur as isolated phenomena, or in combination with other symptoms, such as anæsthesia or paralysis. They

[\* This inability to stand or walk, with the preservation of good strength and co-ordination in the legs when sitting or standing, and the persistence of power to execute certain less usual movements, such as hopping on one foot, has been termed by Bloch *astasia-abasia*. It is often associated with hysteria, but it may exist independently of it.—K.]

are caused by unusually strong tonic muscular contractions. The starting point of the irritation is certainly in the central nervous system. Sometimes the contractures are temporary, but often they are characterized by their intensity and their great persistency. The extremities suffer most frequently, although the trunk or the back of the neck may be affected. In the hands and feet, especially in the toes, flexor contractures predominate, but in the larger joints extensor contractures are the rule. Although many varieties occur, single forms of contracture are especially characteristic. As an example, we will refer to the accompanying illustration (Fig. 109).

The relations of hysterical contractures to the articular neuralgias have already been mentioned (p. 529). They may occur in a hemiplegic, paraplegic, or monoplegic form. They often follow a hysterical convulsive attack (*vide infra*). All hysterical contractures disappear completely in chloroform narcosis and in deep sleep.

FIG. 109. — Hysterical contracture. From Bourneville and Regnard's *Iconographie de la Salpêtrière*.

#### 4. Vasomotor Disturbances. Secretory Disturbances. Symptoms in the Internal Organs.

—Besides the sensory and motor symptoms just described, other symptoms occur in hysteria which fall under the domain of the vasomotor and secretory nerves. The significance of many of these symptoms is, of course, not yet clear.

In the first place abnormal anaemia or abnormal fullness of the vessels (a cool, pale skin in the one, a hot, red skin in the other) is not infrequent, and points to vasomotor influences. Since we know that the vascular nerves are influenced in a high degree by the emotions, we can probably assume a central origin for these symptoms. Haemorrhages from internal organs are harder to explain; they are

apparently not uncommon in hysteria, and they have often been explained by "nervous vasomotor influences," but in our opinion we must be extremely guarded in such an assumption. We most frequently see hysterical haematemesis or hysterical haemoptysis—that is, the evacuation of blood from the mouth, either with cough or with more of a strangulation. Inexperienced physicians have thus often been led to a false belief in dangerous pulmonary disease or gastric ulcer; but if we look more closely we shall find that the blood evacuated is of a clear raspberry-red color, is mixed with a good deal of mucus and saliva, and is of a thin fluid consistency. The whole amount is seldom more than two or three ounces (grm. 50–80). If we inquire more carefully as to its origin, we can usually find a source for the blood in the gums or in the oral or pharyngeal mucous membrane. There are often spasmodic chokings or hiccoughs, by which a haemorrhage of the mucous membrane is mechanically produced. It is also certain that in many cases intentional deception on the part of the patients may lie at the bottom of the haemorrhage. We must be especially cautious in haemorrhages from the genitals, from the skin, from the palms in the "stigmatized," etc.

Finally, among the vasomotor disturbances we must mention one symptom whose significance, in our opinion, has not yet been satisfactorily explained—we mean hysterical fever. In severe hysteria, especially at the time of severe attacks and psychical disturbances, other observers, and we ourselves, have repeatedly seen

high febrile temperatures, 106° (41° C.) and more; and these temperatures come on in a very irregular manner. In none of the cases under our own observation, however, could we wholly exclude the possibility of simulation—that is, of producing a rise of the mercury by rubbing and pressing on the thermometer. In all the measurements we made ourselves in the rectum the temperature was normal, while the high fever was always said to occur in our absence. We therefore recommend great caution with reference to this point.

Anomalies of the secretory and excretory organs have also been met with in hysteria. Many patients have a remarkably dry skin, while others sometimes perspire very freely. The secretion of saliva is subject to similar modifications. Very remarkable observations have been made in a few cases with regard to hysterical ischuria; for days only a very small amount of urine has been passed, although there has been no retention. In one case of this sort, observed by Charcot, there was violent vomiting at the same time, and the vomitus contained a comparatively large amount of urea (vicarious excretion). Hysterical polyuria occurs more frequently than ischuria. A large amount of very light-colored urine of low specific gravity is excreted. This polyuria is in many instances merely the result of excessive ingestion of liquids. Polydipsia (excessive thirst) is a very frequent symptom in hysteria, particularly at the close of a fit.

The digestive disturbances which many patients have are mainly such as have already been discussed on page 400, under the head of "nervous affections of the stomach." Colicky pains, obstinate constipation, occasional diarrhoea, and similar symptoms, are by no means rare. Hysterical tympanites also deserves mention. It is due to the accumulation of a large amount of air and gas in the *primæ viæ*. This may be in part the result of a sort of paresis of the muscular coat of the stomach and intestines, but another frequent cause is the swallowing of large amounts of air. Perhaps the patient does this on purpose. The prominence and tension of the abdominal walls may be so considerable as to simulate grave diseases, such as peritonitis, or a tumor, or pregnancy. Doubts of this sort can always be dispelled by inducing anaesthesia with chloroform. It is possible to remove the gas completely in a short time by pressing upon the abdomen, or by introducing a long tube through the rectum.

Sometimes there are symptoms referable to the genital organs. It has been already pointed out that too much prominence was formerly given to the influence of sexual diseases in exciting hysteria. It is also true that nervous derangements of the genital organs may be among the symptoms of hysteria. In this way pain and hyperaesthesia may be occasioned, and possibly many instances of dysmenorrhoea and leucorrhoea have a similar origin. We can also readily understand that sexual relations often influence very excitable, hysterical individuals to no slight extent, as indeed is very frequently betrayed by the character of their hallucinations and their utterances when delirious.

**5. General Mental and Bodily Constitution of the Hysterical.**—If we regard hysteria as a disease which is largely psychical, which is the only correct view, it will not seem strange if the whole mental constitution and nature of the patient show special peculiarities. In many cases, therefore, the psychical condition of the hysterical is so characteristic that the physician can, from the patient's nature and demeanor form his conclusions as to the form of her disease.

Hysterical persons are irritable and emotional, easily depressed, sensitive, whimsical, and subject to violent extremes of feeling. They are inclined to exaggerate their sufferings, exact a great deal of attention, and are anxious to excite sympathy. They have little energy or force of will, but they are sly and obstinate in carrying out any pet desire. Again, they can be very amiable and attrac-

tive if they take the fancy. They are almost invariably clever. It is comparatively exceptional to see hysteria in dull and stupid persons.

This brief sketch represents many cases, as we have said, but not all. Such patients very frequently present no very great disturbances, but complain merely of all sorts of general derangements, sometimes of one kind and sometimes of another, and yet are able to perform their daily duties tolerably well. A case of paralysis, contracture, or other important localized hysterical trouble may not present any marked mental peculiarities. Either there are none, or, if they exist, the patient conceals them from the physician.

With regard to the general physical constitution of hysterical subjects, it has already been mentioned that any bodily weakness favors the development of the disease; and yet hysteria is by no means confined to the ill-nourished, weakly, and anæmic. On the contrary, many patients seem to be in blooming health and well nourished. In a severe case of hysteria, however, the effects of the disease on general nutrition may be very distinct. Little food is ingested, sleep is disturbed, digestion is affected (*vide infra*), and the bodily health is gradually undermined.

#### HYSTERICAL ATTACKS, CONDITIONS OF SPASM, ETC.

While the symptoms thus far described are largely of a permanent character, paroxysmal nervous symptoms are also very common in hysteria. The diagnosis of the entire morbid condition is often made certain by the onset of such hysterical attacks, which are often very characteristic, and their significance is readily perceived by the experienced physician. There are some cases of hysteria which run their course entirely free from these attacks, where there are only certain permanent nervous symptoms, such as paralysis, contractures, anæsthesia, etc.; but there are also other patients in whom the hysterical attacks dominate the whole scene, and are sometimes the only manifestations of the disease. A hysterical attack is not infrequently the beginning of the trouble, especially in those cases where the disease is excited by fright, etc., and where the attack follows immediately upon the psychical excitement.

In regard to the severity and the variety of the hysterical attacks, they are so manifold that an exhaustive account of all the possibilities can not here be given; but certain features and details are so common in them, and recur so often, that a consideration of them is often in itself sufficient for a correct diagnosis.

The mildest form of the hysterical attack consists of the development of a feeling of distress, anxiety, vertigo, and especially of a loss of voluntary control of the body. The patient sinks on a bed or chair, closes the eyes, and becomes incapable of action or speech. Mild symptoms of motor irritation usually ensue, most commonly an acceleration of respiration, general tremor, winking of the eyes, etc. Mild spastic symptoms in the pharyngeal muscles and the diaphragm are not uncommon. There is very often a lively palpitation during the attack. The face is sometimes quite red, but in other cases pale.

In such mild attacks any impartial observer has distinctly the impression that the patient is humoring her inclinations. If, therefore, she be encouraged, or if cold water be thrown in the face or on the back without too great regard for her feelings, she usually soon regains her will-power and rapidly recovers.

In an unbroken series these mildest forms of attack pass over into the severer types, where the clouding of consciousness is greater and the symptoms of motor irritation are more severe. Complete loss of consciousness, so common in epilepsy, is scarcely seen in hysterical seizures, but there is very often a marked clouding of consciousness, and in the severe forms morbid alterations of consciousness (*vide infra*). If hysterical attacks occur which resemble those of epilepsy ("hystero-

epilepsy"), we must think of the possibility of a combination of the two diseases; but usually the form of the hysterical convulsion is essentially different from that of the epileptic. In severe hysterical convulsions the convulsive movements are more varied, more extensive, and more complicated than in epilepsy. The arms make thrashing and thrusting movements, and often apparently quite well-coordinated movements. Patients strike the bed, and sometimes their own bodies, with the clenched fist; they seize objects, such as the bedclothes or furniture, and cling fast to them. We also see clonic or tonic flexor and extensor spasms in the legs. The eyes almost always converge or are turned to one side, and they often roll. The lids are lightly closed or occasionally open. There is almost always trismus, and there is often grinding of the teeth. The trunk usually twists and turns the most. The patient often thrusts her head hard against the wall or the bed. The whole body may assume positions which a healthy person can scarcely imitate without special practice. The best known, and in fact one of the commonest and most characteristic, is the arched position (*arc de cercle*), of which the accompanying illustration (Fig. 110) gives an idea.

FIG. 110.—Hysterical *arc de cercle* (Bourneville and Regnard).

Many patients rest for a time on the floor supported only by the head and toes. At intervals they sling or roll their bodies to and fro, drum on the floor with their legs, throw themselves into the air, etc. Any one who has once seen such a "grand hysterical convulsion" will never forget the picture.

A different but still common form of hysterical convulsion is characterized by a pronounced implication of the respiratory muscles. The attack begins with a spasmodic acceleration of respiration, and the breathing becomes shorter and more rapid. We have ourselves counted two hundred respirations a minute. Other peculiar spasms of the respiratory muscles, which occur in this way only in hysteria, are also common; hiccough, loud sobbing, grunting, etc. The muscles of the pharynx are usually implicated in producing these noises. Of course, all these spasmodic conditions may be joined in the most varied ways with spasms of the trunk and the extremities.

One of the most essential factors which often gives the most characteristic stamp to the grand hysterical attack, is the relation which the spasms often have to certain co-existing abnormal conditions of consciousness. During the attack the patient is usually not unconscious, but she is under the dominion of inner morbid delusions, and these often mirror themselves in the outward movements. The patient is wholly dominated by a definite circle of ideas; she has hallucinations, and passes through some frightful or exciting event. All this is most strikingly manifested in her movements and her expression. Hence, in an attack the face often expresses terror, rage, threatening, concupiscence, serenity, etc. Very often the internal excitement is forth in words, and there is actual hysterical

delirium, the most marked emotional utterances, etc. The patients often talk continually to themselves, usually very rapidly, with frequent repetitions of the same phrase or word. We can often succeed in giving the delirium a definite direction by questioning the patient, or converse regularly with the patient during an attack, but usually the pure motor spasms again set in, or persist for some time in a tonic form.

We can not go further into the numerous details of the symptoms of the grand attack ("*grande hystérie*"), for an accurate knowledge of which we must thank the observations of Charcot and the school of La Salpêtrière in Paris (Bourneville and Regnard, P. Richer). The descriptions of the French authors apply to the grand hysteria not infrequently seen in Germany. In regard to the whole picture of the attack the French neurologists distinguish several periods which correspond in general with the above-described conditions. The first period consists of severe epileptiform convulsions apparently associated with loss of consciousness. Then comes the period of "contortions and grand movements" (clownism), and finally the period of plastic positions and passionate attitudes (*attitudes passionnelles*). The short and very significant expressions of this scheme are of practical value, but in our experience we can only rarely expect sharply defined "periods" in the individual case: the grand hysterical attack is rather composed in the most varied ways of the different symptoms above mentioned.

There remains one essential relation in order to complete the picture of the hysterical attack, and that is the "suggestibility" of the patient, which is so peculiarly characteristic of hysteria. By "suggestion" we mean the artificial production of a definite psychical state, or a physical state dependent on the mind, by arousing the appropriate ideas. In the general characteristics of the mental constitution of many hysterical persons we have already had to point out how much and how often such patients let themselves be dominated by their imaginations. Suggestion is merely the artificial fostering of this psychical peculiarity and its special application. The more we try to foster and preserve this peculiarity, the more we leave uncorrected the false ideas which the patients have, the better we succeed at last in making the patients merely a shuttlecock for their ideas. Hence the physician's daily experience teaches that, as suggestion experiments are repeated, the patients more easily become susceptible to them, so that finally we can actually "do everything with them." There can scarcely be any difference of opinion as to whether such an experiment without restraint is medically and morally permissible; and even the fostering of suggestion for therapeutic purposes is a two-edged sword whose action is not always rigidly within the physician's control.

Suggestion is most easy during the hysterical attack itself, especially in those forms where the patients speak, hear, and answer. As soon as we give the substance of the patient's ideas a definite direction, and tell them in a convincing tone that they are in a garden or a wood, picking flowers or fruit, that they are attacked, bound, lying on the edge of a precipice or the water, etc., we see in their bearing and speech that they think they are actually experiencing all these conditions in their delirium and hallucinations. The emotional utterances of fear, terror, joy, or aversion are then often expressed with astonishing art. In the same way we can suggest paralyses, contractures, or anæsthesias. The most interesting feature of it all is, that when the attack is over every trace of recollection of what happened during it is lost. The same patients who just now were so much excited by some definite idea, a few seconds later, when the attack has ceased of itself or has artificially been brought to an end (*vide infra*), know nothing more about it. They have not even a vanishing recollection like that of a dream about what they have just said and done, even if it be expressly described; but it is still more remarkable that during the following attack they often remember very well what

they have experienced actually or in their imaginations in the past attack. In such cases we can actually speak of "double consciousness." Processes of the conscious waking life, however often remain in the consciousness during the attack. We often see that the actual event (scene of terror, etc.) which has given rise to the first onset of the attacks, is often gone through with anew in the delirium of subsequent attacks.

Hypnotic symptoms are closely allied to the processes in suggestion. We can not give here a complete review of this field, which, as is well known, has been so much studied of late. The tendency of human nature to mysticism and the influence of suggestions, which may be of value not only with the patients but even with the investigating physicians, are the reasons why the false and the true have often been mixed in the study of hypnosis. We can say only that one great advance is now generally recognized, and that is, that most persons of scientific training have abandoned the hypothesis, once frequently accepted, of a special "magnetic power" (animal magnetism), by which the "magnetizers" could put their "mediums" into the "magnetic sleep" or other abnormal conditions.

Hypnosis is nothing more than the intentional artificial production of a hysterical attack, or a hysterical psychosis by suggestion—that is, by the action of definite ideas on the person to be hypnotized. Therefore, only those persons can be hypnotized in whom these ideas have a strong enough influence. No man can be hypnotized to whom the nature of hypnosis is clear. The essential feature of all hypnotic procedures is merely to produce in the most lively way possible the idea, "It will happen as the hypnotizer says." All other things—the fixation of the eyes on bright objects, the vibrations of a tuning-fork, etc.—are side issues, and serve merely to support the suggestion. In all easily hypnotizable persons the mere closure of the eyes and the remark, "Now go to sleep," are enough to produce the hypnotic sleep. Patients (and here we may actually speak of "patients") reach this suggestibility, of course, only after they have often been hypnotized; for the oftener the same action of an idea is produced the more easily it occurs—a law which follows also from many other experiments in the psychical domain. The different forms of hypnosis are not distinguishable from the various hysterical conditions. Hypnosis is artificial hysteria, and from this alone we note the danger of all hypnotic experiments as soon as they are practiced by the ignorant. In this, too, it has often been shown that we can not become free again from the spirits which we call up. The French physicians (Richer) distinguish four chief forms of the hypnotic state, which show, however, many transitions: 1. The cataleptic state, in which the limbs retain all the positions artificially given them (see the previous chapter). 2. The state of "suggestion," of artificially produced hallucinations. If we put the body passively into certain positions corresponding to definite acts, we can produce in the patient all the appropriate ideas with the distinctness of an hallucination. To this category belong the well-known hypnotic exhibitions where hypnotized adult men toss babies, eat raw potatoes with an expression of enjoyment, etc. 3. The lethargic state, that is, a state of apparent unconsciousness, with the eyes closed, the muscles completely relaxed, and a marked increase of excitability in the muscles and nerves. A light pressure or a slight blow on a nerve, like the facial, suffices to put all the muscles supplied by it into a tetanic contraction which outlasts the irritation. 4. By certain manipulations (for instance, rubbing over the parietal) we can change the lethargic state into one of hysterical somnambulism. The patients remain half unconscious, but answer automatically questions which are put to them, and sometimes show certain sensory hyperæsthesias. The patients remain half unconscious, but answer automatically questions which are put to them, and sometimes show certain sensory hyperæsthesias. The patients remain half unconscious, but answer automatically questions which are put to them, and sometimes show certain sensory hyperæsthesias. The patients remain half unconscious, but answer automatically questions which are put to them, and sometimes show certain sensory hyperæsthesias.

May not suggestions—that is, ideas which lead to unconscious voluntary muscular contractions—also play a part here?

We have thus far omitted to dwell upon an important point in the description of the hysterical attack—namely, the relation to it of “hysterogenous zones.” We have mentioned above how often in hysterical patients certain parts of the body (the ovarian region, the sides of the chest, etc.) are extremely sensitive to pressure. It is by no means uncommon that, in spite of the patient’s resistance, somewhat longer pressure on such a spot may excite a hysterical attack. On the other hand, we sometimes succeed in causing an existing attack to cease by pressure on the same zone. We are of the opinion that in these manipulations also ideas become potent as connecting links.

Finally, we must add that there are also milder forms of hysterical spasm which are limited to a definite muscular region, and are not associated with any marked clouding of consciousness. There are, for example, isolated spasms of the muscles of the neck, isolated respiratory spasms (spasmodic cough, etc.), and isolated spasms in the arms and legs; the laryngeal muscles may also be affected (hysterical spasms of the glottis). Spasms of the diaphragm and other muscles of inspiration are quite common under the form of hysterical hiccough, which may sometimes last in the severest way for days or weeks. To spasmodic conditions in the muscles of the pharynx and œsophagus we refer the well-known symptom of so-called *globus hystericus*: the patients feel as if a ball were moving up and down in the throat.

We sometimes see spasmodic conditions which come on in a clonic fashion, or in single twitchings in this or that muscular territory; sometimes affect symmetrical groups of muscles; are not associated with disturbances of consciousness; cease during sleep, and are often easily cured by appropriate mental treatment. Such conditions have been described under special names as special diseases—electrical chorea, paramyoclonus multiplex, or myoclonia. In our opinion, most of these cases, if not all, are undoubtedly hysterical (see pages 573 and 576).

**General Course of the Disease.**—Our description of the symptomatology of hysteria has been confined to the most important and frequent phenomena; and yet even this meager outline shows what an infinite variety of shapes the disease assumes. 1. In one class of cases there are no severe symptoms whatever. The patient merely displays the general mental condition characteristic of hysteria: she is easily excited, prone to make much of her ills, has all sorts of symptoms, such as pain, palpitation, dyspepsia, and dyspnoea, and these are aggravated by mental excitement, while at other times they may so nearly vanish that the patient does not appear to be ill. 2. A second class of cases has more severe disturbance, coming on after some unfavorable psychical influence. The patient may have displayed a general hysterical tendency previously, or may have seemed perfectly well. Here we may observe all the symptoms above enumerated and described. There may be paralysis, spasm, contracture, anaesthesia, or paræsthesia. The individual symptoms may persist obstinately for weeks and months; but again they may vanish on a sudden or give place to other disturbances. Psychical influences are unmistakably potent, not merely in the incipient stage but also in the further course of the disease. Any aggravation of the symptoms is usually referable to emotional excitement. This is particularly true of the hysterical convulsions. In many cases, almost every fresh paroxysm is due to anger, terror, or some similar cause. 3. The third class comprises the most severe forms of hysteria, with those serious disturbances briefly outlined above. They are as complicated as long, and form manifold combinations with all the other hysterical conditions, including anaesthesia, contracture, and paralysis.

The duration of the disease varies greatly. The true root of all evil is

the abnormal excitability of the nervous system, which always remains in unstable equilibrium; and often it is not possible to cure this. If not, the trouble lasts almost indefinitely. New manifestations of the disease succeed to periods of apparently perfect health. Usually the symptoms do not abate till quite late in life. There are, however, many instances of complete and permanent relief. This favorable termination is more especially to be hoped for where the patient comes into suitable and appropriate conditions of life, having some regular occupation which is not exposed to all sorts of unfavorable psychical influences. Many cases of hysterical disturbance, in previously healthy children or young adults, and due to some distinct cause, terminate comparatively soon, and never recur. It is never possible, however, to be sure that there will be no relapse, inasmuch as a single appearance of hysteria shows unmistakably that the nervous system is abnormally vulnerable to external impressions and the mental emotions excited by them.

**Diagnosis.**—An experienced physician is seldom greatly puzzled by hysterical affections. Although the disease may at first simulate some grave organic disorder, a careful physical examination and continued observation will almost invariably disclose the true character of the case. In the first place, there are never any such symptoms as would absolutely prove the existence of some organic lesion. For example, we never find atrophy or loss of electrical reaction in connection with hysterical paralysis. Secondly, many symptoms are characteristic of hysteria and are never seen in any other disease. Such are numerous forms of convulsions, and hemianæsthesia with amblyopia of one eye. Above all, we should regard the whole psychical behavior of the patient, the influence exerted upon her by emotional disturbances, and the ætiology of the illness—for instance, if caused by some mental excitement or emotion. The discovery of specific hysterical symptoms, the so-called hysterical stigmata, sensory anæsthesias, hysterogenous zones, etc., are especially important. Many symptoms of hysteria, especially certain forms of spasm and hemianæsthesia, are in themselves so characteristic that from them alone a correct diagnosis can be made.

**Treatment.**—What has been said about the ætiology of hysteria at once suggests a possible method of prophylaxis. A watchful eye will often detect, even in childhood, the signs of abnormal nervous excitability, and in such a case the parent will make it his duty to impose a suitable physical and mental regimen, that graver disturbances may be averted.

If hysteria be already developed, the first and most important treatment is mental. There could be no greater mistake than to deride the patient or treat her as a malingerer; for hysteria is a disease, and its symptoms are just as independent of any conscious volition on the part of the patient as those of any other disease. It is, however, absolutely essential to carry out the moral training, which the physician must institute with all the proper strictness and energy, because in this way alone can any good be accomplished. Sometimes this most important indication can be fulfilled only after the patient has been withdrawn from the over-anxious and over-assiduous parents or relatives, and like unfavorable influences. In such cases, treatment in some institution will often be vastly better than the best care at home; and our own experience leads us to recommend most urgently that the eventual necessity of removal to an asylum should be constantly borne in mind with regard to aggravated cases. Often the mere dread of removal to such a place has a favorable mental influence.

Proper moral treatment achieves hysterical paralysis. When we have hysteria, the patient must be instructed of the will over the paralyzed

the best results where there is the paralysis is due to practice the lost power set the lower extremi-

ties, as it usually does, the patient must be set on her feet, regardless of all her opposition and complaints, and kindly but most firmly required to try to walk. Of course, at first she must be well supported. This exercise must be methodically gone through with several times a day. Gradually the patient's gait becomes more and more secure. She regains confidence in her own ability, and, having once begun to improve, usually makes rapid progress toward complete recovery. Every experienced physician can recall numerous instances where hysterical paralysis which had lasted weeks and months was cured in a few days by this mode of treatment. Faradization of the muscles, cold sponging, with friction and bathing, are excellent adjuvants; and the disagreeable element in these procedures of itself stimulates the patient to make every possible exertion to regain the use of her limbs.

When there is hysterical paralysis of the vocal cords, a similar training will be found both practicable and efficient. Electricity is also of great value. It may be applied externally or within the larynx. Often the patient, terrified by the sudden pain it causes, recovers her voice at once.

The treatment of hysterical contractures consists, first, in an effort to loosen up the contracture by massage and energetic passive motion. Faradism will be found of assistance here also. In order to maintain the ground thus gained, the patient must be induced to exercise the muscles regularly by making voluntary movements.

The treatment of hysterical spasmodic conditions often causes greater difficulties. In many cases a sharp sensory irritation, douching with cold water, or a cold bath with cold shower-bath, suffices to restore the energy of the patient's will, which is necessary to regain control over the muscles and thus check the spasms. The dread of the repetition of the bath does its part in warning the patients from giving themselves up unresistingly to a repetition of the attack. The electric current (strong faradism during the attack) may also act favorably in the same way. The action of such measures, however, very often gradually weakens, the patients become accustomed to the cold baths, and they remain without effect.

The milder varieties of hysterical convulsion, such as hysterical hiccough or cough, are often controlled by a stern reproof. It is precisely in these cases that the moral effect of transfer to some institution frequently causes the abrupt disappearance of symptoms which have lasted for months. The severe hysterical attacks are often, of course, peculiarly obstinate, and they may resist for months, and even years, the most intelligent treatment.

Hysterical anaesthesia is best treated with the faradic wire-brush. This vigorous irritation restores the anaesthetic parts to the domain of consciousness. It should be said, however, that these cases may prove obstinate or relapse.

The most difficult of all hysterical cases to treat are those where the symptoms are not strongly pronounced, but where there is a general hysterical condition, expressing itself in a multitude of nervous derangements, such as palpitation, dyspepsia, and general debility, or in purely subjective symptoms, or in emotional tendencies. Such patients are often advanced in years, so that little is to be hoped for from moral training; and their circumstances may be unfavorable without our being able to remedy the situation. Even here, however, the physician may greatly benefit the patient by means of psychological influences, if he once gains her complete confidence. It will also be found advantageous to employ such remedies as invigorate the nervous system (see the next chapter); electricity should be given, either in the form of general faradization, or the faradic brush applied to the back and shoulders, or the galvanic current applied to the spinal column and the sympathetic nerve; and of still greater importance is a methodical cold-water treat-

ment, either by sponging, or bathing, or douches. Such patients are often vastly improved by sea-bathing in summer, or by going to the mountains.

The numerous internal remedies for hysteria are also of more use in these general conditions than where there are marked nervous disturbances in special parts of the body. In the latter, internal remedies do good only indirectly and subjectively, and about in proportion to the confidence of the patient in the virtues of the medicine. This is the explanation of the frequent cases of rapid recovery after taking homœopathic and "electro-homœopathic" remedies, and those still more marvelous cures effected by means of holy water and relics.

Among the "antihysterical" agents contained in our medical thesaurus, *asafoetida*, *valerian*, and *castoreum* are the most famous; but probably few would at the present day claim that they possess any specific virtues. Perhaps the preparations of *valerian* are the most useful where there is hysterical excitement, as evinced by convulsions or palpitation. Bromide of potassium, arsenic, and other medicines which ordinarily exert a favorable influence upon the nerves, seldom accomplish any permanent good in hysteria, although often prescribed. Narcotics do little good, and may do much harm. It is easy to develop the morphine habit in such patients.

If hysteria be complicated by some actual organic disease, the latter, of course, demands special treatment. Great benefit is hoped for by many from the cure of any uterine complaint which may be present. Cases are known where grave hysterical disturbance has vanished upon dilatation of a constricted cervical canal or rectification of a displacement; but there are numerous other instances on record where gynæcological treatment has proved entirely unavailing. It may also be questioned whether, in the successful cases, the main benefit was not due to subjective influences. Hegar has removed the ovaries in a few severe cases, but the operation is not yet fully established. At any rate, it is justifiable only when the ovaries are known to be in an abnormal condition. Friedreich claims to have had excellent results from energetic cauterization of the clitoris. We do not believe that in this he will have many imitators.

In general, we may certainly maintain that all methods of treatment of hysteria are efficient only when associated with the necessary psychical factor. Hence any prescription, no matter how senseless it seems, may have the greatest effect as soon as the patient "believes in it"—that is, as soon as the psychical action of this belief is manifest. Hence we may say that in hysteria, as a rule, treatment either produces rapidly a brilliant success or it has no effect at all.

We must here mention two methods of treatment which have lately been much discussed—metallotherapy and treatment by hypnosis.

In regard to metallotherapy a French physician, named Burq, discovered years ago that by laying plates of metal upon a cutaneous surface affected by hysterical anæsthesia a remarkable result is sometimes produced. Almost at once sensation is restored to the immediate region, and often to a much larger area. Most of the cases have been those of hysterical hemianæsthesia. It is not every kind of metal which will prove effective, nor will the same kind affect all patients. It is said that iron is most frequently efficient; but sometimes copper, zinc, or gold is required. The process of determining the metal essential to each individual case Burq called "metalloscopy"; and he stated that this metal would also have the same effect if given internally! In 1876 a committee appointed by the Parisian Société de Biologie tested these statements, at least with regard to the external application of metals—the idea of their internal administration having been pretty much abandoned—and confirmed them. Charcot also discovered many remarkable facts of a similar nature, which have since received universal substantiation. The most remarkable of the cases is that of a patient who, after the removal of the metal, experienced a complete transfer of the anæsthesia to the opposite side of the body. The return of

sensation to the anæsthetic area, as a result of applying a metal plate, is accompanied by a simultaneous development of anæsthesia upon the opposite, previously normal side, in an exactly corresponding place. Sometimes sensation oscillates from one side to the other and back again, so that now one half of the body and now the other is alternately sensitive or anæsthetic. If the metal be placed at the start upon the normal skin, that part becomes anæsthetic, while the corresponding part upon the opposite side of the body regains its former normal condition.

It has also been discovered that other hysterical symptoms exhibit analogous phenomena. Transfer can sometimes be observed in hysterical amblyopia, achromatopsia, deafness, loss of smell and taste, contractures, and paralysis. Such transfers may be induced by various means other than metal plates. These are classed as æsthesiogenous remedies, and include large magnets, feeble galvanic currents, and static electricity. Vibrating tuning forks and sinapisms have also produced similar results. Hence it seems to us to be an undoubted conclusion that the whole of the group of symptoms just described has no peculiar place. They are simply the results of suggestion, produced once more by ideas. The similarity of the test as performed by the physician produces the similarity of the symptoms that ensue.

Of late the treatment of hysteria by hypnosis has acquired a far greater practical significance than metallotherapy; it is a mode of treatment which has been practiced most extensively by the "school of Nancy" (Bernheim). If, during hypnosis, morbid states can be produced by suggestion, it naturally follows that morbid states can also be cured by suggestion. If by many well-known successes the hypnotizing physician has at the outset acquired the patient's confidence, as relies have the confidence of believers, the most beautiful results can of course be attained in this way. There is no special peculiar principle in the hypnotic treatment. Any other efficient mode of treating hysteria rests on the same conditions and presumptions. Hypnosis has only the one great consequence, that it is artificially produced as a severe abnormal mental state in a patient who previously had not spontaneously fallen into this state. In that lies the sequel, which of course need not always be permanent, but which often enough has been most severe: the attempt to hypnotize a patient who is suffering from a slight hysterical affection has not infrequently been followed by the onset of a severe hysterical attack. The mischance will seldom happen to the physicians and magnetizers who practice hypnotism as a specialty, because their psychical influence on their patients is usually greater from the outset; but we should consider it a misfortune if hypnosis should come into too general use. That in this way apparently the most wonderful cures can often be obtained, is perfectly well established and not at all surprising; but the same cures can also be obtained in other ways, without running the risk of producing first that of which you would cure your patient, for to hypnotize means to make hysterical. Furthermore, it is not hard to prophesy that, as the knowledge of the peculiar nature of hypnosis becomes general, it will lose its halo with the patient, and with that it will lose its healing power.

## CHAPTER X.

## NEURASTHENIA.

*(Nervous Debility.)*

WHEN studying the disorders of the spinal cord, it will be remembered that we found one group of symptoms which did not rest upon any discoverable anatomical basis, but which were merely functional (*vide* page 605). In some part due to abnormal excitability of the nervous system, but mainly, however, the result of impaired vigor, this condition was denominated "nervous weakness." Perfectly analogous phenomena may originate in the brain, and are named cerebral neurasthenia, in contrast with spinal neurasthenia. In most instances we meet with both cerebral and spinal symptoms, and must therefore call the disease cerebro-spinal, or general, neurasthenia.

The American neurologist Beard was the first to recognize the importance of this disease and to give it its present name. Beard was at first inclined to believe that neurasthenia was mainly an "American disease"; but this is by no means the case, inasmuch as sufferers from neurasthenia form a very important contingent among the patients of German specialists. Neurasthenia is certainly one of the most frequent and important nervous diseases from a practical standpoint, nor is its study by any means devoid of scientific interest.

*Causation.*—A full list of the causes of neurasthenia would include almost all those influences which in any way act unfavorably upon the nervous system. Most of these have been enumerated on page 606. Where the disease is mainly of the cerebral form, excessive brain-work contributes very largely to its production, particularly when combined with certain kinds of excitement. The merchant is liable to it, whose bold ventures subject him to deep anxiety and eager hope; and the politician, who is incessantly agitated by party strifes; and likewise the artist or scholar, whose ambition gives him no rest. In all these cases the nervous system finally becomes exhausted—that is, neurasthenia is established. Even here, however, neuropathic tendencies come into play, for some are crushed by a burden which others can bear. In very many instances this liability to the disease is inherited; in others it is acquired (*vide* page 606).

As was mentioned under spinal neurasthenia, hypochondria frequently assumes an important rôle in these cases. It not only exaggerates the existing symptoms, but it contributes others of its own. In this we find one essential difference between neurasthenia and genuine hysteria. In the latter, however much complaint there may be, a genuine hypochondriacal tendency is extremely rare. Hypochondria becomes even the essential factor in those melancholy forms of neurasthenia which so often result from onanism or other sexual abuses. This same element is also probably the main one in the strikingly frequent cases of neurasthenia in physicians.

The symptoms of spinal neurasthenia have been already briefly described, so that we may here confine our remarks chiefly to the still more important cerebral symptoms. Most frequent among these is a subjective sensation of pressure in the head. Patients give a very various description of this sensation. Essentially, however, it is a feeling of pressure and numbness, and makes the patient doubt whether he is in the full possession of his intellectual powers. The pressure is sometimes chiefly frontal and sometimes occipital; it may rise to the height of actual pain, this being frequently associated with marked hyperæsthesia of the scalp.

Associated  
a sense of in

re is, as we have just intimated, in many cases  
d intellectual effort, an intellectual debility

often rendering the patient entirely incapable of performing the duties of his vocation. He can no longer write or read for any length of time, these pursuits being further interfered with, in some cases, by a feeling of weakness and pressure in the eyes themselves (neurasthenic asthenopia). A very important symptom is loss of sleep. This symptom is in many cases the most annoying of any, and makes the patient importunate for relief. There is almost sure to be depression of spirits; the patient does not believe that he will ever recover, and gives voice to the most melancholy predictions. Beard has called attention to peculiar conditions of anxiety sometimes observed in neurasthenic patients. The sufferer dreads to go into society, or to mingle with a crowd, or to be subjected to any physical jar. Vertigo is also frequent, but is rarely very severe.

The lack of intellectual energy is, in most cases of any severity, accompanied by decided bodily weakness. This, too, would often seem to be of cerebral origin, and consequent upon deficient innervation of the muscles by the nervous centers. The patient can not walk far without becoming weary, is incapable of any great manual effort, and in some cases feels so weak that he does not like to leave his chamber, and passes most of his time in bed or on the sofa. The various bodily functions may be interfered with. The appetite is diminished, the bowels constipated, the skin is dry, and the circulation feeble in the extremities, so that there is in many cases constant complaint of cold hands and feet. Sometimes the secretions are increased in amount rather than diminished. There is salivation or profuse perspiration. There may also be palpitation of nervous origin. [In most cases of neurasthenia there is defective metabolism. The urine is scanty, the uric acid increased relatively to the urea, and in sexual neurasthenia there may be an excess of indican. Many neurasthenics, however, drink very little.—K.]

There are numerous other nervous phenomena occasioned by neurasthenia, which we need not here describe with great minuteness. Some of them are most marked in the "spinal form" of the disease; such are pain in the back, spinal irritation, paræsthesia and pain in the extremities, and sexual derangements. Sometimes, however, these symptoms appear to be rather of psychical—that is, of cerebral—origin. Nervous dyspepsia is frequently conjoined with neurasthenia; it has already been described on page 400.

The general course of the disease is almost always chronic. In the milder cases there is little outward evidence of derangement; the patient endeavors to hide his troubles, as his indefinite symptoms seldom gain much sympathy, and are apparently contradicted by his well-nourished and healthy appearance. In the severe cases, however, the patient's vigor is so much impaired that the disease acquires a grave aspect even for others than the patient, and fills them, as well as him, with infinite anxiety. The course of the disease is apt to be varied by alternate improvement and relapse.

**Prognosis.**—It is difficult to make a general statement as to the termination of cases of neurasthenia. The disease is never actually dangerous, nor does its existence often prepare the way for more severe secondary nervous disease. And yet the nervous constitution of many neurasthenic patients is such that complete recovery can not be attained. There are, however, numerous cases, especially such as have resulted from a special exciting cause, which can be removed, where permanent and complete recovery ensues. In other cases the symptoms can be so far abated that the patient is practically well, although not entirely free from discomfort.

**Diagnosis.**—Neurasthenia can usually be detected without difficulty, but the establishment of the diagnosis requires the exclusion of organic lesions of the nervous system. Every case, therefore, must be submitted to a thorough and careful examination. Grave cerebral diseases, such as incipient tumors or general

paralysis, have been repeatedly mistaken for neurasthenia. One important point in diagnosis is the ætiology, including both the outward circumstances and the presence or absence of a constitutional predisposition to nervous diseases. Hysteria has certainly many points in common with neurasthenia, but it is essentially an entirely different disease. In neurasthenia we find none of those innumerable localized nervous disturbances which we saw in the preceding chapter to be so well marked in hysteria; nor do we ever observe in neurasthenia that rapid onset and sudden disappearance of the symptoms, nor their abrupt development as a consequence of some violent emotional excitement. A severe case of neurasthenia is decidedly the graver disease of the two, at least in this sense, that it represents a far more profound functional disturbance of the nervous system than does hysteria. On the other hand, certain special symptoms, such as convulsions or paralysis, may be more severe in hysteria than in neurasthenia.

**Treatment.**—As in hysteria, so also in neurasthenia, moral treatment is of prime importance; but here it must be of a different kind than in hysterical cases. The neurasthenic requires sympathy. He must be repeatedly examined by the physician. Every fresh examination, at the end of which the physician is able to assure him of the absence of any serious objective change, has a most quieting and beneficial effect upon the patient. In so far as hypochondriasis is a prominent symptom, this moral influence may alone restore the patient to health.

Where the neurasthenia rests on some other basis than mere hypochondriasis we must, in addition to moral treatment, employ remedies which have a tendency to invigorate the entire nervous system. In order to bring about any permanent improvement, the treatment must be methodical and long continued, so that the patient may remain under the personal influence of the physician for a considerable length of time. Moral training is always an important and indeed an essential part of the treatment of nervous debility.

In any methodical course of treatment, regimen is of great importance. The rules laid down must be carefully adapted to the special circumstances of each individual. Severe mental labor must be forbidden, and mental excitement avoided. The diet depends upon the individual case. For a corpulent patient, treatment calculated to diminish obesity will sometimes be followed by decided improvement in the general condition and in bodily vigor. In those frequent instances where the patient is pale and thin, and very likely oppressed by nervous dyspepsia (see page 400), we should, on the other hand, make vigorous efforts to improve nutrition.\* Definite instructions must be given in order that the patient may ingest a proper amount of food. Milk, butter, fresh meat, eggs, and simple puddings are appropriate articles of diet. Often the weight and strength both improve rapidly. Any large amount of alcohol or of tobacco should be forbidden. Tea and coffee may be taken in moderation, if the patient is accustomed to their use. In regard to bodily exercise, we must again be guided by the condition of the individual. We would most earnestly warn the physician from the error, frequently committed, of driving weakly and debilitated persons to take long walks. For such, bodily rest is much more desirable; and fresh air may be enjoyed at the same time, if the patient sits out of doors or drives. The sluggish and corpulent, on the other hand, often require an increased amount of exercise.

---

\* Playfair, Weir Mitchell, and certain other neurologists, have built up a special "method" of treating neurasthenia and allied conditions of nervous exhaustion; this consists in "overfeeding" the patient—that is, in introducing as large an amount of nourishment as possible into the system at the same time that complete bodily and mental rest is secured. Faradic electricity and massage are also daily employed. This mode of procedure is certainly excellent in many cases, but it must not be regarded as universally applicable. There are cases of neurasthenia for which it is not suitable.

It is a good plan in many instances to employ the Swedish movement cure, or similar gymnastic exercises.

Less general remedies are electricity and hydropathic treatment. Electricity is warmly praised by many patients. The galvanic current is generally employed, and is applied either over the sympathetic nerve or along the spinal cord. Its use demands great caution. The current should not be too strong, and there should be no abrupt changes in it. Galvanism applied to the head is seldom well borne. Another very valuable mode of treatment was first practiced by Beard and Rockwell, and consists in general faradization. The patient is almost completely stripped, and places both feet upon a large, flat electrode, while the various parts of the body are stroked with another large sponge electrode; in place of this second electrode the "electrical hand" of the physician may be employed. The physician takes the second electrode in his left hand and allows the current to pass through his own body. Various institutions have lately begun to employ electrical baths; these also often seem to produce good results. In addition to peripheral galvanization and faradization of the nerves and muscles, it is also advantageous to employ the faradic wire-brush, particularly on the back of the neck, along the spinal column, and over the shoulders and thighs.

The hydro-therapeutic treatment may be quite well carried out at the patient's home, but a severe case will be better off in some well-conducted institution. Cold sponging, douches, hip-baths, lukewarm baths (or swimming), are all employed. Douches must not be applied to the head. If there is sexual disturbance, hip-baths of cold water are advisable. They should not be taken at night. Douching of the genitals and loins is also excellent. Subsequently sea-bathing will prove extremely beneficial for many patients. We would recommend the seashore especially for emaciated and anæmic subjects, who are frequently greatly benefited by the improved appetite and rest thus obtained. If the patient be well nourished, on the other hand, a journey on foot through the mountains, if made cautiously, may be very valuable.

In neurasthenia, internal remedies should be given only as indicated by the symptoms. If there is anæmia, iron, quinine, or Fowler's solution is prescribed; if there is dyspepsia, some stomachics, such as dilute hydrochloric acid, pepsin, or some bitter. The constipation should be overcome mainly by diet. A valuable adjuvant is massage of the abdomen; and, indeed, massage is coming to be regarded as a valuable tonic for the whole system where there is nervous disturbance. It is especially appropriate where there are painful sensations in the nerves and muscles, and may here be combined with electricity. When there are vasomotor symptoms (a feeling of heat, congestion, palpitation), we often prescribe ergotine, four to six one-grain (grm. 0.05) pills a day. In all states of nervous irritation bromine preparations are much used, a powder of potassic and sodic bromides, or bromine water. In nervous headaches, and also in other nervous states, antipyrine often has a good effect. Antifebrine and phenacetine act in the same way.

The treatment of the wakefulness which results from neurasthenia deserves a brief mention. In the first place, we would warn the physician against the abuse of chloral and morphine. The attempt should always first be made to secure sleep by a rational general treatment, or by some less injurious remedies. Often a warm bath for half an hour at bedtime soothes the patient and brings him sleep; and in other cases a wet cloth laid upon the head or back of the neck produces the same favorable result. Patients often report that general farad at bedtime is an excellent soporific. Sometimes a moderate dose of alcohol is efficient—for instance, a glass of beer or good wine taken before going to bed. If none of these means avail, our next resort should be the bromide of potassium. Very likely small doses of this have only a subjective effect, but the

doubt that a large dose, say about a drachm (grm. 3-5) in a glass of water, does have a direct tendency to produce sleep. We may also mention extract of *cannabis indica*; the preparation known as *cannabinum tannicum*, five to ten grains (grm. 0.2-0.5); paraldehyde, about a drachm (grm. 3-5) at night; and urethane, twenty to forty-five grains (grm. 1.5-3) in water at bedtime. Paraldehyde has a very disagreeable taste. Kast has lately recommended sulphonal, twenty to thirty grains (grm. 1.5-2) in a large amount of water, in soup or tea, two or three hours before bedtime. These various remedies seldom give great satisfaction, and we must therefore rely mainly on general treatment.

## CHAPTER XI.

## THE TRAUMATIC NEUROSES.

As an appendix to the last two chapters on hysteria and neurasthenia, we must now speak of a series of morbid states which are at any rate closely related to the above-mentioned affections, but which yet show certain peculiarities. We have to do here with nervous symptom-complexes which come on as a result of a severe concussion of the whole body, or sometimes after a more circumscribed injury of a definite part of the body, and hence are termed "traumatic neuroses." By the term "neurosis" we would imply that the nervous symptoms produced by the trauma do not depend upon coarse material injuries of the nervous system, but upon finer changes not yet made out anatomically.

Considering first those conditions which arise from severe general concussion of the body, they were first observed, especially after railway accidents, by English and American physicians, and given the name of "railway spine" or "railway brain." It was soon proven, of course, that precisely the same morbid symptoms may arise after other injuries.

The type of disease is very characteristic. Usually the original trauma (overturn, collision, etc.) is so great that immediately after it the well-known symptoms of *commotio cerebri* or *commotio spinalis* ensue with more or less severity—loss of consciousness, general paralysis of the extremities, collapse, small and slow pulse, cool skin, pallor of the face, dyspnoea, vomiting, retention of urine, etc. Such cases may terminate fatally in a few hours with no material visible change in the brain or cord to be found at the autopsy. In other cases the first severe shock passes off and a series of objective and subjective disturbances remain, which may persist for a long time, and which often do not disappear even after years have passed. It is these subsequent states which deserve the name of general traumatic neurosis. It is worthy of note that these appear not only after severe injuries, but also after mild ones in which the initial symptoms of commotion were not especially marked. We will return to this point in speaking of the nature of the traumatic neurosis.

The severe initial symptoms of commotion cease in a few days, or even sooner. The patient recovers, tries to get up, and the improvement goes on to a certain degree; but a number of symptoms remain which do not disappear, and which diminish or wholly take away the victim's capacity for work. If we examine such patients we find no signs of material injury either in the nervous system or in any other internal organ. What first strikes us is a peculiar psychical change. The patients are dull, depressed, disinclined to exertion, and have no more pleasure in intercourse with friends. They brood constantly over their accident and its results, and often rendered un-

easy by dreams. Of other subjective symptoms we must mention especially pains in the part which was hurt; these are commonest in the back, the sacral region, the sides of the chest, the hips, etc. They also complain of headache, vertigo, dullness, dim vision, tinnitus, spots before the eyes, loss of appetite, etc. Objective examination often shows a general motor weakness. Many patients can walk quite well alone, but they are soon fatigued; others walk only slowly and stiffly with support, complaining of pain in the back on walking, and therefore holding the hand on the back, etc. The nutrition of the muscles is usually good. The electrical excitability of nerves and muscles is completely normal. Examination of the sensibility may reveal very important changes, which are of value in diagnosis. This examination must always extend to all the sensory organs. The skin over almost the entire body is often very insensitive to painful irritations, pin-pricks, the electric current, etc. There is analgesia. In some places we find complete anaesthesia, which may affect an entire extremity or only circumscribed parts of the extremities and the trunk. The boundary between the anaesthetic and the normally sensitive parts is usually quite sharply defined, and the arrangement is often very peculiar. Sometimes the skin is peculiarly insensitive to certain irritants (heat, cold, etc.), or, on the other hand, it is peculiarly sensitive. Examination of the eyes sometimes shows loss of visual acuteness, limitation of the visual field, and imperfect color perception. Very often the hearing is poor on one or both sides. The smell is often much blunted, and the taste completely lost, so that even quinine, vinegar, and similar strongly tasting substances no longer excite any sensation of taste.

Besides the symptoms of impairment of sensation and motion just described we often find also symptoms of sensory and motor irritation. Pain in the head, spots before the eyes, and tinnitus, have been mentioned above. Hyperaesthesia of the skin is more characteristic—tenderness of the vertebral column, and particularly great tenderness of such parts of the body as were most affected by the original injury. Among the symptoms of motor irritation we may mention muscular contraction and muscular rigidity, again most common in the limbs most affected by the injury. A marked tremor is also very common. The reflexes differ in different cases; they are often much increased. Among the trophic changes we may mention that the hair may turn gray or fall out. Marked muscular atrophy occurs only in the more local traumatic neuroses (*vide infra*).

If we ask after the cause and the special nature of this peculiar affection, characterized chiefly by psychical disturbances, sensory anaesthesia, and motor weakness, two chief factors are to be considered. First, a purely physical factor, the concussion of the nervous system. That such a cause can produce, without coarse anatomical injury, the severest functional injury to the nervous system, is beyond a doubt; and if the most threatening symptoms can come on immediately after the concussion, it is certainly not to be regarded as impossible that permanent results may be left after the concussion which form the basis of the later symptoms of the traumatic neurosis. Furthermore, a purely psychical factor is undoubtedly to be considered. A great fright is associated with the injury. The accident readily excites a fear of an incurable illness, with permanent incapacity for work and for earning a living. The perplexity and frequent contentions about sick funds, insurance societies, and claims for damages, do their part in keeping the patient disturbed. These factors also bring about a state which has the closest points of contact with general nervousness, neurasthenia, and hypochondria. In the individual case it is often scarcely possible sharply to separate the results of the material injury from this mental activity.

In many patients—and then the causes are purely psychical—the morbid symptoms that follow the injury follow closely the type of hysteria. Then we should

speak not of a traumatic neurosis but of traumatic hysteria. We have already said, in the chapter on hysteria (*vide supra*), that this is very common. We must regard most of the cases of "local traumatic neurosis" as hysterical. We see not very rarely, after injuries which affect one limb, nervous disturbances in the injured arm or leg which can not possibly be due to a local injury of the nerve—flaccid paralysis, anæsthesia, contracture, hyperæsthesia, etc. We have already learned to recognize these conditions either in the chapter on articular neuralgia (*vide* page 528), or in the previous chapter. Here, too, the psychical factor involved in the injury certainly plays the most important part in the ætiology.

We should, however, at present still distinguish the special traumatic neurosis from all these states, although we must admit that we can not draw a sharp boundary between the traumatic neurosis and hysteria, that both states are certainly closely allied, and that the two may also be combined. Theoretically, however, we can make this distinction, that in the genuine traumatic neurosis the purely physical factor of material concussion is of ætiological significance.

In regard to the course of the true general traumatic neurosis almost all observers agree that it is protracted. In fact it is practically important to know that most of the severe cases of this sort are not capable of complete recovery. The patient's complaints and troubles persist for years without becoming much worse, but also without any marked improvement; but the course is often still more unfavorable, since the patient's mental powers may show a progressive decline, and complete dementia may finally develop.

The treatment of the traumatic neurosis is based on the same principles that we have studied in the two previous chapters, in speaking of the treatment of hysteria and neurasthenia. Great stress is to be laid on exerting a favorable mental influence on the patient. The most useful remedies besides are the electric current (galvanization of the spine, galvanization and faradization of the muscles and nerves, and the faradic brush), and also baths and rubbing, and internally quinine, iron, and strychnine.

[It hardly seems proper to regard the "traumatic neurosis" as a single morbid state. In some cases the symptoms point definitely to an affection of the cord, and the mental symptoms are absent. Here the patient complains of pain, weakness of the legs, and disturbances of the sphincters; the sensibility may be diminished, and the reflexes are exaggerated. The most marked changes in the cord have been found in the lateral columns. In other cases the symptoms are clearly those of grand hysteria, but such cases are rare in America. In many cases the symptoms are chiefly neurasthenic. In yet a fourth class there are more pronounced symptoms of mental and physical failure; anæsthesia is marked, the muscular strength is slight, and the symptoms mentioned above are pronounced. These cases may terminate fatally after a few years, and are probably cases of diffuse sclerosis of the brain and cord. Traumatic lumbago is a common complication.—K.]

# DISEASES OF THE KIDNEYS, THE PELVIS OF THE KIDNEY, AND THE BLADDER.

---

## SECTION I.

### *DISEASES OF THE KIDNEYS.*

#### CHAPTER I.

##### **GENERAL PRELIMINARY REMARKS UPON THE PATHOLOGY OF RENAL DISEASE.**

ALTHOUGH some knowledge of the occurrence and significance of renal affections had been acquired even by the older physicians, still the service of having pointed out the frequency of these diseases, and of having clearly recognized their important anatomical forms and their chief clinical symptoms, belongs undoubtedly to the English physician Richard Bright, who was born in 1788 and died in 1858, as physician in ordinary to Queen Victoria. Bright's first work on this subject appeared in the year 1827. In this he brought forward the special doctrine that, in many cases of general dropsy, which are associated with the secretion of an albuminous urine, a primary affection of the kidneys must be regarded as a special cause of the disease. Since then, the disease described by him has almost universally been called "Bright's disease" (*"Morbus Brightii"*), a name much employed, but in whose stead the anatomical terms would be more precise, since many forms were previously classed under it which, according to our accurate present knowledge, must be separated.

Bright's statements were either confirmed or expanded in subsequent times by many other observers. Christison, Osborne, and R. Willis in England, and F. J. B. Solon in France, were the chief students of renal diseases. Frerichs published the first great work in Germany in the year 1851. His division of Bright's disease into three different "stages," based on Reinhardt's histological investigations, was for a long time quite generally accepted, until gradually further clinical experience showed that it was untenable. A more accurate division of renal diseases was first opposed to it in England (Johnson, S. Wilks, and others), and in Germany (Traube, Bartels). Under the incentive of these labors, especially the work of Bartels in 1871, renal pathology thus fell into a doubtful classification with which the facts of experience could be harmonized only by force. Our late years have a natural theory of renal diseases, derived from general pathological observations, at last become accepted—a theory which is based chiefly upon the anatomical work of Weigert, but which may also be brought into complete harmony with the data of clinical observation.

The chief reason why the kidneys are so often diseased, either alone or in conjunction with other organs, is to be found in the fact that the body must elim-

doubt that a large dose, say about a drachm (grm. 3-5) in a glass of water, does have a direct tendency to produce sleep. We may also mention extract of *cannabis indica*; the preparation known as *cannabinum tannicum*, five to ten grains (grm. 0.2-0.5); paraldehyde, about a drachm (grm. 3-5) at night; and urethane, twenty to forty-five grains (grm. 1.5-3) in water at bedtime. Paraldehyde has a very disagreeable taste. Kast has lately recommended sulphonal, twenty to thirty grains (grm. 1.5-2) in a large amount of water, in soup or tea, two or three hours before bedtime. These various remedies seldom give great satisfaction, and we must therefore rely mainly on general treatment.

## CHAPTER XI.

### THE TRAUMATIC NEUROSES.

As an appendix to the last two chapters on hysteria and neurasthenia, we must now speak of a series of morbid states which are at any rate closely related to the above-mentioned affections, but which yet show certain peculiarities. We have to do here with nervous symptom-complexes which come on as a result of a severe concussion of the whole body, or sometimes after a more circumscribed injury of a definite part of the body, and hence are termed "traumatic neuroses." By the term "neurosis" we would imply that the nervous symptoms produced by the trauma do not depend upon coarse material injuries of the nervous system, but upon finer changes not yet made out anatomically.

Considering first those conditions which arise from severe general concussion of the body, they were first observed, especially after railway accidents, by English and American physicians, and given the name of "railway spine" or "railway brain." It was soon proven, of course, that precisely the same morbid symptoms may arise after other injuries.

The type of disease is very characteristic. Usually the original trauma (overturn, collision, etc.) is so great that immediately after it the well-known symptoms of *commotio cerebri* or *commotio spinalis* ensue with more or less severity—loss of consciousness, general paralysis of the extremities, collapse, small and slow pulse, cool skin, pallor of the face, dyspnoea, vomiting, retention of urine, etc. Such cases may terminate fatally in a few hours with no material visible change in the brain or cord to be found at the autopsy. In other cases the first severe shock passes off and a series of objective and subjective disturbances remain, which may persist for a long time, and which often do not disappear even after years have passed. It is these subsequent states which deserve the name of general traumatic neurosis. It is worthy of note that these appear not only after severe injuries, but also after mild ones in which the initial symptoms of commotion were not especially marked. We will return to this point in speaking of the nature of the traumatic neurosis.

The severe initial symptoms of commotion cease in a few days, or even sooner. The patient recovers, tries to get up, and the improvement goes on to a certain degree; but a number of symptoms remain which do not disappear, and which diminish or wholly take away the victim's capacity for work. If we examine such patients we find no signs of material injury either in the nervous system or in any other internal organ. What first strikes us is a peculiar psychical change. The patients are dull, depressed, disinclined to any occupation, and have no more pleasure in intercourse with their families and friends. They brood constantly over their accident and its results. The sleep is disturbed and often rendered un-

easy by dreams. Of other subjective symptoms we must mention especially pains in the part which was hurt; these are commonest in the back, the sacral region, the sides of the chest, the hips, etc. They also complain of headache, vertigo, dullness, dim vision, tinnitus, spots before the eyes, loss of appetite, etc. Objective examination often shows a general motor weakness. Many patients can walk quite well alone, but they are soon fatigued; others walk only slowly and stiffly with support, complaining of pain in the back on walking, and therefore holding the hand on the back, etc. The nutrition of the muscles is usually good. The electrical excitability of nerves and muscles is completely normal. Examination of the sensibility may reveal very important changes, which are of value in diagnosis. This examination must always extend to all the sensory organs. The skin over almost the entire body is often very insensitive to painful irritations, pin-pricks, the electric current, etc. There is analgesia. In some places we find complete anæsthesia, which may affect an entire extremity or only circumscribed parts of the extremities and the trunk. The boundary between the anæsthetic and the normally sensitive parts is usually quite sharply defined, and the arrangement is often very peculiar. Sometimes the skin is peculiarly insensitive to certain irritants (heat, cold, etc.), or, on the other hand, it is peculiarly sensitive. Examination of the eyes sometimes shows loss of visual acuteness, limitation of the visual field, and imperfect color perception. Very often the hearing is poor on one or both sides. The smell is often much blunted, and the taste completely lost, so that even quinine, vinegar, and similar strongly tasting substances no longer excite any sensation of taste.

Besides the symptoms of impairment of sensation and motion just described, we often find also symptoms of sensory and motor irritation. Pain in the head, spots before the eyes, and tinnitus, have been mentioned above. Hyperæsthesia of the skin is more characteristic—tenderness of the vertebral column, and particularly great tenderness of such parts of the body as were most affected by the original injury. Among the symptoms of motor irritation we may mention muscular contraction and muscular rigidity, again most common in the limbs most affected by the injury. A marked tremor is also very common. The reflexes differ in different cases; they are often much increased. Among the trophic changes we may mention that the hair may turn gray or fall out. Marked muscular atrophy occurs only in the more local traumatic neuroses (*vide infra*).

If we ask after the cause and the special nature of this peculiar affection, characterized chiefly by psychical disturbances, sensory anæsthesia, and motor weakness, two chief factors are to be considered. First, a purely physical factor, the concussion of the nervous system. That such a cause can produce, without coarse anatomical injury, the severest functional injury to the nervous system, is beyond a doubt; and if the most threatening symptoms can come on immediately after the concussion, it is certainly not to be regarded as impossible that permanent results may be left after the concussion which form the basis of the later symptoms of the traumatic neurosis. Furthermore, a purely psychical factor is undoubtedly to be considered. A great fright is associated with the injury. The accident readily excites a fear of an incurable illness, with permanent incapacity for work and for earning a living. The perplexity and frequent contentions about sick funds, insurance societies, and claims for damages, do their part in keeping the patient disturbed. These factors also bring about a state which has the closest points of contact with general nervousness, neurasthenia, and hypochondria. In the individual case it is often scarcely possible sharply to separate the results of the material injury from this mental activity.

In many patients—and then the causes are purely psychical—the morbid symptoms that follow the injury follow closely the type of hysteria. Then we should

speak not of a traumatic neurosis but of traumatic hysteria. We have already said, in the chapter on hysteria (*vide supra*), that this is very common. We must regard most of the cases of "local traumatic neurosis" as hysterical. We see not very rarely, after injuries which affect one limb, nervous disturbances in the injured arm or leg which can not possibly be due to a local injury of the nerve—flaccid paralysis, anaesthesia, contracture, hyperaesthesia, etc. We have already learned to recognize these conditions either in the chapter on articular neuralgia (*vide* page 528), or in the previous chapter. Here, too, the psychical factor involved in the injury certainly plays the most important part in the aetiology.

We should, however, at present still distinguish the special traumatic neurosis from all these states, although we must admit that we can not draw a sharp boundary between the traumatic neurosis and hysteria, that both states are certainly closely allied, and that the two may also be combined. Theoretically, however, we can make this distinction, that in the genuine traumatic neurosis the purely physical factor of material concussion is of aetiological significance.

In regard to the course of the true general traumatic neurosis almost all observers agree that it is protracted. In fact it is practically important to know that most of the severe cases of this sort are not capable of complete recovery. The patient's complaints and troubles persist for years without becoming much worse, but also without any marked improvement; but the course is often still more unfavorable, since the patient's mental powers may show a progressive decline, and complete dementia may finally develop.

The treatment of the traumatic neurosis is based on the same principles that we have studied in the two previous chapters, in speaking of the treatment of hysteria and neurasthenia. Great stress is to be laid on exerting a favorable mental influence on the patient. The most useful remedies besides are the electric current (galvanization of the spine, galvanization and faradization of the muscles and nerves, and the faradic brush), and also baths and rubbing, and internally quinine, iron, and strychnine.

[It hardly seems proper to regard the "traumatic neurosis" as a single morbid state. In some cases the symptoms point definitely to an affection of the cord, and the mental symptoms are absent. Here the patient complains of pain, weakness of the legs, and disturbances of the sphincters; the sensibility may be diminished, and the reflexes are exaggerated. The most marked changes in the cord have been found in the lateral columns. In other cases the symptoms are clearly those of grand hysteria, but such cases are rare in America. In many cases the symptoms are chiefly neurasthenic. In yet a fourth class there are more pronounced symptoms of mental and physical failure; anaesthesia is marked, the muscular strength is slight, and the symptoms mentioned above are pronounced. These cases may terminate fatally after a few years, and are probably cases of diffuse sclerosis of the brain and cord. Traumatic lumbago is a common complication.—K.]

# DISEASES OF THE KIDNEYS, THE PELVIS OF THE KIDNEY, AND THE BLADDER.

---

## SECTION I.

### *DISEASES OF THE KIDNEYS.*

#### CHAPTER I.

##### **GENERAL PRELIMINARY REMARKS UPON THE PATHOLOGY OF RENAL DISEASE.**

ALTHOUGH some knowledge of the occurrence and significance of renal affections had been acquired even by the older physicians, still the service of having pointed out the frequency of these diseases, and of having clearly recognized their most important anatomical forms and their chief clinical symptoms, belongs undoubtedly to the English physician Richard Bright, who was born in 1788 and died in 1858, as physician in ordinary to Queen Victoria. Bright's first work on this subject appeared in the year 1827. In this he brought forward the special discovery that, in many cases of general dropsy, which are associated with the secretion of an albuminous urine, a primary affection of the kidneys must be regarded as the special cause of the disease. Since then, the disease described by him has been almost universally called "Bright's disease" (*"Morbus Brightii"*), a name still much employed, but in whose stead the anatomical terms would be more proper, since many forms were previously classed under it which, according to our more accurate present knowledge, must be separated.

Bright's statements were either confirmed or expanded in subsequent times by many other observers. Christison, Osborne, and R. Willis in England, and Rayer and M. Solon in France, were the chief students of renal diseases. Frerichs published the first great work in Germany in the year 1851. His division of Bright's disease into three different "stages," based on Reinhardt's histological investigations, was for a long time quite generally accepted, until gradually further clinical experience showed that it was untenable. A more accurate division of renal diseases was first opposed to it in England (Johnson, S. Wilks, and others), and then in Germany (Traube, Bartels). Under the incentive of these labors, especially the work of Bartels in 1871, renal pathology thus fell into a doubtful classification, with which the facts of experience could be harmonized only by force. Only of late years has a natural theory of renal diseases, derived from general pathological observations, at last become accepted—a theory which is based chiefly upon the anatomical work of Weigert, but which may also be brought into complete harmony with the data of clinical observation.

The chief reason why the kidneys are so often diseased, either alone or in conjunction with other organs, is to be found in the fact that the body must eliminate

all forms of injurious matter, which circulate in the blood, in great part by the kidneys. Consequently the action of any injurious substance is often manifested chiefly in the kidneys, since they must, in a certain measure, be repaid for the service which they do for the rest of the body by their own disease. According to their nature and character, the injurious substances, which are here to be considered, are divided chiefly into two great groups—the chemico-toxic and the organized infectious substances. In this way the kidneys may be involved sympathetically after the ingestion of many poisons, and also in the great majority of all the infectious diseases. In these cases, of course, as we shall see later, certain chemical and infectious poisons exert their action in a particularly frequent and in a particularly severe or definitely characterized fashion. Beside these forms of origin for many renal diseases, which are the chief ones to be considered, we must consider other causes of disease which are much rarer. One way in which the morbid agents may also enter is especially important—namely, from the lower urinary passages, the bladder, and pelvis of the kidney upward into the kidney. In this way those renal diseases arise which come on secondarily to cystitis, pyelitis, etc. Finally, of course, disturbances of circulation and mechanical traumatic injuries may also make themselves manifest in the kidneys.

The clinical symptoms which are caused by the different forms of renal disease, and which serve for its recognition, are referable only in very small part directly to the diseased organ itself. In renal diseases characteristic subjective local symptoms—like local pain—are but rare, and the anatomical position and the physiological conditions of the kidney make it almost impossible to discover any changes in their size, their physical consistency, etc., by a direct objective examination. In the diagnosis of renal diseases we are therefore confined chiefly to the investigation of two groups of symptoms: in the first place, to the examination of the secretion from the kidneys, the urine, whose character, as we know by experience, may be materially altered when there is renal disease; and, in the second place, to the discovery of certain phenomena in other portions of the body, which are immediately dependent upon the renal affection. Since both the pathological changes in the urine, and the symptoms in other organs occurring in renal affections, have much in common in almost all the forms of renal disease, it is advisable first to describe the main features, at least, of the general symptomatology of renal diseases. We shall then be obliged, in the following special chapters, to mention only the precise circumstances of the occurrence and onset of each symptom; the general significance of the symptoms being already known.

#### I. ALBUMINURIA.

The most constant symptom, and one which in many cases first of all, and often even alone, renders the diagnosis of a renal affection possible with complete certainty, is albuminuria—that is, the appearance of albumen, and especially of serum albumen and serum globuline (paraglobuline), in the urine. From recent investigations (Leube, Fürbringer, and others) we know that in some cases the urine may contain a very slight amount of albumen even in healthy persons, especially after physical exertion, in emotional disturbances, etc. These rare exceptions, however, do not invalidate the correctness of the assertion that when a definite amount of albumen is persistently eliminated by the urine it must be regarded as something pathological.

The detection of albumen in the urine for clinical purposes, wherein no regard need be paid to the separation of serum albumen and serum globuline, is performed almost exclusively by means of the so-called heat test. If the urine is cloudy, it must be filtered before heating. The reaction of the urine must always be tested first. If it is acid, as usually is, the urine is heated in a test-tube with-

out any further addition.\* If the reaction of the urine is neutral or alkaline, we acidify it, before heating, with a few drops of acetic acid. If the urine contains albumen, a decided flocculent precipitate of coagulated albumen appears on heating it. We can make a mistake only where there is an alkaline reaction in the urine, which sometimes happens in neutral or very faintly acid urine, owing to the escape of carbonic acid during the heating, and the consequent precipitate of phosphates, especially of calcic phosphate. In order not to mistake such a precipitate of phosphates for a precipitate of albumen, it is necessary, after the urine has been heated for a short time, to add to the precipitate, if present, nitric acid (an excess does no harm). A precipitate of phosphates is dissolved at once, but a precipitate of albumen usually becomes thicker and more compact. We can measure the amount of albumen contained in the urine approximately by the height of the settled precipitate on the bottom of the test-tube. We often speak of "one half or one fourth of the volume being albumen," but we can not state any definite relation between this estimate of the volume and the precise amount of albumen. Of other tests for albumen we will mention here the very accurate one with ferrocyanide of potassium and acetic acid. If we add acetic acid to a urine containing albumen, and then add drop by drop a solution of ferrocyanide of potassium, a very distinct precipitate of albumen is at once formed.

If we have found out that the urine certainly contains albumen, we must then decide whether we have really a true renal albuminuria—that is, whether a urine already albuminous is secreted in the kidneys, or whether the albumen is not mixed with a perfectly normal or at least non-albuminous urine later, in the kidneys themselves or in the urinary passages, the pelvis of the kidney, or the bladder (spurious, accidental albuminuria). Such a spurious albuminuria occurs when the urine is contaminated with blood (as in hæmorrhages from the kidneys, the pelvis of the kidney, the bladder, or the urethra), or with pus (in pyelitis, cystitis, etc.). In these cases, of course, the albumen contained in the serum of the blood or pus is found in the urine. Spurious albuminuria is usually easily recognized, since the presence of pus or blood in the urine, which is shown by the appearance of the urine or upon microscopic examination (red blood-corpuscles, pus-corpuscles), points with immediate certainty to the origin of the albuminuria. Beside that, the amount of albumen in these cases is usually but slight, and corresponds to the amount of pus or blood in the urine. A disproportion in this respect must excite the suspicion whether, beside the spurious albuminuria, there is not perhaps at the same time an affection of the kidneys causing a true renal albuminuria. The determination of this point is not always perfectly easy, but we can usually come to a decision by finding abnormal morphological constituents of the urine, the so-called urinary casts (*vide infra*), which give indubitable evidence of the existence of a disease of the kidneys.

What general pathological significance has the true renal albuminuria, and what are the causes of its origin? According to our present theories, the answer to these questions is simply this: Almost every pure albuminuria is a direct sign of an abnormal perviousness of the walls of the glomeruli; and the pathological changes, which the glomeruli undergo in the different diseases of the kidney, have as their immediate result this abnormal perviousness, and the consequent transudation of albumen into the urine. The fact that the easily filtrated serum albumen of the blood, as well as the water, does not pass through the vascular loops of the glomeruli, even under normal conditions, is due entirely to the circumstance that the capillaries of the Malpighian bodies are not inserted bare into the beginning of the uriniferous tubules, but that they are covered with

\* The heat-test becomes still more certain, but it is rather more elaborate, if we first add to the urine a few drops of acetic acid and about one sixth of its volume of a concentrated solution of common salt or Glauber's salt, and then heat it.

epithelium. This epithelium of the glomeruli has the task and the power of providing for the retention of the albumen in the blood. If it suffer a pathological change in any way, it loses this power, and then the albumen passes into the urine (Heidenhain). The simplest experimental proof of this theory is furnished by the albuminuria which appears whenever the supply of arterial blood to the kidney is checked by a temporary constriction of the renal artery. The epithelium of the glomeruli thereby suffers a visible microscopic change, as its nuclei are found considerably swollen. If the kidneys in this condition are removed as rapidly as possible and boiled, according to Posner's suggestion, we can discover under the microscope in the capsules of the glomeruli the albumen that is thus coagulated (Ribbert)—the most certain sign that the passage of the albumen from the blood-vessels into the urinary passages has in fact taken place in the glomeruli.

Almost all cases of albuminuria may readily be referred to analogous disturbances of nutrition in the epithelium of the glomeruli, whether they be excited by anomalies of the circulation, like arterial anæmia or venous stasis, by toxic or infectious influences which have reached the glomeruli, or by any other circumstances. In these cases the changes in the glomeruli need not always be of a very severe or irreparable nature; for we often see a slight albuminuria appear under the most different conditions, and rapidly pass off again. This is the so-called "transitory albuminuria," which is seen, for example, in various febrile affections, after slight intoxications, after epileptic attacks, or in other severe nervous conditions, in lead-colic, etc. We will show later, in the separate chapters, how the anatomical changes which are found in severe renal diseases explain the occurrence of albuminuria.

The other factors, which have also been made answerable for the origin of albuminuria, are without doubt quite subordinate to the changes in the epithelium of the glomeruli, and at most they can affect the amount of albumen eliminated. The changes in the composition of the blood, on which formerly great stress was laid, especially the hydræmia and hypalbuminosis (the diminished amount of albumen) of the blood, have probably only an indirect significance, since the nutrition of the walls of the glomeruli suffers in such a faulty consistency of the blood, and this circumstance again is the special cause of the elimination of the albumen.

The significance of the blood-pressure for the occurrence of albuminuria was also formerly very much overrated. According to the older hypothesis, it was believed that, in an increase of the blood-pressure, the molecules of albumen in the blood could be pressed through the filter formed by the membrane of the glomeruli. This hypothesis, which was not based upon experiments, has been disproved, especially by the experiments of Runeberg; these experiments showed that, in the filtration of solutions of albumen through animal membranes, a rise in the filtration pressure was followed by a decrease, and a fall in the pressure by an increase of the per cent. of albumen in the filtrate. Runeberg attempted to refer the origin of albuminuria in many cases directly to a diminution of the blood-pressure in the renal vessels; but the attempt, on the ground of these results, is not sufficiently justified. A diminution of the blood-pressure hardly ever is itself followed by albuminuria, and the clinical facts which may be brought to support the above hypothesis may all be explained by the change in the character of the walls of the glomeruli, which is always present at the same time with the decreased pressure.

Although in the preceding paragraphs only the Malpighian bodies have been regarded as the spot where the transudation of the albumen of the blood into the urine takes place, we must also note that, under some circumstances, we may admit the possibility of a passage of albumen directly into the tubules from the

capillaries that encircle the uriniferous tubules; but we must also necessarily assume in such cases that there is a disturbance of nutrition in the membrane propria, or at least in the epithelium of the uriniferous tubules. Such an assumption seems to explain the albuminuria, according to Senator's experiments, in venous stasis in the kidneys, although in these cases the epithelium of the glomeruli also suffers soon, and then becomes pervious to albumen.

Finally, we may briefly mention that in some cases other soluble albuminous substances are also found in the urine in renal diseases as well as serum albumen and globuline, especially paralbumen, hemialbumose, etc., but the presence of these substances has not yet attained any practical diagnostic significance.

## 2. CASTS AND OTHER ABNORMAL MORPHOLOGICAL CONSTITUENTS OF THE URINE IN RENAL DISEASE.

Beside albuminuria, certain peculiar morphological constituents of the urine, visible under the microscope, are of especial importance for the diagnosis of renal affections—the urinary casts, whose significance was first correctly recognized by Henle in 1842. These are cylindrical bodies, whose breadth corresponds to the width of the uriniferous tubule, and whose length only exceptionally reaches a millimetre, and which must be regarded in their chemical nature as consisting mainly of a coagulated albuminous substance. To the latter circumstance we owe their old name of "fibrine casts," or "fibrous casts," a name which can

FIG. 111.—Different forms of casts. *a*. Hyaline cast with occasional granules. *b*. Hyaline cast with fat-drops and granular cells. *c*. Hyaline cast with red blood-corpuscles attached. *d*. Hyaline cast with white blood-corpuscles attached. *e*. Epithelial cast. *f*. Waxy cast. *g*. Cast with a large number of fat-drops.

no longer be used with propriety, since the coagulated albuminous substance of most casts is, at any rate, not identical with fibrine.

Since the precise conditions of the occurrence, and the character of the renal casts in the different diseases of the kidneys, will be spoken of later, we need discuss here only the general properties, the origin, and the significance of casts (see Fig. 111).

1. *Hyaline Casts*.—The hyaline casts are the commonest and most important form of casts, and, to a certain extent, are the ground-form for different varieties. They are perfectly homogeneous, clear as glass, colorless, soft, and flexible. We find them either wide or narrow, sometimes broken off short, sometimes quite long, usually straight, but in many cases partly curved. They are easily stained with carmine or gentian-violet. On heating the urine, they are dissolved, but they are quite resistant to acids.

The hyaline casts are very often covered to a greater or less extent with all sorts of deposits, which are usually affixed to the soft substance of the cast in the kidney itself, but which may often be attached to it later. These deposits may consist, first, of red blood-corpuscles. This condition is important, because it points with certainty to the existence of hæmorrhages in the kidneys themselves. Second, of white blood-corpuscles. These are often considerably swollen, so that we must guard against mistaking them for epithelium. Third, of renal epithelium, which may be recognized by its size, its more angular shape, and its nuclei. Of course, we often find the epithelium cloudy and granular, or shriveled and atrophied. Fourth, of fatty granular globules—that is, both fatty degenerated epithelium and also white blood-corpuscles which are filled with fat-drops from the fatty degenerated cells. Fifth, of little granular masses whose nature can not always be easily recognized. They are either coagulated granules of albumen, or fat-drops,\* or urates, or bacteria, or, finally, granules of hæmatoidine, which have come from the destruction of red blood-corpuscles, and are usually easily recognized by their dark, brownish-yellow color. Sixth, we rarely find in the casts drops like myeline, as to whose precise significance nothing is known.

2. The so-called granular casts are in most cases nothing but hyaline casts which are completely covered with the above-mentioned granular masses, but sometimes the coagulated masses of albumen or the granules of hæmatoidin may themselves assume cylindrical forms.

3. The pure blood-casts are not very common. They consist of coagulated blood, and form casts of the uriniferous tubules into which the hæmorrhage has taken place.

4. The epithelial casts are composed exclusively of renal epithelium, although probably a hyaline cast often affords a basis for the epithelium to cling to. The epithelial casts are usually easily recognized, and always point to a marked desquamation of epithelium in the diseased kidney. We must guard against mistaking renal epithelium for swollen white blood-corpuscles, as we have already said. On the epithelial casts the single epithelial cells may also present different changes, such as granular opacity, fatty degeneration, or atrophy.

5. The so-called waxy casts are almost always quite broad, uniformly yellowish, opaque casts, which proceed, perhaps, from a metamorphosis of the albumen of the hyaline casts. Their special diagnostic significance is unknown. At all events, they are not by any means found chiefly in the amyloid kidney, but they are found most commonly, comparatively, in acute and subacute nephritis.

Nothing definite can at present be stated as to the mode of origin of hyaline casts; the origin of the blood and epithelial casts is self-evident. Hyaline casts are most probably formed from the coagulated albumen eliminated from the kidneys, since the formation of casts is almost always coincident with albuminuria. We can not state definitely how far destroyed white corpuscles or degenerated renal epithelium participate in the formation of casts.

The clinical diagnostic significance of renal casts is very great. They are, in the first place, always a sure sign of the existence of some renal disease, since in normal urine casts are not found at all, or, at most, they are exceptional and are present in small numbers. The consideration of the special forms of casts, and of the deposit upon them, is also of great diagnostic importance, although from it we can never decide immediately upon the general form of the renal disease, but we can recognize with certainty the type of special pathological processes in the kidneys. The blood-casts and the red blood-corpuscles sticking to the cylinders point to the occurrence of renal hæmorrhages; the epithelial casts to a desquamation

\* It is doubtful whether the hyaline casts themselves may in part undergo fatty degeneration.

of the epithelium in the kidneys; the white blood-corpuscles to an emigration of the colorless cells from the vessels; the fatty granular cells and the fat-drops to the presence of processes of fatty degeneration in the kidneys.

We have already learned to recognize in a great measure in the preceding, as occasional deposits on the casts, the other morphological constituents found, beside the casts, in the sediment of the urine in renal disease. Briefly recapitulated, they are as follows:

1. Red blood-corpuscles. A large amount of blood in the urine (hæmaturia) is almost always to be recognized by its blood-red color. The presence of blood may be made out with certainty by the microscope, or by Heller's blood-test. The latter is performed by heating the urine in a test-tube with sodic or potassic hydrate. The blood-corpuscles are thus dissolved, and the hæmatine is precipitated with the phosphates, giving to the precipitate of the latter a very characteristic blood-red color. Finally, of course, the spectroscope may serve for the detection of hæmaturia. Hæmoglobinuria will be described in a special chapter later.
2. White blood-corpuscles. Only when they are also attached to the casts can we assume with certainty that these come from the kidneys, and not from the lower portions of the urinary tract.
3. Renal epithelium.
4. Fat-drops and fatty granular cells.
5. Uric-acid crystals, urates and calcic oxalate, bacteria, etc.

### 3. THE DROPSY OF RENAL DISEASE.

Although the changes in the urine must be alone decisive in the diagnosis of any renal disease, there are yet certain other symptoms which are also due immediately to the renal affection, and which may first direct our suspicions to the existence of a disease of the kidneys, and consequently lead to a careful examination of the urine. Among these symptoms the dropsy of renal disease is one of the commonest and most important. This may, indeed, quite frequently be entirely absent, both in acute and chronic nephritis, and in other diseases of the kidneys; but in many cases it is decidedly prominent in the whole clinical picture.

If we ask what is the reason of the frequent occurrence of dropsy in renal disease, the answer at first does not seem difficult. Since the main function of the kidneys is to excrete water from the body, and since, as we shall see later, in many cases the diseased kidney can no longer fulfill this task, or it can fulfill it only to a slight degree, we are not, in fact, very much out of the way in considering the retention of water in the body as the main cause of the consequent œdema. Clinical observation seems in general to agree completely with this assumption. The œdema in renal disease seldom appears until the daily amount of urine has been below the normal for some time, while, on the other hand, in those cases where the amount of urine passed is normal, or even abnormally great, in spite of the existing renal disease, the œdema is usually wholly absent. In individual cases, too, we very often see a decrease of the œdema associated with an increase in the amount of urine, and an increase of the œdema associated with a corresponding diminution in the excretion of urine. The pathological process accordingly seems to consist of an accumulation in the body of the water which can not be excreted from it, and which transudes from the vessels and thus gives rise to the development of œdema.

On more careful consideration, however, there are some objections to this theory, which is apparently so simple. In the first place, it might be supposed that, when there is a retention of water, the body must get rid of the surplus water by employing to a greater degree the other channels of elimination which are at its service—the skin and the intestines. Since we can never determine accurately

the time when the water first begins to be retained in the body, the clinical experience just mentioned may also be thus interpreted, that the lessened excretion of urine is not the cause of the œdema, but that, on the contrary, the appearance of œdema is rather the cause of the diminished elimination of water by the kidneys. For many cases this objection seems somewhat artificial, because the anatomical changes in the kidneys must often, without doubt, have a direct influence upon the secretion of urine; but, still, this can not be entirely and conclusively demonstrated. The results of Cohnheim's and Liehtheim's experiments also are not in harmony with the above theory of the origin of œdema. By injecting a large amount of a half-a-per-cent. solution of common salt into the vascular system of an animal we can so greatly overload its blood with water as to produce an artificial "hydræmic plethora," and nevertheless there is not the slightest œdema, not even when the animal's renal arteries are tied. In conclusion, we must also state that cases have been seen repeatedly where a complete anuria has existed for several days, as a result of the plugging or compression of the ureters, and where there was nevertheless not a trace of œdema.

There seems to be, then, another factor beside the retention of water in the body which plays a part in the origin of œdema; but it is not easy to decide what it is. Cohnheim lays the greatest stress upon a change in the walls of the vessels, by which they become abnormally pervious and permit the water accumulated in the blood to pass out into the tissues. This hypothesis seems plausible, especially with reference to the dropsy in scarlatinal nephritis, and in the cases that arise after the skin has been thoroughly chilled; but we must also admit that in many cases such a vascular change has not been certainly discovered.

The discussion so far relates mainly to the origin of the dropsy in the acute and subacute forms of nephritis. In chronic nephritis the œdema, without doubt, often arises in quite another fashion, especially as a result of the disturbance of compensation in the final paralysis of the hypertrophied left ventricle (*vide infra*). This œdema is then a true general œdema of stasis, and may be regarded as analogous to the œdema in uncompensated heart disease.

The special peculiarities in regard to the appearance of œdema in the different diseases of the kidney will be described later. The first signs of the development of dropsy are generally noticed in the skin, usually in the face, and especially in the eyelids. The ankles and legs also swell, then the scrotum, the dependent parts of the trunk, etc. In all severe cases the whole subcutaneous cellular tissue finally takes part in the dropsy, so that the whole body is swollen to the utmost degree. We almost always find at the same time an effusion into the cavities of the body, hydrothorax, ascites, and finally even hydropericardium. In some cases the dropsy of the serous cavities may attain even a high degree without there being very much anasarca—that is, general œdema of the skin. More rarely we see œdematous swelling in the mucous membranes, especially in the conjunctivæ, the soft palate, and the arytaeno-epiglottic ligaments (œdema of the glottis). Among the œdemas of internal organs, œdema of the lungs has a great practical significance. The questions as to the occurrence and significance of œdema of the brain will be spoken of below (see uræmia).

In its chemical composition, the dropsical fluid corresponds to a very thin blood-serum. The amount of water is usually 97 to 98 per cent., the amount of salts one to one and a half per cent. The amount of albumen is usually very slight. Urea has been repeatedly found in it.

#### 4. URÆMIA.

If the diseased kidneys can no longer perform their secretory functions in a satisfactory way, not only does the elimination of water from the body thereby

suffer, but the soluble constituents of the urine, the salts, the urea, and the other final products of tissue metamorphosis may also be retained in the blood and accumulate there. Hence we often find the blood, in patients with renal disease, not only more watery than under normal conditions, so that the specific gravity of the serum may fall from 1030 to 1020, or even lower, but, in almost all cases where there is a diminished excretion of urine, it is also richer in urea, as many experiments have shown, and under corresponding conditions it is probably also frequently richer in the other constituents of the urine.

This accumulation of the urinary constituents in the blood, and further, perhaps, in the tissues themselves, is the cause of a class of symptoms which are often seen in diseases of the kidneys, and which are termed uræmic symptoms or uræmia. It is probable that the retention of urea plays the main part here, but it is also probable that the retention of other constituents of the urine, perhaps the potassium salts chiefly, is likewise not without significance. Many experiments have shown that, by extirpating the kidneys or by tying the ureters in animals, we can provoke a symptom-complex, characterized by vomiting, convulsions, and coma, which corresponds almost perfectly to the uræmia of renal disease. We almost always see at the same time a very pronounced anæmia of the brain and cord, so that the accumulation of the products of tissue metamorphosis seems to excite a vascular spasm (Fleischer). We must also, perhaps, consider this secondary cerebral anæmia as well as the direct toxic action, in studying the origin of the severe nervous uræmic symptoms. That large amounts of urea injected into the blood of healthy animals usually have no injurious results, is explained simply by the fact that in this case the urea is very rapidly and completely eliminated again by the kidneys. If, when feeding an animal with large amounts of urea, we hinder its elimination, as Voit has shown, by withholding water at the same time, uræmic symptoms also appear.

Clinical experience in most cases also agrees perfectly with the theory that uræmia is caused by a retention of urinary constituents in the body. In most cases the uræmic symptoms appear only when the daily amount of urine has previously fallen to a very low figure, or when the secretion of urine has wholly ceased for several days. That in these cases not only the elimination of water, but also the elimination of an amount of urea corresponding to the food taken, and also the elimination of the other urinary constituents, is very much diminished, is shown by the experiments in regard to this point made by Fleischer and others. Furthermore, a great increase of the amount of urea in the blood in uræmic patients has been found in many if not in all cases.

Of course there can be no question that some clinical facts can not be brought into exact harmony with what has been previously said. If cases are repeatedly reported in which no uræmic symptoms have appeared in spite of anuria for several days, it does not prove too much, since we can never make an exact estimate of the matter accumulated in the blood which ought to have been eliminated; for the organism can certainly get rid of the final products of tissue metamorphosis in other ways than through the kidneys—for instance, through the skin or the intestines—and we must also bear in mind that different individuals show a great variation in tolerating the action of any poison in the body. It is harder, however, to explain those cases which are sometimes seen, where uræmic symptoms suddenly appear in patients with renal disease without being preceded by any noticeable diminution of the secretion of urine. In these cases we must assume that, in spite of the abundant elimination of water—that is, in spite of a normal amount of urine—there is a retention of the solid constituents. Such cases, however, should always make us consider whether, in renal disease, other circumstances than the retention of urinary constituents may not give rise to the

development of severe nervous symptoms. In some such cases the appearance of uræmia coincides with the disappearance of the previously existing cedema. It has therefore been conjectured that, in such cases, the blood all at once becomes rich in urea from the rapid absorption of the cedema fluid which contains urea, and that therefore uræmic symptoms now arise, in spite of the abundant elimination of urine which at once sets in. This hypothesis does not seem to us very probable, since, as was said above, very large amounts of urea may be injected into the blood of animals with healthy kidneys, without the appearance of uræmia. In the cases above mentioned we must therefore still further suppose that nothing but the water is rapidly passed off again by the kidneys, while the solid constituents remain.

Among the other theories of uræmia which have therefore been advanced to explain the apparent contradictions in the clinical observations mentioned, Traube's theory must be mentioned especially; according to this, an acute cedema of the brain is the cause of the uræmic symptoms. There is no doubt that this theory does not apply to many cases of uræmia; but, on the other hand, we can not claim that it never finds an application. It seems to us that, in general, the possibility of actual anatomical changes in the brain in renal disease has not yet been sufficiently considered as a cause of severe nervous symptoms, since the frequent occurrence of special changes in the retina, which also consists of nervous elements, is closely connected with such a theory. In most cases of uræmia we can, however, hold to the original explanation, according to which these symptoms owe their origin to the retention of the urinary constituents in the blood; but we can not exclude the possibility that, under some circumstances, severe nervous symptoms may arise from other causes in patients with renal disease, which of course do not deserve the name of "uræmia," although clinically they may greatly resemble it.

Finally, we may mention here the theory advanced by Frerichs in the year 1851, which at first found much favor, but which at present is almost universally abandoned. According to this, the urea retained in the blood was not in itself the cause of the uræmic symptoms, but it was changed into carbonate of ammonia by the action of a ferment in the blood, and from this the severe nervous symptoms arose. This theory is untenable, because carbonate of ammonia is scarcely ever found in the blood of uræmic patients. It is much more probably formed first in the stomach and intestinal canal of uræmic patients from the urea there excreted (*vide infra*), as Claude Bernard, Treitz, Voit, and others have shown.

In regard to the clinical symptoms of uræmia in the individual case, they show all possible transitions from the mildest symptoms, which are only intimated, up to the severest nervous symptoms, which may be the immediate cause of death. The severe forms of uræmia may sometimes come on quite suddenly, while in other cases they may be preceded for a long time by milder uræmic symptoms, which are then termed prodromata. The severest symptoms may not appear at all, and the milder symptoms may exist alone for a longer or shorter time. This latter condition is called chronic uræmia.

The milder uræmic symptoms, which are observed either alone or as precursors of severe uræmia, consist of headache, somnolence, and mental stupor, of a peculiar uneasiness, or of a feeling of anxiety and constraint (sometimes associated with hurried respiration), and very often of nausea, spasmodic eructations, and repeated vomiting; and, finally, not infrequently, of various symptoms of motor irritation, of slight twitchings or temporary tonic rigidity of the face or the extremities, etc.

The most characteristic symptom of severe uræmia is the uræmic convulsion,

or the so-called uræmic eclampsia. It corresponds almost exactly in its details to the pure epileptiform attack; it usually begins with a short tonic stage, in which the whole body is generally in a position of extension in opisthotonos, and then follow vigorous clonic contractions in the face and extremities. The face becomes cyanotic, a bloody froth comes from the mouth, the pupils are usually dilated and almost without reaction, the respiration is accelerated (but at times it is intermitting from spasm of the respiratory muscles), the pulse is small and accelerated, and it can scarcely be felt in the radial artery, and the temperature is sometimes raised. In other cases the spasm begins with short jerky contractions in one extremity, as in the arm, and then invades the trunk muscles, the face, and the legs. One half the body is often more affected in the attacks than the other. The spasms usually cease in a few minutes, and are followed by deep coma and stertor, which last for several hours or more. There is only rarely a single attack. The attacks are much oftener repeated after longer or shorter intervals, so that there may even be twenty or more in the twenty-four hours, during the whole of which time a complete loss of consciousness persists. Severe and fully developed epileptiform attacks often alternate with slighter convulsions.

Some other uræmic symptoms besides the convulsions have already been briefly mentioned, but they merit a somewhat fuller description.

The uræmic amaurosis occasionally seen is especially interesting. It is usually left after recovery from the convulsions. Only rarely does it precede them or appear without them. It always develops quite rapidly, so that the first disturbance of vision soon passes into complete blindness. The reaction of the pupils to light is almost always retained, and the ophthalmoscope shows a perfectly normal retinal image. From this we can scarcely doubt that genuine uræmic amaurosis is of purely central origin; it is probably due to a disturbance in the cortex of the occipital lobe. Its prognosis is on the whole favorable, since the disturbance of vision usually disappears completely in a day or two, though sometimes not until after a longer time. Anomalies are only rarely seen in the region of the other nerves of special sense, the most frequent, comparatively, being a difficulty in hearing, or even complete deafness.

Other motor disturbances, except twitchings and convulsions, are rare. Only in a few cases have hemiplegic or monoplegic paralyses, contractures, etc., been observed. Mental symptoms are more common. Delirium, and maniacal or sometimes melancholic states, occasionally follow uræmic coma.

Those uræmic symptoms have also a great interest which are to be regarded as a sort of self-help on the part of the organism, since they often lead to a vicarious elimination of urea. The first of these is uræmic vomiting, which is a frequent and often an extremely obstinate symptom both in acute and chronic uræmia. In many cases it is of central origin, and is to be regarded as analogous to the vomiting so frequent in different forms of cerebral disease; but it is often produced by the irritation which the gastric mucous membrane suffers from the urea eliminated, or rather from the carbonate of ammonia arising from it. The latter is always first formed from the urea in the stomach itself, and we find in the vomitus of uræmic patients either the still undecomposed urea or the carbonate of ammonia in considerable quantities. Sometimes there is quite a violent hiccough besides the vomiting.

Uræmic diarrhœa has the same significance as uræmic vomiting. It is usually provoked by the carbonate of ammonia arising from the urea in the intestines. The latter often causes quite a severe catarrhal, and even at times a diphtheritic, inflammation of the intestinal mucous membrane.

Another way in which the organism sometimes tries to get rid of the amount of urea accumulated in it is by the sweat-glands. Schottin first described the

remarkable discovery of a coating of urea on the skin in the uræmia of cholera, an observation which since then has been repeatedly confirmed in other cases of uræmia. This coating is most frequently seen on the face, especially on the sides of the nose, to which little faintly lustrous scales are seen sticking after the evaporation of a clammy sweat. Chemical examination shows that these scales are urea. The excretion of urea is much more rare in other parts of the skin, but perhaps the occasional severe uræmic itching of the skin is due to an irritation of the cutaneous nerves by some of the constituents of the urine that are excreted.

Other organs besides the skin and the digestive tract are but rarely to be considered as a means of the vicarious elimination of urea, but Fleischer was once able to discover considerable amounts of urea in the sputum of a uræmic patient.

In conclusion, we must describe the condition of the pulse, of the temperature, and of the respiration in uræmia. The pulse is often very slow before the appearance of severe symptoms, sometimes 48 or 40, but it is almost always tense and hard. In chronic uræmia, also, a moderate slowness of the pulse is not infrequent. When uræmic convulsions appear, however, the pulse usually becomes small and very frequent, especially in cases that terminate unfavorably. The temperature but rarely remains unchanged in severe uræmia. If there are convulsions, it usually rises several degrees, in severe cases even to  $106^{\circ}$  or  $108^{\circ}$  ( $41^{\circ}$ – $42^{\circ}$  C.). We have seen these high temperatures, especially as a terminal rise with an unfavorable issue, although there may sometimes be an improvement even in such cases. On the other hand, there are also great declines in temperature, down to  $93^{\circ}$  or  $91^{\circ}$  ( $34^{\circ}$ – $33^{\circ}$  C.), most frequently again as a terminal temperature of collapse, in cases which end in deep coma without marked symptoms of motor irritation. We might also mention the "uræmic chills" which we have seen several times—that is, a chill coming on suddenly along with other uræmic symptoms, with a great increase of temperature, and followed by a rapid fall in the temperature. The respiration in uræmic patients is sometimes very much accelerated, and is especially deep—a symptom which recalls the peculiar breathing in diabetic coma (*vide infra*). Certain severe attacks of dyspnoea in patients with renal disease have been described as "uræmic dyspnoea" or "uræmic asthma"; but it is not always easy to decide whether this is really a uræmic nervous symptom in these cases, since similar conditions of sudden dyspnoea may depend upon insufficiency of the left ventricle or upon inflammatory affections of the lungs.

In regard to the general course of uræmia, we have already spoken of the different ways in which it occurs, either coming on quite suddenly or announcing itself by different prodromata. In most cases the special exciting cause of uræmia is to be found in a failure of the renal activity caused by the anatomical lesion of the kidneys, either because the glomeruli are unable to perform their functions owing to the disease, or because the uriniferous tubules are considerably plugged by casts, or from similar reasons. In the more chronic forms of nephritis with cardiac hypertrophy (*vide infra*) the activity of the heart sometimes plays a very considerable part in the occurrence of uræmia, since, when insufficiency of the left ventricle sets in, the insufficiency of course leads to a fall in the arterial pressure and to a consequent diminution in the excretion of urine.

In regard to the duration of uræmic symptoms and to the different forms and ways in which the various uræmic symptoms may be combined in the clinical picture, we can give only a few general statements. The division of uræmia into an acute and a chronic form, already mentioned, is generally very useful practically. In the acute form we usually have the severe uræmic symptoms, especially uræmic convulsions and uræmic coma. This condition usually lasts some days,

while chronic uræmia, in which the milder cerebral symptoms—uræmic vomiting, difficulty in breathing, etc.—are most prominent, may last as many weeks.

The termination of uræmia is always doubtful in every severe case, but it is by no means always unfavorable. Even after coma lasting for several days, with very severe and often-repeated convulsions, the uræmic symptoms may wholly disappear, while on the other hand, of course, uræmia is by no means a rare cause of death in the most diverse forms of acute and chronic renal disease. In judging of the individual case, the most stress is to be laid on the condition of the pulse, the respiration, and the temperature; we must also consider, of course, the character of the urinary secretion, and especially the other morbid symptoms dependent upon the primary disease.

##### 5. THE CHANGES IN THE CIRCULATORY APPARATUS IN RENAL DISEASE.

Although it had not escaped Bright's observation that changes in the heart are also present in diseases of the kidney, this condition was first generally known when Traube, in 1856, in a treatise which has become famous, discovered that a change in the heart was very common in certain renal affections, and thus gave the chief impulse to the numerous clinical and experimental investigations that have been made since then as to the connection between cardiac and renal disease.

This connection, generally considered, may be accounted for in three ways.

First, the heart disease may without doubt be the primary disease, and secondarily lead to a disease of the kidneys, as a result of disturbances of circulation. In this way develop the kidney of passive congestion (*vide infra*, p. 300) and the embolic processes in the kidney (*vide infra*).

Secondly, heart disease and renal affections may also develop independently of each other, as a result of an injurious influence that affects both organs at the same time. Thus, for example, a general arterio-sclerosis leads to cardiac hypertrophy or to myocarditis, and also to a granular kidney (*vide infra*) and to the implication of the renal vessels. Certain other injurious influences, such as alcohol, syphilis, or impure blood, and constitutional influences, may also cause a disease of the heart and the kidneys at the same time. In such cases, if affections have developed, their influence upon each other is considerable—a circumstance which may render our judgment decidedly difficult.

In the third place, finally—and this is the point of view most generally concerned—the renal affection may be the primary disease, and lead to a change in the heart, and especially of the left ventricle. At present there can no longer be any doubt of this influence. We also know now that the secondary hypertrophy is not confined to one form of renal disease, but may occur in all forms of kidney, as was at first believed, but especially in the various forms of nephritis. Opinions are still divided as to the nature of this connection, and a more detailed account will show.

The theory which Traube has formulated, according to which the hypertrophy in nephritis is caused by the blood in nephritis, in the second place, the hypertrophy is caused by the changes in the blood, and by the changes in the arterial system. According to the theory formulated, Traube's

is untenable because it may be of acute or chronic nature, and co-existing with general disease, such as septicæmia, or with water by the kidneys, and hence, some cases of acute nephritis, arterial pressure. The glomerulus, however, is not affected on the second line of the disease, and hence, the disease of the kidneys—although it is not the only one of the disease of the general circulation, it is not the only one because the flow of arterial blood is not affected. In Abnormal function of the kidneys, the disease of the kidneys which is accompanied by a general disease, such as arterial pressure.

This disease, however, is not the only one of the disease of the kidneys, and hence, some cases of acute nephritis, arterial pressure. The glomerulus, however, is not affected on the second line of the disease, and hence, the disease of the kidneys—although it is not the only one of the disease of the general circulation, it is not the only one because the flow of arterial blood is not affected. In Abnormal function of the kidneys, the disease of the kidneys which is accompanied by a general disease, such as arterial pressure.

Besides the disease of the kidneys, the disease of the kidneys which is accompanied by a general disease, such as arterial pressure. The glomerulus, however, is not affected on the second line of the disease, and hence, the disease of the kidneys—although it is not the only one of the disease of the general circulation, it is not the only one because the flow of arterial blood is not affected. In Abnormal function of the kidneys, the disease of the kidneys which is accompanied by a general disease, such as arterial pressure.

We can see a very great practical importance. It is one of the most frequent diseases of the kidneys, and hence, some cases of acute nephritis, arterial pressure. The glomerulus, however, is not affected on the second line of the disease, and hence, the disease of the kidneys—although it is not the only one of the disease of the general circulation, it is not the only one because the flow of arterial blood is not affected. In Abnormal function of the kidneys, the disease of the kidneys which is accompanied by a general disease, such as arterial pressure.

Acute nephritis (scarlatinal, early stage). 1. Bowman's capsule; 2. Glomerulus, increase of ground substance; 3. Hyaline casts in renal tubes, the appearance of the casts is such as to suggest nuclear figures. Obj. 8, without eyepiece. (Eosinated Logwood.)

we sometimes see, however, very severe forms of nephritis in the septic diseases (septic nephritis, see page 112), in acute ulcerative endocarditis verrucosa, and allied affections, such as puerperal fever, wounds, etc. Among other acute diseases which, in comparatively rare may be accompanied by nephritis, we may mention croupous pneumonia,

## CHAPTER II.

## ACUTE NEPHRITIS.

*(Acute Bright's Disease.)*

**Ætiology.**—Acute nephritis, like most of the other forms of nephritis, is not a disease whose ætiology is uniform. The same anatomical change, which we term "nephritis," and which is attended by about the same morbid phenomena, may be excited by influences of very different kinds. Almost all these influences have one thing in common, namely, that, as we have stated in the preceding chapter, they reach the kidneys by way of the circulation and are here in part eliminated, and thus exert their specific injurious action upon the parenchyma of the kidneys; but they differ considerably from one another in their precise chemical or biological nature. Since the pathological change in the kidneys depends upon the amount of the noxious material, upon the intensity of its action and the duration of its influence, we see that the cases of nephritis that arise in this way must present a perfectly continuous series from the mildest to the severest, from those that pass off rapidly to those that last perhaps for years and years. The history of renal pathology teaches us in the plainest way that all attempts to divide the forms of nephritis into different clinical and pathological "varieties" can not be strictly carried out. The more scientific experience increases, the more numerous must be the forms established, and still we only too frequently have to assume all sorts of "transitional forms" merely to bring the reality into harmony with the scheme. It therefore corresponds merely to our practical needs if we take certain types from this whole list and divide nephritis into various groups; for, from the nature of the case, there can be no question of a sharp separation of the various forms.

We accordingly call those inflammatory renal affections acute nephritis which arise comparatively rapidly from any of the injurious influences soon to be enumerated, and which terminate, after a few days or a few weeks, either fatally or with recovery. Acute nephritis, on the one hand, follows immediately, without any fixed boundary, the mildest morbid changes in the kidney, which are usually not termed actual nephritis, but simple "parenchymatous degeneration"; while on the other hand it shows a continuous transition to those forms which last for several weeks or months, or longer, and hence are called subacute or subchronic nephritis.

Among the causes of acute nephritis we must mention first a large group which consist of infectious influences (acute infectious nephritis). In these cases the nephritis usually develops as a secondary complicating disease upon an already existing primary infectious disease, and may be regarded in most cases as a special "localization" of the specific morbid poison present in the body. In other cases there may be chemical substances which act injuriously; these may develop in the body under the influence of infection, be excreted by the kidneys, and thus exert a morbid action on the renal tissue. There is scarcely a single infectious disease in which there may not be occasionally a renal affection as a complication. We observe these affections in our experience much more frequently in certain infectious diseases than in others, so that we may rightly assume that certain infectious substances have a special injurious relation to the kidneys. Since we have already dwelt upon the occurrence, the frequency, and certain peculiarities of secondary nephritis in the description of the different infectious diseases, a brief recapitulation of the facts, which have already been for the most part described, will suffice here.

The infectious disease which most frequently gives rise to an acute nephritis is scarlet fever. As has been shown previously (see page 41), the renal affection appears but rarely at the beginning of the disease, and then in a very mild form, while the special severe scarlatinous nephritis usually attains its development only toward the end of the third week of the disease. In measles, secondary nephritis is very much rarer than in scarlet fever; in r  theln it is only of very exceptional occurrence. It is commoner again in smallpox, especially in the severe h  morrhagic forms. In varicella, renal affections are very rare, but they have been occasionally observed. They are always of but slight intensity. In typhoid fever a slight albuminuria is very common, but genuine acute nephritis is quite rare. There are some cases, however, where a nephritis appears very early, and where the other typhoid symptoms are so crowded into the background by it that it is decidedly more difficult to make the diagnosis of typhoid; this is called the "renal form of typhoid fever." In typhus and recurrent fevers severe cases of nephritis are not especially common, but they are seen more frequently than in typhoid fever.

The nephritis that often comes on in cholera is of great practical importance. This is seen in the earlier stages, and is especially one of the most frequent causes of the so-called cholera typhoid (see page 86). Of course it may appear questionable whether the renal affection here is always of an inflammatory infectious nature, or develops only in consequence of the disturbance of circulation.

Nephritis develops quite frequently in the course of diphtheria, especially in severe cases of this disease; but the renal affection only rarely reaches a high

FIG. 112.—Acute nephritis (scarlatinous, early stage). 1. Bowman's capsule; 2. Glomerulus, increase of nuclei and swelling of ground substance; 3, 4. Hyaline casts in renal tubes, the appearance of the nuclei in places is such as to suggest nuclear figures. Obj. 1, without eyepiece. (Eosinated Logwood.)

degree. We sometimes see, however, very severe forms of nephritis in the so-called septic diseases (septic nephritis, see page 112), in acute ulcerative endocarditis and endocarditis verrucosa, and allied affections, such as puerperal fever, septic wounds, etc. Among other acute diseases which, in comparatively rare cases, may be accompanied by nephritis, we may mention croupous pneumonia,

epidemic meningitis, erysipelas, certain forms of sore throat, certain acute intestinal affections, acute articular rheumatism, and tetanus.

Finally, acute nephritis may also develop in the course of chronic infectious diseases, especially tuberculosis and syphilis. We have ourselves repeatedly seen a mild or even a severe acute nephritis come on in the secondary stage of the latter disease. A genuine acute nephritis may also arise in the course of pulmonary tuberculosis, but for the present we can not decide whether this is directly connected with the tuberculosis, or whether, as is more probable, it arises in consequence of the absorption of septic substances from the contents of the cavities.

We ought also to speak of the acute nephritis sometimes seen in patients with pustular eruptions, such as impetigo, pustular eczema, severe scabies, etc. It may, however, appear doubtful whether the cause of the nephritis is to be sought in the absorption of some injurious substance from the diseased skin, or whether the disturbance of the cutaneous activity may not in itself exert a deleterious influence on the kidneys.

Besides the infectious forms of nephritis just described, there is a second great group, which may be classed under the general heading of toxic nephritis. In these cases we are dealing with the deleterious action of chemical substances which enter the body from without and are excreted from it by the kidneys. It is wholly impossible to enumerate all the substances which have this injurious effect; we will therefore confine ourselves to mentioning those of the greatest practical importance. Among the poisons proper we may mention the mineral acids, sulphuric, hydrochloric, and nitric acids, oxalic acid, phosphorus, arsenic, lead, and chromate of potassium. Among remedies used internally, which may excite nephritis when given in too great doses, we may mention cantharides, squills, balsam of copaiba, turpentine, salicylic acid, and chlorate of potassium. It is also very important to know that many remedies applied to the external skin are absorbed by the skin, and in this way may reach the kidneys and excite severe changes there. Among these are cantharidal plaster, preparations of tar, petroleum, styrax, naphthol, and pyrogallie acid. We must mention, in addition to these, the renal affection which may arise from the too abundant use of carbolic acid or iodoform to the surface of open wounds. Under some circumstances renal affections may even arise in individual cases from taking excessive amounts of certain foods and drinks, such as spices, alcohol, or very acid foods.

In the forms of acute nephritis which can not be immediately referred to infectious or toxic influences, and whose number is comparatively small, we can sometimes find no definite cause at all. We then speak of a primary idiopathic acute nephritis. We are indeed justified in thinking of causes of origin here similar to those in the cases previously described, but causes which at present escape direct detection. In other cases an acute nephritis immediately follows exposure to severe cold or wetting of the skin. We can not doubt the possibility of such a connection after quite numerous and indubitable clinical experiences, although the exact conditions to be considered here are still almost wholly unknown. We usually take refuge in a rather noncommittal reference to the "well-known connection between the activity of the skin and of the kidneys." The experiments on this point have also confirmed the fact itself, but have furnished no precise explanation of its cause.

We have still to mention the nephritis of pregnancy (*nephritis gravidarum*) as a special form of acute nephritis. This usually comes on in the last months of pregnancy in women previously perfectly healthy, and is decidedly more frequent in primiparæ than in the course of later pregnancies. The precise causes of the nephritis of pregnancy are still very obscure. Some authors lay the blame on the

pressure of the pregnant uterus on the renal vessels, others on its pressure upon the ureters, etc. (compare the text-books on obstetrics).

Finally, we must mention that an acute nephritis may ensue on a chronic nephritis that has existed for a long time, perhaps without symptoms (acute recurrent nephritis of Wagner).

**Pathological Anatomy.**—The anatomical changes, which are excited in the kidneys by the causes mentioned in what has gone before, show a continuous series from the mildest to the severest degrees, according to the intensity of the injurious action. The mildest changes, which, as we have said, are not called actual "inflammation," but usually simple parenchymatous degeneration, affect exclusively the parenchyma of the kidney—that is, the epithelium—while the interstitial tissue, the connective tissue, and the vessels remain perfectly normal. This fact is especially important since it implies that, in almost all the injurious influences acting on the kidneys, the specific renal parenchyma itself is diseased first and before any other. On macroscopic examination, the kidneys may show scarcely any plainly perceptible changes, but it sometimes strikes the practiced eye that the kidneys are a little enlarged, that the cortex on section shows either a more reddish-gray, dimmed coloring (cloudy swelling), or a more grayish-white, yellowish hue (fatty degeneration). The microscopic examination gives more accurate information as to the degree and the extent of the disease. We distinguish different conditions according to the form of change in the epithelium, of which the three following are most important: 1. *Cloudy Swelling*: It is most easily made out in the epithelium of the cortical tubules, but it may also be seen in the epithelium of the glomeruli. The cells swell, their contents become uniformly granular and cloudy, the nuclei swell, and finally disappear. Such changes are often found in acute infectious diseases, like typhoid, small-pox, and diphtheria. 2. *Fatty Degeneration*: This may proceed from the cloudy swelling, or may develop independently. Many fat-drops appear both in the cells of the uriniferous tubules and also in the epithelium of the glomeruli, and they may finally lead to the disintegration of the cells. Simple fatty degeneration of the kidneys is sometimes found in acute infectious diseases, after certain poisons, like phosphorus, and finally in anæmic conditions. 3. *Necrosis of the Renal Epithelium*: The nuclei of the cells disappear, and the cells are changed to clear homogeneous flakes, while in some cases they are greatly swollen ("dropsical degeneration" of Nauwerck-Ziegler). Genuine epithelial necrosis is found in the kidneys, chiefly after the action of toxic substances—like cantharides, the chromic and chloric salts, etc.—but sometimes also in infectious diseases. Combinations of simple necrosis with granular cloudiness and fatty degeneration are not infrequent. Both the last-named states may undergo resolution if they have not reached a high degree. Otherwise all the degenerations mentioned lead to the destruction and disintegration of the cells; nevertheless, a complete restoration is possible, from the regeneration of new epithelial cells from epithelium that is still present.

We term those changes in the kidneys genuine acute nephritis, in which not only the renal parenchyma proper, the epithelium, but also the interstitial tissue, especially the vessels, is affected; so that we can make out the exudative changes characteristic of all inflammatory processes—the escape of fluid and cells from the vessels. In these cases the different histological processes may be combined in the most varied ways, so that the anatomical picture presents quite great variations, although it is almost always principally concerned with the same processes.

If we begin with the histological lesion in acute nephritis, in order to learn to recognize at once the essential changes, we have first precisely the same processes of degeneration in the epithelium which have been already described, but they are

usually present here in a more marked degree. In some cases the simple necrotic processes predominate; in others, the fatty degeneration. We often find degenerated cells, and not infrequently a more or less marked desquamation of epithelium. We see besides the special inflammatory changes. We find a fluid inflammatory exudation, rich in fibrine, and therefore soon coagulating in the interstitial connective tissue, which is dilated and swollen by it—inflammatory œdema. The same exudation is also found in the uriniferous tubules, and, by the proper methods, by alcohol or by boiling the fresh kidney, the albuminous effusion can be made out both in the capsules of the glomeruli and in the uriniferous tubules. The interpretation of the exudation is, of course, made very difficult, or often wholly impossible, by the presence of albuminous urine in the uriniferous tubules. The second characteristic of inflammation, the "cellular exudation"—that is, the emigration of white blood-corpuscles—is also present. In the interstitial tissue we find accumulations of round cells, usually distributed in foci, and white blood-corpuscles in greater or less numbers also enter the interior of the uriniferous tubules. We often find many hyaline casts in the lumen of the straight tubules or of Henle's loops, whose origin is, in all probability, connected with the albuminous exudation and the emigrated white blood-corpuscles (see page 776). The vessels themselves are often hyperæmic and dilated, but in some cases they are compressed by the interstitial inflammatory œdema. It is of special significance that in very many cases there are hæmorrhages, either into the interstitial tissue or into the interior of the uriniferous tubules, or even into Malpighi's capsules.

All the changes described are not always found uniformly distributed over the whole kidney. Some parts are often much diseased, others but slightly, while others still are nearly, if not quite, intact. We may accordingly speak in individual cases of a diffuse or of a localized nephritis, although there are no strict limits here.

If the histological processes have been made clear, the understanding of the macroscopic appearance of the inflamed kidney is very simple. We can understand that either this or that "form" of acute nephritis must be present according to the predominance of this or that histological process. If an abundant interstitial exudation is present, the kidney is much enlarged; if this exudation is slight, the kidney varies but little, or not at all, from its normal size, notwithstanding any other severe changes. In the first case it usually feels soft, from inflammatory œdema; in the second case, it is comparatively firm. If there is a marked hyperæmia of the kidney, it appears much reddened; if the kidney is anæmic, it is paler; and if an extensive fatty degeneration is also present, it is yellowish-white or yellow. If hæmorrhages are present, they can easily be recognized with the naked eye on the outer surface beneath the capsule as dark-red points that can not be wiped away. We speak then of an "acute hæmorrhagic nephritis." On section, the medullary substance is more or less dilated, its normal striated appearance is almost always obliterated, and its color shows the same variations as the outer surface of the kidney. Since, as we have said, the nephritic changes often show not a uniform, but a nodular arrangement, we can understand that the kidneys sometimes have quite a mottled appearance, since hyperæmic or hæmorrhagic red spots alternate with the lighter anæmic and the yellow fatty-degenerated parts.

There are, accordingly, cases of nephritis which show almost nothing abnormal to the naked eye, while, on the other hand, there are hæmorrhagic and non-hæmorrhagic forms, appearing pale, yellow, red, or variegated, none of which can in the essential features be separated from one another, but which are combined with one another in all conceivable ways. The forms of nephritis that

differ in aetiology have, to a certain degree, definite and characteristic anatomical types, but strict rules can not be laid down in regard to this.

In addition, quite a characteristic anatomical form of acute nephritis deserves a brief mention, in which the changes are almost exclusively limited to the glomeruli, and which are therefore called *glomerulo-nephritis* (Klebs, Friedländer, Ribbert). In the purest cases of this form, as it is seen especially in scarlet fever and also in other infectious diseases, we find degeneration and abundant desquamation of the epithelium only in the glomeruli of the kidneys; and we usually find, besides, a marked disease of the vessel-walls, which swell and acquire a homogeneous hyaline appearance. The glomerulo-nephritis can not in its essentials be perfectly definitely separated from the other forms of acute nephritis, since in these, under some circumstances, the glomeruli may first be chiefly affected; but, as it seems, this need not happen in all cases by any means.

**Clinical History.**—The most essential symptom of acute nephritis is the abnormal character of the urine. In most of the milder, and even in many of the severer cases of nephritis, the change in the urine is the sole objective clinical symptom which renders the diagnosis possible. The physician must, therefore, make it his practice to submit the urine to repeated examinations in every case of disease where there is any possibility of the presence of a nephritis.

The simple parenchymatous degenerations of the kidneys, cloudy swelling, fatty degeneration, etc., which we will first briefly touch upon, may probably sometimes exist without being followed by any discoverable change in the urine; but they often lead to a slight albuminuria, which is easily explained from the change in the epithelium of the glomeruli. If, then, the urine contains a slight amount of albumen (which usually soon passes off) in the course of any febrile infectious disease or other affection (the so-called febrile albuminuria, etc.), we are justified in assuming some of these mild conditions of degeneration in the kidneys. Usually the urine shows no other peculiarities, but sometimes we find in the sediment a few hyaline casts, a few white blood-corpuscles, etc. As we have repeatedly stated, these conditions pass into nephritis proper without any sharp limitations.

**CHARACTER OF THE URINE IN ACUTE NEPHRITIS.**—In almost every severe nephritis the amount of urine for the twenty-four hours is more or less diminished. This is either caused directly by the lessened elimination of water by the kidneys, or by the plugging of many uriniferous tubules by casts, desquamated epithelium, etc. The amount evacuated daily is often only fifteen or twenty ounces (400–700 c. c.), but it sometimes falls to a much lower figure, two or three ounces (100–50 c. c.), and there may finally be even complete anuria. In general, though not without exceptions, the diminution of the amount of urine runs parallel to the severity of the anatomical changes in the kidney. Improvement in the disease is very often first seen in an increase of the amount of urine. If there was a previous oedema, and this is absorbed, the daily amount of urine often rises during convalescence to a very considerable quantity, eighty to a hundred ounces (2500–3000 c. c.).

The specific gravity of the urine is at first usually increased, since the urine is poor in water, but comparatively rich in solid constituents, especially in albumen (*vide infra*). Of course there are great differences here, and a urine secreted in an abnormally small amount may show a specific gravity of only 1010 or 1015, while, on the other hand, urines with a specific gravity of 1020 to 1030, or even more, have been observed. If during convalescence a very abundant, watery urine is passed, it of course usually has a low specific gravity, 1005 to 1008.

In many cases, but of course not in all, we may suspect the abnormal character of the urine from its appearance. This depends chiefly upon an admixture of

abnormal morphological constituents. If these are present in large numbers, as is usually the case, the freshly passed urine is cloudy, and deposits a more or less abundant floccular sediment. The appearance of the urine is most altered if blood be mixed with it (hæmorrhagic urine). According to the amount of blood, the urine is a light or dark red, or even a dark black-red, and often has a greenish reflection when the light falls on it.

The microscopic examination of the sediment gives more accurate information upon the different morphological constituents. We can not, of course, enumerate all the possibilities that may exist in these cases (see page 826 *et seq.*). It is generally the case that in most of the severe forms of acute nephritis the urine contains many casts of all sorts, usually hyaline, but sometimes partly fatty or waxy, and very often covered with red or white blood-corpuscles, epithelium, detritus, etc. The different cases are often characterized by a striking predominance of some one constituent—epithelium, white blood-corpuscles, or red blood-corpuscles—but no special rules in regard to this can be given. We have spoken previously (page 827) of the special conclusions we can draw from the different objects found in the sediment. We can accordingly distinguish an acute hæmorrhagic, or non-hæmorrhagic, an acute desquamative, and a fatty degenerative nephritis, but we must always bear in mind that all these forms pass into one another without sharp boundaries.

The chemical examination of the urine gives, as the most important and constant result, usually a considerable amount of albumen. Since the reaction of the urine is almost invariably acid, the albumen is immediately precipitated on heating the urine, and sinks to the bottom of the test-tube, where it usually takes up about one half or three fourths of the volume of urine used for the heat-test. More accurate quantitative determinations of albumen give most frequently in acute nephritis an amount of albumen of from three tenths to one per cent.; higher percentages are rare. The daily total amount of albumen eliminated amounts to about one or two drachms (5-8 grammes), or sometimes more, but the daily loss of albumen from the body hardly ever exceeds the amount of five drachms (20 grammes). The variation in the amount of elimination of albumen in different cases is quite noticeable.

The examination of the other solid constituents, which is not generally employed in practice, usually gives a diminished secretion of urea, phosphoric acid, etc., corresponding to the diminution in the whole amount of urine.

**THE OTHER SYMPTOMS OF ACUTE NEPHRITIS.**—Local symptoms in the kidneys themselves are only rarely present. There is, of course, a certain tenderness in the region of the kidneys, which, however, is too ambiguous to have a great symptomatic importance. It is more frequently the case that the abnormally concentrated urine causes the patient to micturate more frequently than usual, and that micturition itself is associated with a disagreeable burning—a sort of vesical tenesmus.

The subsequent symptoms of acute nephritis, which appear in the rest of the body, and among which dropsy takes the first place, are far more important than the local symptoms. Although œdema may be entirely absent in acute nephritis, it is present in most severe cases, and often is predominant in the clinical picture. We must always be prepared for its appearance, especially when the amount of urine shows a considerable diminution.

The œdema is usually discovered first in the face, which has a bloated, and often a pale and somewhat shiny appearance. The eyelids are usually most swollen at first. Beside the face, the ankles, the legs, the scrotum, and the dependent parts of the trunk may be the chief seat of the œdema, the severity and extent of which may of course vary greatly in different cases. If a high degree of gen-

eral dropsy develops, this is a source of great distress to the patient. The movements of the body are much restrained, and all changes of position are difficult, associated with great exertion, and painful. In the severest degrees of dropsy small fissures may form here and there in the excessively tense skin, from which the dropsical fluid oozes. Such little wounds are sometimes the starting-point for disagreeable erysipelatous inflammations, etc.

If great œdema of the skin is present, we usually find at the same time a more or less marked dropsy of the serous cavities. It is often hard, however, to make out ascites or hydrothorax on physical examination, owing to the œdema of the skin that is present. The symptoms mentioned acquire their chief clinical significance from the difficulty of respiration necessarily associated with them, since the diaphragm is pressed upward by ascites, and the lungs are compressed by hydrothorax. If a hydrothorax is more marked on the left, or especially if hydropericardium sets in, the activity of the heart is materially impaired.

A marked œdema of the mucous membranes develops but rarely; in a few cases we have seen œdema of the conjunctivæ, œdema of the soft palate, and œdema of the glottis. Of the œdemas of internal organs, œdema of the brain has already been mentioned as a possible cause of severe nervous uræmic symptoms. Œdema of the lungs, which often comes on toward the end of the disease, when it terminates unfavorably, is usually not to be regarded as a part of the general œdema, but as a result of the final cardiac weakness.

In regard to the other symptoms in the different organs, the symptoms on the part of the circulatory apparatus must first be mentioned. The pulse is often abnormally tense, hard, and full (see page 835). In the beginning of the disease it is often somewhat slow; later it is usually accelerated. A beginning cardiac hypertrophy can often be made out post mortem, and sometimes clinically, in cases which have lasted a somewhat longer time, two to four weeks. It seems to develop most rapidly in children who were previously well and strong. We pay especial regard to the condition of the apex-beat, and to the accentuation of the aortic second sound. The occasional nose-bleeds are probably connected with the increased arterial tension. Pericarditis is seen as a very rare complication—a complication which is connected with the general fact that in all forms of nephritis the different internal organs, especially the serous membranes, have a tendency to inflammation. Whether this circumstance is connected with the retention of urinary constituents, as has been repeatedly imagined, can not at present be decided with certainty.

Of the symptoms in the respiratory apparatus, we have mentioned above the dyspnœa consequent upon the dropsical symptoms. In severe cases the lungs themselves are often drawn into sympathy, since a diffuse bronchitis or a peculiar form of pneumonia develops in them, which latter stands midway between a catarrhal and a croupous inflammation. It exhibits, to a certain degree, a form of stiff inflammatory œdema, and occurs in just the same way in the chronic forms of nephritis as in acute nephritis. When it involves both lungs to a great extent, it may be the immediate cause of death. The development of a pure general pulmonary œdema is almost always a sign of beginning weakness of the left ventricle, as we have said above.

Vomiting is the most important symptom in the digestive apparatus. If it appears in a marked degree, it may almost always be considered as a uræmic symptom, and then is often the precursor of severe nervous symptoms. The appetite is almost always diminished in acute nephritis; the bowels are usually constipated, but there may be quite severe diarrhœa (see page 832). We may mention peritonitis, which is sometimes purulent, as a very rare complication (*vide supra*).

The temperature is markedly influenced by acute nephritis only in those cases

where the disease develops in previously healthy persons, or at least in those free from fever. Then we see quite frequently a moderate fever, with an irregular rise of temperature of about  $100^{\circ}$  to  $102^{\circ}$  ( $38^{\circ}$ – $39^{\circ}$  C.). It is quite rare that an apparently primary acute nephritis begins suddenly with a chill and high fever,  $104^{\circ}$  ( $40^{\circ}$  C.). The condition of the temperature on the onset of uræmic symptoms has already been described (page 833).

The state of the general nutrition suffers in quite a noticeable degree in most of the severe cases of acute nephritis. The emaciation is often concealed by the œdema; but the anæmia is the more prominent, and often lends to the bloated face a peculiar pallid aspect.

Uræmic symptoms may come on at any time in the course of acute nephritis. We are often prepared for the onset of uræmia by a previous marked decrease in the secretion of urine, or by the well-known prodromal symptoms, but in other cases it begins very suddenly with severe symptoms of eclampsia. In regard to all further details we may refer to what was said on page 829 *et seq.*

THE COURSE AND DIFFERENT FORMS OF ACUTE NEPHRITIS.—The whole clinical picture of acute nephritis depends very materially upon the form of its development. If an acute nephritis comes on in the course of a severe infectious general disease, as in the course of a septic affection, of ulcerative endocarditis, or of severe typhoid, the changes in the urine are often the sole factor pointing to the occurrence of the complication. The type of the severe febrile general disease is in no way materially modified by the added renal affection; œdema and uræmic symptoms do not usually appear, often because the primary disease soon ends in death.

Also when nephritis comes on in previously healthy persons or in chronic invalids, the tuberculous, etc., in many cases the changes in the urine are the chief symptom, while the other general and secondary symptoms are scarcely evident at all, or at least only in a very slight degree. Such mild cases are associated only with more or less general dullness and loss of appetite. Œdema is entirely absent, or present only to a very slight degree. Of course such cases demand great caution, since even in them we may have a sudden outbreak of severe uræmic symptoms.

The fully developed type of severe acute nephritis is seen especially in scarlatinous nephritis (*q. v.*), which comes on in children who are fully convalescent or apparently wholly well; it is also seen in many cases of apparently idiopathic nephritis, or nephritis coming on after exposure to cold, etc. In these cases there is often the development of a general dropsy, secondary pulmonary affections, uræmic symptoms, the symptoms mentioned in the circulatory apparatus, etc. In these cases, too, the examination of the urine affords the only certain means of judging accurately of the condition, but the other morbid symptoms which appear early—œdema, anæmia, and vomiting—may direct our suspicions to the developing renal affection.

Scarcely any more general statements can be made as to the whole course and the duration of acute nephritis, since the variations in this respect are too great. To describe here in particular all the different forms of nephritis according to the ætiological conditions in question would lead us too far. We will therefore refer to the description of the different primary diseases in which the characteristic marks of any renal complication are always stated. The primary nephritis from exposure to cold and the nephritis of pregnancy still demand a few remarks.

THE NEPHRITIS FROM EXPOSURE TO COLD—primary idiopathic nephritis—usually comes on quite speedily after the exciting cause. The first symptoms of the disease are sometimes insignificant, but at other times they are quite severe—chills, fever, renal pain, etc. Sometimes other "rheumatic symptoms," like angina or

articular pains, are also present. The further course may be mild or severe. In the former case the œdema that has appeared is but slight, the changes in the urine (albuminuria, hæmaturia, etc.), do not attain a very high degree, and after a few weeks complete recovery ensues. In other cases, however, the type of a severe, acute, and very often hæmorrhagic nephritis develops, with great general dropsy, uræmia, etc., which in three or four weeks, or sooner, may lead to death; but improvement may follow in spite of the severest symptoms. Then the amount of urine gradually increases, and the abnormal constituents of the urine, the œdema, and the other morbid symptoms, gradually disappear. Of course, it is often a long time before complete recovery ensues, since, even when the patient feels perfectly well subjectively, the urine may still sometimes contain some albumen, a few casts, or a few red blood-corpuscles. We must also bear in mind the possibility of a transition from acute to chronic nephritis.

The NEPHRITIS OF PREGNANCY usually begins gradually. Frequent micturition and œdema of the lower extremities make their appearance, and beside these there are often nausea and even vomiting. If we examine the urine, we usually find it quite rich in albumen, but comparatively poor in corporeal elements. The slight sediment consists of hyaline casts, a few white blood-corpuscles, and some epithelium. Only rarely does the urine assume a hæmorrhagic character.

The condition described almost always lasts to the end of pregnancy. In the cases that proceed favorably a very rapid recovery often follows after the birth of the child; but the onset of *eclampsia gravidarum* is to be dreaded as a not infrequent and a dangerous complication. This is to be regarded as entirely analogous to uræmia. It begins after mild prodromal symptoms, or even quite suddenly, with violent general convulsions, during which the child is usually born. A more or less persistent coma follows the convulsions. The convulsions may be very frequently repeated. Death ensues in about one third of the cases; the other cases usually recover, only rarely passing into chronic nephritis. The prognosis is still more unfavorable for the child than for the mother, inasmuch as the child dies in nearly one half of the cases.

The anatomical changes in the nephritis of pregnancy are hardly ever very striking to the eye. The kidneys are usually pale and but little enlarged. Under the microscope we usually find a slight interstitial œdema and degenerative changes in the epithelium. Only rarely are more marked nephritic appearances present.

**Diagnosis.**—Acute nephritis can be overlooked only when the examination of the urine is neglected or can not be carried out. The latter sometimes happens, for example, when the patient does not come under observation until after the onset of severe uræmic symptoms. Otherwise, however, the changes in the urine always furnish evidence enough to recognize the existence of the affection of the kidneys. We can, of course, decide that the nephritis is acute only by consideration of the history, the ætiological conditions, and the whole course of the disease. We must also bear in mind the possibility that there may be an acute exacerbation in a chronic nephritis that has already existed for a long time, and has been perhaps without symptoms—acute recurrent hæmorrhagic nephritis.

**Prognosis.**—The prognosis of acute nephritis depends in many cases not only upon the renal affection, but also upon the underlying primary disease. We can not here describe in detail the numerous conditions that must be considered, but they are to be found in the appropriate chapters.

Many cases of primary nephritis from toxic action, or exposure to cold, and also many cases of secondary nephritis after scarlet fever, in pneumonia, typhoid fever, or syphilis, during pregnancy, etc., recover perfectly in a short time or after several weeks, according to the severity of the individual case. On the

other hand, however, it must be said that every nephritis must be judged with great caution, partly because it may be the starting-point of a subsequent chronic renal disease, and partly because dangerous sequelæ may sometimes develop in cases that at first are apparently mild. The dangers of acute nephritis are chiefly, first, the appearance of severe general dropsy, especially in the internal cavities of the body. Of the forms of dropsy hydrothorax is the most dangerous, as it may produce suffocation by compression of the lungs. Second, uræmia, especially in its severe convulsive forms, with high temperature and finally cardiac paralysis. Third, the inflammation of internal organs, among which secondary pneumonia, in particular, is a frequent cause of death, while secondary pericarditis and peritonitis, as we have said, are seen in but very few cases. We must bear in mind, however, that in individuals otherwise healthy the severe sequelæ just mentioned may also be recovered from. The most extreme dropsy may be re-absorbed, and we sometimes see recovery, especially in children, after the severest uræmic symptoms.

**Treatment.**—Since we may omit the description of the treatment of any primary disease, we have here to speak only of those remedies which the physician has at his command against the nephritis itself and its sequelæ.

Although it seems alluring to try to exert a favorable influence upon the nephritic process by drugs which, like the injurious substances, also reach the kidneys directly, we can not report any definite practical results from such treatment. The remedies employed with this object in view—tannin in one- to five-grain powders (gram. 0.05–0.2) several times a day, and the drugs containing tannin, like uva ursi, in a decoction of 10 to 150, and also nitric acid, tartar emetic, etc.—prove, on sober observation, to be almost wholly useless. We may, therefore, try them only when there are no more pressing indications to be fulfilled. Fuchsin, which has of late been often praised, is also not to be recommended.

We expect as little result at present from "external antiphlogosis" as from the internal remedies mentioned—that is, from local blood-letting, applications of ice to the region of the kidneys, etc. Only in the rare cases where severe pain in the region of the kidneys comes on at the beginning of nephritis, in an otherwise robust individual, are we at present justified in trying leeches or a few dry cups. The warm baths, to be described more fully below, have perhaps an immediately favorable action on the process in the kidneys, since they produce a hyperæmia of the skin, and thus lessen the flow of blood to the kidneys.

Although we must accordingly admit that there is scarcely any remedy at our service which has a direct therapeutic influence upon the diseased kidneys, the treatment of nephritis may nevertheless produce very significant results, since both a number of hygienic measures and the fulfillment of certain symptomatic indications are of the greatest importance.

Among the general hygienic measures we must mention first strict confinement to bed. In the severe cases its necessity is self-evident; but, even in the milder cases, which run their course without any severe subjective symptoms, constant rest in bed is necessary throughout. In this way we not only avoid the unfavorable action of cold upon the external skin, but the activity of the skin, which must act vicariously for the kidneys, is also excited by the uniform warmth of the bed, while any useless muscular exertion, which would tax the heart's capacity for work, is also avoided by staying in bed. In general it is advisable to cover the patient quite warmly, so as to keep him in a constant slight perspiration.

The regulation of the diet is very important. All those foods and drinks which may irritate the kidneys are to be strictly avoided, especially spices, very sour substances, strong tea and coffee, or alcoholic drinks. Milk has for a long time proved itself to be by far the most suitable and best food. This has won for itself

the reputation of a remedy in renal disease, and the best results have often been seen from a methodical "milk-cure"—that is, from feeding the patient almost exclusively with milk. The great aversion of some patients toward milk, however, is sometimes an obstacle to its use. We may often be aided, then, by making the milk more acceptable to the patient by the addition of a little coffee, salt, a little cognac, or soda-water. Among other foods to be recommended are buttermilk, milk-gruel with rice or groats, and flour-gruel. We should be very cautious about giving meat as long as there are severe symptoms. We may allow meat-broths, with eggs, sooner. For drinks, beside milk, we may give water and lemonade, which latter is especially suitable. Of alcoholic beverages, a little weak red wine is usually the only thing to be permitted. Stronger wines are given only when there is cardiac weakness, and then they are of doubtful benefit.

The chief object in the symptomatic treatment consists in preventing the injurious results of the defective elimination of the water and the solid constituents of the urine by the kidneys, or in removing these results if they have already occurred. This purpose can be attained only by exciting, as far as possible, the activity of other organs which in this respect may act vicariously for the kidneys. The skin deserves the first attention here, through which, by means of the sweat-glands, large amounts of water, and also, to a certain extent, the solid constituents of the urine, which have been retained, may be eliminated. The diaphoretic treatment of renal diseases has, therefore, been generally in vogue for a long time. If the patient's general condition permits, we always begin with it as early as possible, even before there have been any signs of oedema, uræmic symptoms, etc. Hot baths from 95° to 105° (36°–40° C.) are best. The patient stays about half an hour or an hour in the bath, is then rapidly dried somewhat, wrapped up in bed in a previously warmed sheet, and then is well covered up to the neck with blankets. In order to make the procedure somewhat easier for the patient, it is a good plan to cover the forehead with a cold compress, always to wipe the sweat carefully from the face, and frequently to give him a little swallow of fresh cold water. The production of sweat is, of course, better excited during the pack if the patient takes some hot drink, hot milk with soda-water, or hot elder-tea. It sometimes seems to aid diaphoresis if an internal diaphoretic be given at the same time, the best being five to ten grains of Dover's powder (grm. 0·3–0·5), or three or four drachms (grm. 10–15) of liquor ammonii acetatis (*spiritus Mindereri*) in a cup of elder-tea. We have also found a good rubbing of the whole body with dilute warm French brandy of service before the pack. The pack may last two or three hours.

In this way we succeed in many cases in causing a considerable production of sweat, so that the patient loses several pounds in weight at each pack, and an existing dropsy may sometimes be made to disappear completely in a comparatively short time. On the other hand, however, we can not deny that it is very hard sometimes to make patients sweat, even when there is oedema of the skin, and also that many patients do not bear hot baths and packs at all. The latter is especially true if the patient has dyspnoea, and if signs of cardiac weakness have already set in. Then we have to be very cautious about using sweating as a remedy. Sometimes we can bathe the patient, but we have to omit the pack, while in other cases he can take the hot pack in bed; but we must avoid carrying him to the bath and back. We also have to get along with hot wet packs, if baths can not be used for extrinsic reasons.

Beside hot baths and packs, one diaphoretic remedy is to be especially considered in renal disease, and that is the hydrochlorate of pilocarpine, derived from the jaborandi-leaves. We use it best in the form of a subcutaneous injection, of one sixth to a third of a grain in one dose (grm. 0·01–0·02); but it may also be giv

internally in the form of pills, in like doses. Its action consists in the production of a copious sweat, and also usually of a very considerable flow of saliva, which is often very disagreeable to the patient. In general, we prefer the baths to pilocarpine, and we try the latter only when the baths are contra-indicated or do not exert any satisfactory action. The diaphoretic action of pilocarpine, moreover, is often decidedly less in dropsical patients with kidney disease than in other cases.

Next to the skin, the intestinal mucous membrane is the organ from which we may soonest expect to produce a vicarious elimination of water, and also of urea, for the kidneys. It is sometimes, therefore, of distinct service to prescribe drastic cathartics in nephritis with a diminished secretion of urine, especially if there is a tendency to constipation beside the dropsy, dyspnoea, etc. The drastic cathartics chiefly used are infusion of senna, decoction of colocynth, 3 or 6 to 150, gamboge in two-grain powders (grm. 0.1), etc.

Finally, it may be asked whether we should not excite the secretory function of the kidneys themselves by the exhibition of diuretics. The objection is, however, that all diuretic remedies irritate the kidneys, increase the flow of blood to them, and therefore can act only injuriously upon the nephritis. We must, therefore, be very cautious in using diuretics. Only the milder remedies, especially acetate of sodium, may sometimes be used with advantage, especially in the less acute cases or during the period of convalescence. The diuretic action of digitalis, which is very important under some circumstances, will be mentioned later.

The therapeutic measures so far spoken of correspond to the task of preventing as far as possible the retention of urinary constituents in the body. They are also very much employed when the signs of this retention have already appeared. The dropsy especially can be successfully treated only by methodical sweatings, with the aid, eventually, of drastic and diuretic remedies. When uræmia is threatening, and often even when it has broken out, we may try to produce an elimination of the injurious products of tissue metamorphosis from the body in the well-known ways above described, by sweating or drastic purgatives. Beside this, the uræmic symptoms, however, often demand a special symptomatic treatment. If very violent and frequent uræmic convulsions appear, we consider it advisable to try to suppress the attacks by chloroforming the patient. At any rate, it seems to us to be better to use chloroform in uræmia than to give narcotics internally, because with this we can watch the action of the remedy better, especially the condition of the pulse and respiration. Chloroform is also generally used by the obstetricians as the main remedy in the eclampsia of pregnancy. If the attacks are not very frequent, but if there is marked somnolence or coma, tepid baths with cold shower-baths are often employed with distinct advantage. Cool baths are also serviceable where there is a great increase of the temperature. If we are treating a robust individual with a full pulse, and during severe uræmia there is a decided redness or cyanosis of the face, venesection may be indicated. This sometimes has a striking and instant effect, as has lately been confirmed by various observers. Great attention is to be paid to the condition of the heart. As soon as the pulse becomes small and weak, energetic stimulants, like subcutaneous injections of camphor, must be used. If the signs of cardiac weakness appear before the beginning of severe uræmic symptoms, digitalis must be used in infusion or powder. Through its action in raising the blood-pressure—it being advisable under some circumstances to combine with it acetate of potassium—a greater diuresis sometimes comes on, and with it a disappearance of the danger from uræmia. The *tinctura nervina Bestuscheffii* [nearly equivalent to the tincture of the chloride of iron, U. S. P.] may also be sometimes used to advantage in uræmia. We are not apt to interfere with uræmic vomiting or uræmic diarrhoea, because these symptoms, as we have said, are to be regarded as a form of self-help

by the organism. Only when these symptoms are very distressing do we give cracked ice, morphine, opium, etc. If the vomitus contains ammonia, it is a good plan to give ten or fifteen drops of dilute hydrochloric acid in water several times a day.

[A method of treatment of uræmic convulsions, whether post partum or connected in no way with parturition, which gives excellent and prompt results, is the administration of pilocarpine hypodermically—grain  $\frac{1}{4}$ , and repeat in twenty minutes—followed by the hot-air bath, to maintain the action of the skin after it has once been started.

Pilocarpine sometimes acts as a decided cardiac depressant, so one must be ready to administer stimulants—brandy or ether—under the skin if, as is apt to be the case, there is doubt as to the readiness with which they will be absorbed from the stomach or rectum.]

In severe cases, the patient's dyspnoea often demands urgent relief. If this be caused, or at least increased, by hydrothorax, and we do not succeed in removing the hydrothorax in any other way, it is necessary to evacuate it by puncture. In acute nephritis, indeed, we may hope by this means sometimes to preserve the patient's life until improvement sets in. Great ascites must also sometimes be punctured. Against "renal pneumonia" our remedies are powerless. Tepid baths and shower-baths sometimes procure relief. In "uræmic asthma," morphine injections may act beneficially. If pulmonary oedema ensues, the heart again is chiefly to be considered. We may try, besides, large mustard plasters, baths, and acetate of lead.

We accordingly see that many remedies are at our service in the treatment of nephritis, the choice of which in the individual case must be committed to the personal judgment of the physician. In the main, we should always begin with the necessary hygienic measures, and, if possible, with a methodical diaphoretic treatment, and govern ourselves otherwise by any symptomatic indications. After recovery has set in, great caution is still necessary for a long time. The patient must guard against physical over-exertion, errors in diet, and exposure to cold. Preparations of iron are to be prescribed when there is a subsequent anæmia.

In regard to the influence of the onset of an acute nephritis on the treatment of the primary disease, we may yet mention that cold baths are in general not to be freely used, as in typhoid fever with nephritis, but they are not absolutely contra-indicated if they are otherwise urgently desirable. We may mention besides that certain internal remedies, especially salicylic acid, must be used only with great caution when there is nephritis. In the eclampsia of lying-in women the induction of premature labor is only rarely indicated, since the child is usually born during the paroxysms without interference.

### CHAPTER III.

#### THE SUBCHRONIC AND CHRONIC FORMS OF NEPHRITIS, WITH THE EXCEPTION OF THE GENUINE CONTRACTED KIDNEY.

(*"Second Stage of Bright's Disease." Chronic Parenchymatous Nephritis, Chronic Hemorrhagic Nephritis, Large White Kidney, Secondary Contracted Kidney.*)

**Ætiology.**—While the acute nephritis described in the preceding chapter runs its course in several days or weeks, and only rarely extends over some months, we will now speak of inflammatory degenerative affections of the

last at least several months, and often go on for a year or two. The term "sub-acute" or "subchronic" is chosen for the cases that last a comparatively short time. As we must once more repeat, there is no sharp limit in this respect.

In regard to the ætiology of these forms of nephritis, they do arise from an acute nephritis, but this is quite rare. Formerly such an origin was erroneously regarded as the rule, and this is the reason why the changes in the kidney in these cases were described as the "second stage of Bright's disease" (Frerichs). The English clinical observers Wilks and Johnson, whom Bartels followed in Germany, first pointed out the fact that in most cases the disease shows a chronic character from the start, and that we can only exceptionally, as after scarlet fever, recognize an acute "first stage." The name "chronic parenchymatous nephritis," since frequently used, is chosen entirely from practical reasons, inasmuch as it briefly states the distinction from the genuine contracted kidney; but it is incorrect in principle, as will be shown from the description of the anatomical conditions later.

If we look for the ætiological conditions in cases that have a chronic course from the beginning, we can often discover nothing definite at all. The disease seems to have developed "of itself" in previously healthy persons. Most probably we have here some toxic or infectious agency that acts on the kidneys, whose detection, however, is at present impossible. In malarial regions the malarial poison may often lead to chronic nephritis. It is also attributed to syphilis and tuberculosis, but the cases met with are usually combinations of these diseases with amyloid kidney (*vide infra*). Frequent exposures to wet and cold, damp dwellings, etc., seem sometimes to be of more material significance, but it is, of course, hard to form a definite opinion on this point.

Persons in middle life are most frequently affected by the disease, and men more often than women. In children and old people the disease is quite rare.

**Pathological Anatomy.**—There is no essential distinction between the anatomical lesions of the kidney in acute and in chronic nephritis. The changes that are seen in both are essentially the same, only they develop and extend more slowly in the chronic forms; and they also, during their longer duration, lead to certain sequelæ in the kidney, which can not develop at all in acute nephritis, owing in part to the lack of time. Even in chronic nephritis the individual cases differ from one another in many respects. First this and then that histological process is especially prominent, and thus lends certain peculiarities to the macroscopic appearance of the kidneys. Certain sequelæ—like contractions—have also developed but little in many cases that soon end fatally, but they develop far more in other cases of longer duration. Hence it happens that we can quite well regard certain anatomical forms that are more frequently observed as types, although we must never lose from sight the principle, to be firmly held, of the pathological unity of all these forms and types. Then we shall not lose the clew to the understanding of the morbid process if the individual case does not always harmonize with the scheme of the text-books.

We distinguish the three following chief anatomical types of subchronic and chronic nephritis:

1. **CHRONIC HÆMORRHAGIC NEPHRITIS** in the form of the **LARGE RED or VARI-EGATED KIDNEY.**—The kidney is at least of normal size, and often a little or a good deal enlarged. It feels firmer than normal; its capsule is often adherent to the surface in some places. The surface looks either uniformly a more gray red or more mottled, while dark-red spots alternate with lighter gray or even yellow spots. The red spots on the surface can not be wholly wiped off, and thus prove to be hæmorrhages. The gray or yellow parts correspond to the anæmic and fatty degenerated portions. On section, the cortical substance is usually broader, its

normal boundary is obliterated, and its color is a uniform gray red, or also mottled and striated.

Under the microscope we find in part the same changes as in acute nephritis—parenchymatous and fatty degeneration of the epithelium, casts or hæmorrhages in the uriniferous tubules, inflammatory œdema or granular infiltration of the interstitial tissue, the capsules of the glomeruli sometimes thickened, the epithelium of the glomeruli sometimes proliferated or desquamated, etc. The special characteristic of this chronic form, in contrast with acute nephritis, is that in many places a complete destruction of the uriniferous tubules has occurred, and that a genuine interstitial connective tissue, richer or already poorer in cells, has taken their place. In this lies the anatomical evidence of the longer duration of the disease, since the two processes—both the complete atrophy of the epithelium, and especially the secondary proliferation of connective tissue—of course need a certain time for their development. The atrophy and the proliferation of connective tissue usually predominate in some parts, while in others nothing but fresher inflammatory and degenerative changes are perceived.

2. THE INFLAMMATORY FATTY KIDNEY, or the LARGE WHITE KIDNEY (yellow would be more proper).—In this form of chronic nephritis the kidney is usually enlarged, or at least of normal size. Its outer surface is smooth and of a yellow or an alternating yellow and gray-yellow color throughout. The broader cortical substance shows a yellow and usually somewhat mottled appearance, while the pyramids almost always appear considerably reddened. Hæmorrhages are also almost always present in this form, usually, of course, in smaller numbers than in the variegated kidney, but they are sometimes quite abundant, as in the hæmorrhagic fatty kidney.

The microscope shows the great affinity between this form of nephritis and the preceding. We have almost precisely the same changes, and we always have especially a partial destruction of renal tissue with a subsequent increase of interstitial connective tissue. The macroscopic appearance of the kidney is due to the fact that it is anæmic, and that the fatty degeneration preponderates in the epithelium. It is worthy of note that in these kidneys marked changes in the glomeruli are usually present.

3. THE SECONDARY CONTRACTED KIDNEY.—While in the two forms of nephritis thus far described the outer surface of the kidney is still smooth, and the kidney, on the whole, is somewhat enlarged, we have to do here with kidneys of about normal size, on whose surface there are granulations, which as yet are slight, but which still are already plain. This granulation signifies nothing more than that the destruction of the renal tissue has here advanced farther, and that the newly formed connective tissue has in part undergone cicatricial contraction. These kidneys, therefore, represent a later stage of the two forms first-named. They usually come under observation when the nephritis has lasted about a year and a half or two years, or even somewhat longer. The first beginnings of granulation may, of course, show themselves earlier, while, on the other hand, when the process lasts a longer time, a completely contracted kidney may develop.

The color of these kidneys is usually reddish or mottled, the red spots corresponding to the sunken atrophic parts, and the gray or yellowish spots to the elevated parts. Yellow kidneys, however, may also show at times decided granulations. Microscopically, we find already marked atrophy of the renal parenchyma, with a corresponding increase of the interstitial connective tissue.

Formerly these kidneys were called the "transition between the second and third stages of Bright's disease." As follows from the above, they are to be regarded only as a more advanced form of chronic nephritis. In spite of their granulation, have on the whole a normal si

this, and from the clinical course, that they were usually, though of course not always, previously enlarged. Therefore the name of "secondary contracted kidney" is quite suitable, in opposition to the genuine contracted kidney, which represents a much more chronic form of renal atrophy.

Of other pathological lesions, apart from the changes in the kidney, we will mention here only the hypertrophy of the left ventricle, which is found with few exceptions (*vide infra*) in all the above-mentioned forms of nephritis. The chronic parenchymatous nephritis without cardiac hypertrophy, alleged by Bartels in his time, does not exist. Such cases were probably confused with amyloid kidneys.

**Clinical History.**—Only in the comparatively rare cases when the renal affection begins acutely, do the symptoms of chronic nephritis follow immediately on the first acute stage. In most cases, however, the disease develops slowly and gradually from the start, as we have said, like most of the other chronic organic diseases, so that it is usually impossible to determine accurately the moment when the disease begins.

The first signs of the disease consist of certain general symptoms, pallor, dullness, loss of appetite, nausea and headache, and later of oedema. The latter is often the first symptom which sends the patient to the physician, since in the beginning he often pays little attention to the symptoms first named. The oedema usually appears first in the ankles and legs, more rarely at an early period in the face. It often disappears at first after a night's rest, but always develops afresh during the day, gradually increasing in intensity. The patient himself now sometimes notices a change in the urine, either an abnormal color or cloudiness or a diminished amount. The accurate examination of the urine by the physician first establishes the diagnosis with certainty.

In regard to the more special symptomatology of chronic nephritis, we meet exactly the same symptoms as have been described in the preceding chapter on acute nephritis. The characteristic distinction is based merely upon the whole course of the affection and the order of development of the different symptoms, and not by the symptoms themselves.

The urine almost always is diminished. Of course the figures vary quite considerably both in different cases and at different times in the same case. The small amount of urine, ten to twenty-five ounces (300-700 c.c.) a day, is almost always an unfavorable sign, while a free diuresis signifies an improvement of the condition, an absorption of the dropsy, and finally a passage of the renal affection into a still more chronic condition, the secondary contracted kidney (*vide infra*). Under such circumstances the amount of urine may even be increased above the normal, to fifty or sixty ounces (1500 or 2000 c. c.) or more.

The specific gravity of the urine is often increased to about 1015-1025, corresponding to the amount of albumen and of other solid constituents. It is of course correspondingly lower when there is a more abundant elimination of water by the kidneys.

The amount of albumen in the urine is quite marked in all severe cases, being one third to three fourths of its volume. It amounts to about 1.5-3 per cent. by weight, so that the patient's daily loss of albumen may reach half an ounce to an ounce (15-30 grammes).

The examination of the sediment, which is usually abundant, is of the greatest importance for the accurate determination of the form of the anatomical changes in the kidneys. Above all, the question arises as to the presence or absence of blood in the urine. Every abundant hæmaturia may be recognized by the naked eye from the color of the urine. The detection of smaller amounts of blood can be made only by the aid of the microscope. It goes without saying that the amount

of blood in the urine varies quite considerably in the different cases, and in the same case the urine often contains much more blood during certain periods in the course of the disease than at other times. The portions of urine passed at different times taken separately often show quite marked variation in this respect; the day's urine especially usually contains more blood than the night's. From the detection of renal hæmorrhages, of course in connection with other symptoms, we can always make with certainty the diagnosis of a "chronic hæmorrhagic" nephritis.

In most cases casts are quite abundant in the sediment of the urine, but of course their amount and variety undergo quite great variations in different cases and at different times in the same case. They are the direct sign of the presence of an inflammatory exudative process in the kidneys, although the deposits on the casts are more important for the diagnosis of the special form of renal disease than are the casts themselves. Those formed constituents of the sediment are most characteristic in this respect which point directly to the processes of fatty degeneration in the kidneys: the fatty granules and fatty granular cells, free or attached to the casts. The number of these elements is especially great in the chronic inflammatory fatty kidney, the "large white kidney." The usually clear, non-hæmorrhagic urine may in some cases have even a fatty lustrous surface. Renal epithelium is, on the whole, more rarely present in the sediment in chronic nephritis than in acute, but it occurs at times in some cases.

Of the other symptoms, the one that usually most strikes the eye is dropsy. It usually comes on, as we have said, in the beginning of the disease, and slowly or rapidly reaches a great extent and intensity. A medium or even a high degree of general dropsy may often persist almost unchanged for months. In other cases it shows either spontaneous variations or variations influenced by treatment; it decreases for a time only to increase anew. The severer and more acute the case, the greater in general is the dropsy. In the more chronic cases, in secondary contracted kidney, its intensity may be slight for a time or even permanently. The dropsy may even be absent in some cases, as we learn especially from the observations reported by Wagner under the name of "chronic hæmorrhagic Bright's disease without œdema." In regard to the different localizations of the dropsy, and to dropsy of the internal cavities, hydrothorax, ascites, and hydropericardium, and their results, the same holds true as was described in the account of acute nephritis.

Of the internal organs, the condition of the heart lays claim to the most interest. In all cases of chronic nephritis, in which we do not have to do with especially weak and run-down patients, who can not save the necessary nutritive material for the formation of a cardiac hypertrophy, we find a pronounced and often a very marked hypertrophy of the left ventricle, either with or without a co-existing dilatation of its cavity. A chronic nephritis without cardiac hypertrophy, which was put forward by Bartels and others as the type of "chronic parenchymatous nephritis," does not exist, as we have said, except under the above-mentioned conditions. The detection of cardiac hypertrophy during the patient's life is sometimes difficult, especially when there is general dropsy, but the diagnosis can usually be correctly made with proper attention to the abnormally tense radial pulse, the accentuated, valvular aortic second sound, and the displacement outward of the apex-beat, or at least its increased strength. We often find in the cadaver, and can sometimes make out during life, a hypertrophy of the right ventricle. This is usually a sign of a disturbance of compensation—that is, the paralyzed left ventricle can no longer send forward in a sufficient manner all the blood coming from the pulmonary veins, so that there ensues a stasis in the pulmonary circulation, and a consequent hypertrophy of the right ventricle.

A second important sequel of chronic nephritis consists of the changes in the retina—albuminuric retinitis. Although very rare in acute nephritis, these changes are present in by far the greater majority of the cases of this class. Sometimes the patient's subjective visual disturbance (dimness of vision, defects in the field of vision), point to a disease of the retina, but the existence of disease can be established with certainty only by ophthalmoscopic examination. In these cases we find two changes, in varying numbers and combinations: first, retinal hæmorrhages; and, second, white spots and streaks, especially in the vicinity of the optic nerves. The origin of the spots, which may appear and disappear again, is not yet entirely clear. At any rate, there are circumscribed fatty degenerations of the special retinal elements. The degree of amblyopia depends, of course, chiefly upon the localization of the changes, whether in the macula lutea, or other parts.

We can say little in regard to the other symptoms, since they agree essentially with those of acute nephritis. The general anæmia is very pronounced in many cases, but it is less marked in the very chronic forms. The cerebral symptoms, especially the headache and the mild vertigo, may depend in part upon the cerebral anæmia; otherwise, they are a uræmic symptom (*vide infra*). Cerebral hæmorrhages have been observed in a very few cases. Hæmorrhages on the inner surface of the dura mater are more frequent, but they are usually without clinical significance. The mouth, larynx, and pharynx usually show nothing particular, except accidentally complicating inflammations. We must, however, remember the occasional occurrence of a very distressing or even dangerous œdema of the soft palate, or of the aryteno-epiglottic ligaments—œdema of the glottis. Similar forms of bronchitis and pneumonia, as in acute nephritis, are found in the bronchi and lungs. Bronchitis and chronic œdema of the lungs also make their appearance in the more advanced stages of the disease as a result of cardiac insufficiency. Finally, we must remember the hindrance to respiration from hydrothorax, and also from uræmic dyspnoea. The changes in the heart have already been spoken of. Endocarditis or pericarditis may occur, but they are very rare.

Loss of appetite is a very common symptom on the part of the stomach. Very persistent vomiting is usually to be regarded as a chronic uræmic symptom. The bowels, as a rule, are constipated, but there may also be severe diarrhoea, as in acute nephritis. In severe cases, especially in the last stages of the disease, ulcerative and dysenteric processes have repeatedly been observed in the large intestine and the ileum. Peritonitis may occur, but it is at all events extremely rare. The liver and spleen usually show no peculiarities.

Uræmic symptoms, both of the milder chronic variety and also in their severest acute form, may come on at any time, although they do not by any means attain their full development in all cases, and are somewhat rarer than in genuine contracted kidney.

The temperature remains normal, as a rule, as long as it is not influenced by complicating inflammations, or by the appearance of uræmia.

**Course, Duration, and Termination of Chronic Nephritis.**—In general, the whole course of chronic nephritis presents quite a great uniformity. The different symptoms may show certain variations within long periods, but the patient often presents almost the same appearance day after day for months. The duration of the disease shows all the transitions from three to six months, in the subacute cases, to two or three years, or even more, in the very chronic cases. The cases of long duration are almost all cases of secondary contracted kidney. They sometimes show in their clinical relations the transition from the enlarged to the granular kidney, since the picture in many of its details is more like that in the genuine contracted kidney: the œdema decreases, disappears completely, or, at least, con-

tinues in a lesser degree; the amount of urine becomes more abundant, and the specific gravity and the amount of albumen become correspondingly less. The condition thus lasts for a long time until it grows worse again, through uræmia, or disturbance of the compensation in the heart.

The final termination of chronic nephritis is in most cases unfavorable. In the severe forms death ensues in from three months to a year, either in consequence of general dropsy or from uræmia, from complicating inflammations, etc. The conditions when the nephritis goes on to secondary contraction are comparatively more favorable, inasmuch as the patient may then find himself in a tolerable condition for a time at least. Complete recoveries doubtless occur in chronic nephritis, but they are rare. An apparent recovery may be simulated by the appearance of secondary contraction. Even after signal improvement, however, relapses are always to be feared. There are even genuine acute attacks in the course of chronic nephritis.

**Diagnosis.**—On careful examination of the urine in all suspicious cases of cedema, anæmia, etc., the diagnosis of chronic nephritis can always be correctly made. In regard to the more exact distinction of the different anatomical forms, we will here give a brief schematic glance at the most important conditions:

*Chronic Hemorrhagic Nephritis* (large variegated or mottled kidney).—Duration from six to eighteen months. Urine often hemorrhagic; usually quite rich in red blood-corpuscles and casts. Cedema. Cardiac hypertrophy. Retinal changes. Quite frequently uræmia.

*Inflammatory Fatty Kidney* (large white kidney).—Duration also six to eighteen months, but usually somewhat shorter than in the preceding form. Urine not at all, or only slightly, hemorrhagic. Frequently many white blood-corpuscles, and especially signs of fatty degeneration in the kidneys, fatty granular cells, fat-drops in the urine, etc. Significant amount of albumen in the urine. Marked cedema. Cardiac hypertrophy. Very often retinal changes. Death by uræmia frequent.

*Secondary Contracted Kidney.*—Longer duration of the disease, from a year and a half to three years. At first the symptoms of the preceding forms; later, urine more abundant, less cedema, etc. Death from an increase of the dropsical symptoms due to cardiac insufficiency, uræmia, etc.

**Treatment.**—The treatment of chronic nephritis corresponds in all its details so closely to that of acute nephritis that we can refer almost entirely to the preceding chapter.

The main thing here is also regimen and symptomatic treatment. The patient must always keep himself warm, wear flannels, or stay in bed. Under some circumstances climatic cures, like Italy, Egypt, etc., are indicated in the more chronic forms. A milk diet is to be carried out as far as possible.

The treatment of dropsy follows entirely the methods previously described, and so does the treatment of any uræmic symptoms.

In the more chronic cases with great anæmia preparations of iron, such as iodide of iron, are often to be used, and also frequently stomachics, cathartics, etc. The condition of the heart always deserves careful attention (digitalis &c.). The retinitis rarely demands a special treatment.

## CHAPTER IV.

## CONTRACTED KIDNEY.

(*Genuine Contracted Kidney. Granular Atrophy of the Kidney. Granular Kidney. Renal Sclerosis. "Third Stage of Bright's Disease." Chronic Interstitial Nephritis.*)

**Definition and Ætiology.**—The genuine contracted kidney is the result of an extremely chronic and very slowly but constantly progressive atrophy of the renal tissue. The term "chronic nephritis" is also used for contracted kidney, but the special inflammatory processes are very subordinate here, for the anatomical process consists essentially in nothing but a simple degenerative atrophy of the renal parenchyma, and in a corresponding gradual increase of the interstitial connective tissue. From a general pathological point of view the process is to be regarded as wholly analogous to the corresponding changes in the liver in cirrhosis of that organ, in the spinal cord in the chronic degenerations of the different systems of fibers, etc. In all these cases we have a primary destruction of the special tissue-elements as a result of some deleterious action, and, following a general pathological law (Weigert), a partial replacement of the parts destroyed by a newly formed cicatricial connective tissue.

In the "genuine" contracted kidney the atrophy of the renal parenchyma begins in a previously healthy kidney. Cell after cell of epithelium, islet after islet of tissue, are slowly attacked, while other parts still remain intact. It was therefore an error of the older pathologists to regard the contracted kidney as the "third stage of Bright's disease," as if every granular kidney were first found in the stage of acute inflammation, and then passed into the stage of chronic enlargement, and lastly into that of contraction. This theory, of course, suits certain cases in part, for chronic nephritis at least may often finally pass into contraction, but these "secondary contracted kidneys" (*vide supra*) can clinically, and almost always anatomically, be differentiated from the genuine contracted kidneys. On careful examination, as it seems to us, the contracted kidney may of course arise from an acute nephritis in some cases, which perhaps are not very rare; but then the process hardly ever passes through the three stages mentioned above, for the acute nephritis apparently recovers. A slight remnant of it is left—a little fire, as it were, glimmering under the ashes; its work of destruction advances, wholly in secret, and perhaps only after many years do the symptoms of a pronounced renal contraction appear.

If we inquire into the causes which produce the atrophy of the renal tissue in the ordinary cases of contracted kidney, which are chronic from the first, we are very often unable to make out any special causes. Of course, we must again bear in mind first the two great groups of injurious influences, the chemico-toxic and the organized parasitic, but at present only a small number of ætiological factors have a more or less definite significance.

Experience teaches us that there are three chemical substances to be mentioned which may favor the development of contracted kidney: alcohol, lead, and uric acid. Chronic alcoholism is often to be regarded as the most probable cause of renal contraction, especially in people who have "lived well" otherwise, and have become corpulent. This is the explanation of the combination of contracted kidney and cirrhosis of the liver repeatedly observed. The connection between contracted kidney and chronic lead-poisoning, in type-setters, painters, etc., is also incontestable. It is also a remarkable circumstance, and one not yet fully explained, that in these cases we very often see at the same time a genuine gout (*arthritis uratica*). Gout, however, alone, without any co-existing chronic lead-

poisoning, often leads to the development of contracted kidney, "gouty kidney," in which we probably have to do with the noxious action of an abnormal amount of uric acid on the renal parenchyma.

Infectious influences are, probably, first to be considered in those cases where the contracted kidney can be referred to a former infectious nephritis, as after scarlet fever. We may also mention here the appearance of contracted kidney sometimes observed after severe acute articular rheumatism. We may perhaps imagine a similar connection in the cases where contracted kidney is found combined with chronic endocarditis (valvular heart disease), or with chronic arthritis not of gouty origin. Of the chronic infectious diseases, which may probably sometimes have a connection with the origin of contracted kidney, we may mention malaria and syphilis. The latter ought especially to be considered more than it is at present, because we may have either an immediate action of the syphilitic poison, or a renal atrophy as the result of specific disease of the renal arteries.

We must here spend a little time in the general consideration of the connection between renal contraction and primary disease of the vessels, which has been much discussed. It is true that we often find general arterio-sclerosis, and also atheroma, especially in the renal arteries, in the bodies of persons who have died from contracted kidney, but this frequent coincidence can not be remarkable in such cases, because contracted kidney is seen chiefly in advanced age, and in those persons in whom atheroma of the arteries is also a very common symptom. The theory advanced by the English authors, Gull and Sutton and others, that the vascular disease, "arterio-capillary fibrosis," always represents the primary process, to which the renal atrophy is only secondary, is, however, utterly untenable. We often find the most pronounced contraction of the kidneys without any vascular changes sufficient to explain the atrophy; and where the latter can be found in the small renal arteries, we usually have not a primary but a secondary process—namely, the well-known obliterating arteritis, which is seen in almost all chronic inflammations and degenerative atrophies of various organs.

Of course, it can not be denied that under some circumstances primary vascular diseases of the renal arteries may lead to secondary atrophy in circumscribed spots by checking the blood-supply to certain parts of the tissue—"vascular contracted kidney"—just as indurated myocarditis arises after primary arterio-sclerosis of the coronary arteries. The "senile kidney"—that is, the granular kidney of old people—is also due to vascular changes like atheroma, as are also, which is worthy of special note, the rare cases of unilateral contraction of the kidney, which is observed chiefly in syphilis.

The relation of contracted kidney to amyloid disease of the kidney, and to chronic diseases of the urinary passages, especially of the pelvis of the kidney, will be spoken of later in the appropriate chapters.

**Pathological Anatomy.**—In the genuine contraction of the kidney, both kidneys are always diminished in about the same degree. Their size is sometimes reduced to one half or even one third of the normal, so that it is almost difficult to find the little kidney in the very abundant and thick fatty capsule that is often present. The kidneys feel firm and dense, and show on their surface a very plain, coarse or fine, uniform or irregular, granulation. On pulling off the somewhat thickened fibrous capsule, these granulations become more prominent, and the capsule usually adheres quite firmly to the depressed portions. The raised portions are almost always darker and redder—that is, richer in blood—than the lighter and grayer depressions. Whether the whole kidney appears more red or more white depends only upon the amount of blood in the organ, and there is no reason for separating the "small red" from the "small white" contracted kidney.

On section of the contracted kidney, we find the cortex much smaller, and pale

atrophic streaks alternating with the darker portions. The pyramids are also somewhat smaller, and, as a rule, are darker than the cortex. In the pelvis of the kidney, which is often somewhat dilated, there are frequently a number of uric-acid concretions. Striated uric-acid infarctions in the pyramids are a very characteristic mark of the gouty contracted kidney. The microscope shows an advanced destruction of the renal parenchyma, which is replaced by a cicatricial connective tissue which is still granular or which has begun to be poor in granules. We can always make out signs of degeneration and atrophy of the epithelium, and the formation of casts in the uriniferous tubules which still remain, but which are always diseased. Atrophy, thickening of the capsule, etc., are found in many of the glomeruli. The uriniferous tubules that are still preserved in some places are often in part dilated. We can not here go more fully into the manifold histological details, especially the formation of cysts, the changes in the vessels (*vide supra*), the deposition of lime-salts, etc. Hæmorrhages are only very rarely present.

Thus the contracted kidney may be regarded as the form of chronic nephritis with by far the longest course (lasting from three to five years, and even much longer), and also the form with the widest extent. Its essential nature can in no way be contrasted with "chronic parenchymatous nephritis" as a "chronic interstitial nephritis"; for we always find interstitial processes in the former, which have reached a far higher degree in the contracted kidney only because the slow atrophy of tissue is compatible with a much longer duration of life, and hence can attain a much greater extent.

The anatomical changes in the other organs of the body beside the kidneys will be spoken of in connection with the symptomatology of contracted kidney.

**Clinical Symptoms.**—Except in the comparatively rare cases where we can refer the origin of a contracted kidney to a previous acute or chronic nephritis, the clinical symptoms of contracted kidney develop as gradually and unnoticeably as the anatomical process itself. There is no doubt but that a contraction of the kidney may exist for years, without calling the patient's attention to his disease by a single serious subjective symptom. This follows in part from the chance discoveries on autopsy of a contraction of the kidney in people who have lost their lives in some other way, but especially from the cases where the severest symptoms, like uræmia, cerebral hæmorrhage, etc., which often lead immediately to death, suddenly come on in persons previously regarded as perfectly healthy, while the autopsy often shows quite a far advanced contraction of the kidney as the special cause of these symptoms. The less prominent the subjective symptoms of renal contraction are in the earlier stages of the disease, the more we should consider the objective changes, which in fact usually permit the diagnosis of the disease quite early on careful examination of the patient.

The condition of the urine is most important in this respect. As soon as changes have taken place in the epithelium in different parts of the kidneys, the results previously spoken of must make themselves manifest in the secretion of the urine, although still in a slight degree, and the diseased patient will secrete a urine diminished in amount and in solid constituents, but containing albumen. Since, however, many normal uriniferous tubules and glomeruli are still present, and since the whole process, as we have seen, develops only very slowly, the body gains time for the formation of one of those judicious compensatory contrivances which we recognize in so many pathological processes, and which we must regard in a teleological sense. This compensatory process consists of an increase in the arterial pressure, coming on as gradually as the renal contraction itself, and constantly increasing, and of a hypertrophy of the left ventricle dependent upon it. The blood therefore courses through the many normal glomeruli of the contracting kidney under an increased pressure, and the consequence is that in these portions

the secretion of the urine, especially of the water, is much more abundant. This is the reason why, as a rule, in contraction of the kidney, the patient passes an abnormally large amount of urine, which is more watery, and therefore lighter and of a lower specific gravity, and which contains only a slight amount of albumen coming from the diseased portions. The daily amount of urine is often seventy to a hundred and twenty ounces (2000-3500 c. c.) or more; the urine looks light-yellow and clear, contains scarcely any morphological constituents, has a specific gravity of 1010-1005 or even lower, and gives, on heating, only a slight precipitate of albumen, the amount excreted in the twenty-four hours being about half a drachm to a drachm (two to five grammes). On careful microscopic examination of the urine, we usually succeed in finding a few hyaline casts, which only exceptionally may be more abundant. The urine also frequently contains some white, and more rarely a few red blood-corpuscles. In rare but definitely attested cases it may happen that for a time, or even during the main part of the disease, the urine contains no albumen at all, or only a trace of it. This is probably explained by the fact that the diseased glomeruli have wholly ceased secreting, and that therefore the urine is secreted only by the healthy portions of the kidney.

It is apparent of how great significance this abundant secretion of water, as a result of the abnormally high blood-pressure, must be for the whole morbid process; for, in spite of the renal disease, there is now absolutely no retention of water in the body, and we therefore understand why there is no oedema in contracted kidney, even after a course of years. The secretion of the solid constituents of the urine is not quite in such a favorable condition as the secretion of water. It is self-evident that the percentage of the former decreases with the increased amount of urine, but the whole amount of urea, uric acid, phosphoric acid, etc., eliminated is also at times somewhat less than normal in relation to the food. This diminution, however, is not very great, as long as the work of the heart is sufficient, and at certain times, especially in the earlier periods of the disease, it may certainly be entirely absent. We accordingly see that the symptoms dependent upon an accumulation of the urinary constituents in the blood do not appear at all for a long time. Thus it happens that the patient may still feel perfectly well up to a time when the objective examination of the urine discovers marked pathological changes. Many patients, of course, notice the polyuria, but often no further attention is paid to it, and it is attributed to drinking a good deal of fluid. The patient gets accustomed to it, even if, as often happens, he has to pass his urine much more frequently than formerly, and even during the night.

We need not go into detail here in regard to the special causes of cardiac hypertrophy (compare page 834). It was with regard to contracted kidney that Traube advanced his mechanical theory of cardiac hypertrophy, which, however, brought up the considerations previously mentioned, and therefore was properly replaced by the chemical theory, which was also very applicable to this form of renal disease. In its clinical relations it is especially important that the cardiac hypertrophy causes no subjective symptoms at all, as long as the heart can suffice for the work put upon it without strain, a condition which is perfectly analogous to that of any fully compensated valvular disease. We can usually recognize the condition correctly only by a careful physical examination of the heart and the vascular apparatus, although in contracted kidney the percussion and palpation of the heart are often rendered difficult by a co-existing pulmonary emphysema. We can often perceive, however, the displacement and the increased strength of the apex-beat, the extension of the cardiac dullness to the left, and almost invariably the abnormal tension of the radial pulse, and the accentuation of the aortic second sound. In the later stages of the disease a hypertrophy of the right ventricle is often added to that of the left (compare page 853). Complete, or almost complete,

absence of the cardiac hypertrophy is observed, as we have said, in weak and cachectic patients.

As long, therefore, as the high arterial pressure kept up by the cardiac hypertrophy regulates the condition of the renal secretion in the way above described, the condition of the patient as a rule shows no special abnormality. At most it happens that certain cerebral symptoms now appear, especially attacks of headache and occasional vertigo, which are probably to be referred to active cerebral hyperæmia. Frequent nose-bleed is also sometimes the result of the abnormally high blood-pressure.

The picture is quite different as soon as the first signs of a beginning cardiac insufficiency appear. Here, as in most diseases of the heart, the disturbance of compensation does not usually come on suddenly. Its results begin quite gradually, disappear for a time, to come on afresh and to increase quite slowly. In the first place, the abatement of the heart's energy usually makes itself manifest by symptoms on the part of the heart itself, and of the lungs. The pulse loses in tension, and becomes smaller, more frequent, and sometimes a little irregular toward the end of the disease. The patient begins to be short of breath, comparatively slight physical exertion affects him more than formerly, and there is often palpitation. Certain anatomical results of stasis may also temporarily or permanently develop in the lungs, especially a mild transitory catarrh, or a more obstinate and recurring bronchitis. In the more advanced stages of the disease the dyspnoea often comes on in pronounced paroxysms, which have an asthmatic character. This long-known asthma of renal disease, often termed, without reason, "uræmic asthma," does not always have the same origin. It usually depends distinctly upon the attacks of cardiac weakness, and is, accordingly, a genuine cardiac asthma, and corresponds precisely to angina pectoris in its different symptoms (see page 318); but in other cases there is a transudation into the lungs from stasis, coming on as a result of the cardiac weakness, so that the dyspnoea is associated with the signs of an acute pulmonary oedema, and is sometimes accompanied by a copious expectoration of a frothy, serous, and often somewhat bloody sputum. This is the condition which may pass away again and be often repeated, which was formerly termed humid asthma. In the last stage of the disease the dyspnoea often becomes continuous, and forms the patient's chief disturbance. It is then usually due, not merely to the stasis in the lungs, but often, besides, to co-existing lobular pneumonia (*vide infra*), to hydrothorax, etc.

As a further sequel of the disturbance of compensation, oedema often appears in different parts of the body, in the later course of the disease. It has, indeed, been repeatedly observed that dropsy may be entirely absent in contracted kidney; but this is the case only when death ensues from some intercurrent attack before the pronounced cardiac insufficiency. Otherwise oedema is by no means rare in contracted kidney. It usually appears first in the ankles, the eyelids, or the prepuce, disappears again when the patient is in a quiet condition, and, after a longer or a shorter pause, comes on anew, until finally, in the last period of the disease, a high degree of general dropsy may develop.

Among the results of the cardiac insufficiency on the internal organs we must first mention the cerebral symptoms. While at first, as we have said, these have more of an active hyperæmic character, the frequent and very violent headaches that come on later, in so far as they are not of a uræmic nature, certainly depend mainly upon the passive hyperæmia of stasis, or the arterial anemia of the brain. The pain sometimes shoots into the back of the neck, and sometimes is localized chiefly in one half of the head; it is often associated with symptoms of vertigo, with a gloomy or morose disposition, with troubled sleep, etc. The stasis is also apparent in the abdominal organs. Chronic dyspeptic disturbances appear, the appetite fails, the bowels become

irregular, and we can even make out a moderate enlargement of the liver. The influence which the altered activity of the heart exerts upon the function of the kidneys themselves is, however, particularly important. From what has been previously said of the dependence of the secretion of urine upon the arterial pressure, it follows directly that any compensatory activity of the still normal renal territory must at once experience a reduction, as soon as the blood-pressure can no longer be kept at the same level. Corresponding to this we see, in fact, that the secretion of urine also usually suffers a decline at the same time with the other symptoms of stasis already mentioned. The amount of urine is less abundant: it falls to forty or fifty ounces (1500-1000 c. c.), and even lower; the specific gravity rises, rarely to a high figure, but still up to 1010 or 1012, or over. The urine often retains its clear color for quite a long time, but may finally more and more resemble the genuine urine of stasis. The point, however, which is especially to be considered, is the co-existing and increasing retention of the solid constituents of the urine in the blood, and the consequent allied possibility of the onset of uræmic symptoms.

It must be stated that, in contracted kidney, the immediate exciting causes of uræmia are not always clear. Thus, it is a well-known and very important fact, clinically, that very severe and often fatal uræmic convulsions may sometimes attack the patient quite suddenly, apparently when in the best of health. Cases have been repeatedly seen, by other observers and by ourselves, where the daily amount of urine has shown no discoverable diminution in the days preceding the uræmia. The precise explanation of these cases must remain undecided; we do not know whether there has been a previous retention of the solid constituents, in spite of the abundant secretion of water, or whether other changes, like œdema of the brain, are to be considered. It is certain, however, that in many cases at least, the onset of the uræmia is connected with the cessation of the secretion of urine, produced either gradually or suddenly by the cardiac insufficiency. In the former case the type of chronic uræmia (see page 829) develops with especial frequency; this consists of headache, vomiting, diarrhœa, severe pruritus of the skin, etc., but these symptoms are, of course, often combined with the immediate symptoms of stasis, and are not always to be easily and distinctly separated from them. Such a condition of chronic uræmia, in patients with contracted kidney, often presents a very mournful picture, since the unrestrainable and constantly recurring vomiting, the headache, and the general mental anxiety may last for weeks. The severe acute uræmia either follows the preceding chronic uræmic symptoms, or comes on at once with the severest symptoms, general and often-recurring convulsions, and coma. The uræmia may pass off again, even in contracted kidney, but quite frequently it is the immediate cause of death (*vide infra*).

Beside the symptoms so far described, we must now mention a set of anatomical complications which may appear in the course of contraction of the kidney. From its diagnostic and clinical importance the albuminuric retinitis, already known to us from the preceding chapter, takes the first place. It may come on at any time in the course of the disease; but it often develops so early that the patient, up to this time, knows nothing at all of his other disease. He merely consults an oculist, who often first recognizes, from the ophthalmoscopic picture (see page 854), the special seat of the primary disease. Even in the cases where no subjective visual disturbance is present, the retinal examination sometimes shows a positive image. In general, the contracted kidney is that form of renal disease in which retinal changes are comparatively the most frequent.

Another rarer but clinically important complication consists of the hæmorrhages of internal organs, whose cause is to be found either in the increased arterial pressure, or in an abnormal weakness of the walls of the vessels—arteriosclerosis in older persons, defective nutrition of the vascular walls in young and

anæmic patients. Hæmorrhages into the brain are comparatively the most frequent. They cause both mild and severe apoplectic attacks, which pass off completely or leave a hemiplegia behind, and sometimes they are the direct cause of death. Beside the hæmorrhages into the brain itself, there may also be hæmorrhages on the inner surface of the dura mater—hæmatoma. Nose-bleed is also of significance; in many patients it is frequent and very stubborn; we have ourselves seen two cases where the fatal termination was caused directly by an unrestrainable nose-bleed. Hæmorrhages into the other organs are more rare, but they have also been observed in the skin, the stomach, the intestines, or the lungs. In a few cases, indeed, a sort of hæmorrhagic diathesis seems to develop.

Among the complicating inflammations of internal organs, pneumonia is the most frequent; it appears in the lobar croupous form or in the lobular form peculiar to all varieties of nephritis. Inflammations of the serous membranes, pleurisy, or pericarditis, occur, but they are rare. The catarrhal inflammatory affections—laryngitis, bronchitis, gastric catarrh, intestinal catarrh—are either to be regarded as catarrhs from stasis, or they are perhaps connected with the retention of the urinary constituents in the body. We must also refer here to the acute exacerbations of inflammation in the kidneys themselves (acute recurrent nephritis), which is, of course, rare.

Quite great variations appear in regard to the general nutrition. In most cases where the disease develops quite gradually in persons in middle or advanced life, the general nutrition for a long time shows no striking anomaly. The patient is often very well nourished, and even corpulent, at the period when the first cardiac symptoms begin. To the more practiced and attentive eye, of course, he shows a certain appearance of suffering, which later becomes more pronounced. He becomes emaciated, and has a faded and often somewhat cyanotic color to his skin. Marked anæmia usually develops only in younger patients, who then show the pallid exterior characteristic of so many patients with renal disease.

**General Course, Duration, and Termination.**—The most important peculiarities in the course of renal contraction have already been spoken of above. We have stated that the disease may be latent for a long time; that the severest symptoms—like uræmia or apoplexy—sometimes come on suddenly and unexpectedly; that in other cases the disturbances of compensation in the heart, dyspnoea, palpitation, or slight œdema, are the first symptoms; that, under some circumstances, certain complicating conditions, such as retinitis, or frequent nose-bleed, first direct suspicion to a renal disease, and demand an examination of the urine; while, finally, in a last class of cases, only general disturbances, loss of appetite, pallor, general physical weakness, and similar symptoms induce the patient to consult a physician. It is usually hard to decide how long the disease has lasted before a diagnosis is made. Beside any mild symptoms we must especially inquire into the existence of polyuria, which is often not observed, but which many patients notice.

The further course may also vary according to the onset of complications, the external conditions under which the patient lives, etc. In general, as we must repeatedly emphasize, almost everything depends upon the heart's capacity for work and its staying qualities. If death does not ensue sooner from some intercurrent disease, the last stage of the disease almost always presents itself under the picture of cardiac insufficiency with predominant symptoms of dyspnoea and general dropsy.

As has been said, we usually can not determine with any accuracy the whole duration of the disease. It may, at any rate, last many years, probably sometime even ten years or more, although there may be many variations in its course. It is not impossible that, during the earlier period of the disease, there may be a cer-

sation in the process of renal atrophy, but it is hard to decide with certainty. At all events, the disease must generally be termed completely incurable, although life may not only be preserved for a long time, but the patient may even exist without much discomfort. We need not refer especially here to the different intercurrent attacks, the possibility of which must always be kept in mind in regard to prognosis.

**Diagnosis.**—The diagnosis of contracted kidney can be made with certainty only by examining the urine. We must, therefore, dwell again on the necessity of making this examination in all suspicious cases, because only in this way can we avoid overlooking the condition. The suspicion of a developing renal contraction should demand an examination of the urine, especially in all cases where the patient complains of frequent headache, of congestive conditions, of palpitation and dyspnoea, asthmatic attacks, disturbances of vision, general dullness, and dyspeptic symptoms, without finding any other reason for these symptoms. The polyuria, the clear urine of low specific gravity, containing a slight amount of albumen, in connection with the signs in the circulatory apparatus, the tense pulse, and the hypertrophy of the left ventricle, permit us to recognize the disease correctly in most cases. If retinal changes are present, they may sometimes be of much aid in confirming the diagnosis. The aetiological conditions—lead, gout, alcoholism, etc.—of course also merit attention.

The diagnosis presents great difficulty in the quite rare cases where albuminuria is absent. In these cases we are sometimes able to reach the correct interpretation of the morbid condition only by repeated examinations of the urine. Otherwise we can scarcely avoid mistaking it for chronic affections of the heart, such as myocarditis or idiopathic hypertrophy.

The diagnosis is also very difficult if the patient does not come under observation until the stage of fully developed disturbance of compensation. The characteristic features of the urine of contracted kidney are then absent, the urine is scantier, darker, richer in albumen, and it is often scarcely possible to decide whether we have a primary renal affection with secondary cardiac hypertrophy or a primary heart disease with a secondary congested kidney. If general arteriosclerosis or marked pulmonary emphysema is present at the same time, the judgment as to the condition is still more difficult. In such cases a correct diagnosis is possible only by very carefully balancing all the different symptoms, and considering the whole course of the disease.

Finally, the diagnosis of contracted kidney is very difficult in cases where the first examination of the patient is made during a sudden attack of uræmia or after an apoplectic seizure. Here the albuminuria is the symptom which points most to the existence of a renal disease, although, in spite of this symptom, the judgment as to the condition, and its differentiation from other acute cerebral affections, often presents great difficulties.

**Treatment.**—As soon as the diagnosis of renal contraction is established, the whole hygienic condition of the patient must be regulated so as to prevent the advance of the affection in every possible way. In this respect two indications are to be fulfilled, to guard against any irritation which may have an injurious action on the kidneys, and to relieve the work of the heart as much as possible, in order to keep off cardiac insufficiency as long as we can. The diet must be carefully regulated, and must be of scant measure or abundant and strengthening, according to the patient's physical constitution. In these cases, too, milk is the chief food to be considered. Alcoholic beverages are to be permitted only in a moderate degree. All physical over-exertion is to be avoided, although moderate methodical exercise is to be recommended for corpulent patients. We should always provide for regular evacuation of the bowels by appropriate remedies,

dietetic prescriptions, fruits, bitter waters, etc. The general condition is often materially improved by proper air and recreation, and in this way the use of a bath may be of service, chosen according to the individual conditions, such as iron baths, Marienbad, Carlsbad, Kissingen, Ems, or Baden-Baden.

If disturbances of compensation appear, the dietetic *régime* and the utmost bodily rest possible are still more strictly to be advised, and a symptomatic treatment should be instituted according to the prevailing symptoms. First of all we must try to excite the heart's energy anew by the exhibition of digitalis. The details of treatment here are almost precisely the same as are considered in the treatment of chronic heart disease (*q. v.*) and the other renal affections. [The nitrites, especially nitroglycerine, are of great service in some cases of contracted kidney, and may be used persistently when the arterial tension is unduly high, and the compensatory hypertrophy of the left ventricle shows signs of failing. In these cases strophanthus, which is said not to increase arterial tension, may at times be substituted for digitalis with advantage.]

At present it is impossible to influence the process of contraction in the kidney favorably by the direct use of drugs. The iodine preparations—iodide of potassium, and in anæmic patients iodide of iron—are alone recommended, and are worth trying in this respect.

The prophylaxis of renal contraction is evident; we should consider as far as we can the known ætiological conditions. We may compare, in this regard, the chapter on gout.

## CHAPTER V.

### AMYLOID KIDNEY.

**Ætiology.**—The amyloid kidney is invariably a part of the more or less extensive amyloid degeneration of the organs in the rest of the body. In its clinical relations, however, it claims the most interest of all amyloid diseases, since it has by far the greatest significance for the whole clinical picture of amyloid degeneration.

As is well known, we understand by amyloid degeneration a peculiar change which, under certain pathological conditions, is observed in the connective tissue, and especially in the smaller vessels. The walls of the vessels are thicker, they have a lustrous, homogeneous appearance, and they show peculiar reactions on treatment with certain coloring agents. These reactions are due to the presence of an albuminoid substance—amyloid—which is either deposited in the tissue from the blood, or, as is much more probable, is developed in that place and spot from the albuminoid substances present. In marked amyloid degeneration the diseased organs often show macroscopically an altered, "bacon-like" appearance, and assume a characteristic red-brown color on treating the affected parts with Lugol's solution of iodine. The microscopic examination alone affords more accurate conclusions as to the presence and distribution of the degeneration. Here we make use chiefly of staining the tissues with methyl-violet or gentian-violet. The amyloid portions thus take on a very characteristic and easily defined red color. In this way we can discover that the amyloid degeneration begins everywhere in the walls of the small vessels, that the interparenchymatous connective tissue may also be affected later, but that the parenchymatous cells proper, liver cells, renal epithelium, etc., almost always remain perfectly free. The latter often show atrophic and fatty degenerative changes (*vide infra*), but never amyloid degeneration.

Nothing is known as to the special causes which effect that peculiar metamorphosis of the albumen of the connective substance into amyloid. We know only that there are a number of primary diseases in which it is known empirically that amyloid degeneration quite frequently develops as a secondary condition in the

different organs. These conditions have mainly the common feature that they go along with a general cachexia and weakness of the body. The following conditions (arranged in about the frequency of the occurrence of amyloid degeneration) are the special ones in which amyloid degeneration in general, and therefore amyloid kidney in particular, are chiefly observed :

1. Chronic pulmonary tuberculosis, particularly the ordinary ulcerative phthisis. Tubercular ulcers of the intestines, with or without co-existing marked pulmonary tuberculosis, may also lead to amyloid disease.

2. Long-continued chronic suppuration in the bones or soft parts, especially chronic fungous processes with fistulæ into the bones or joints, empyema with fistulæ, vertebral caries, etc.

3. Constitutional syphilis, chiefly the cases with ulcerative and usually tertiary processes in the bones and mucous membranes.

4. Other ulcerative processes or processes associated with chronic suppuration: saccular bronchiectases, chronic intestinal ulcers (for example, of dysenteric origin), purulent pyelo-cystitis, vesico-vaginal fistula, ulcerated new growths, like cancer, etc.

5. In rare cases amyloid has also been observed in other chronic diseases, as in malaria, gout, and other chronic articular affections. In the medical clinique here at Leipsic we once saw a case of marked amyloid kidney in a girl of twenty-one with aortic insufficiency.

6. Finally, in a small class of cases, of which we have ourselves seen some examples, no discoverable cause at all may be found at the autopsy for a usually quite extensive amyloid degeneration. In these cases there accordingly seems to be a primary amyloid disease.

**Pathological Anatomy.**—Since the text-books on pathological anatomy have been referred to in regard to the anatomical conditions of amyloid in other organs (compare also page 498), we must here describe in detail only the pathological anatomy of amyloid kidney.

In very slight and not extensive amyloid degeneration in the kidneys the latter present a perfectly normal appearance to the naked eye. Careful microscopic examination alone shows amyloid degeneration of the walls of different vessels in the cortex, and especially in the medullary substance.

The commonest and most characteristic form of amyloid kidney is the so-called large white amyloid kidney (waxy kidney, lardaceous kidney). The kidney is usually enlarged, and the surface is smooth and of a grayish-white or yellowish color, and usually somewhat mottled. On section, the cortex is wider and also of a yellowish-white color, and the glomeruli may often be recognized with the naked eye as dull, lustrous, translucent points. Hemorrhages are scarcely ever seen. The medullary substance is either also pale or darker. In many cases the cortex may also have a darker reddish or mottled appearance, which is due merely to the greater amount of blood in the organ. The pale-yellow color is due either to the anemia or to the fatty degeneration, while the amyloid spots show a more translucent character with a bacon-like luster.

If we examine the kidney microscopically, we find first the amyloid degeneration, which, in varying extent and combination, affects most frequently the glomeruli and also the capillaries of the cortex, the vasa recta, and sometimes the membrance propria of the uriniferous tubules. In pure amyloid kidney the rest of the renal tissue is normal, but in many cases we also find changes in the epithelium, fatty degeneration, desquamation and disintegration, and also not infrequently interstitial cellular infiltration.

Thus amyloid degeneration is often combined with degenerative inflammatory changes in the kidneys. If the process has lasted for a long time, it leads, as in

ordinary nephritis, to a complete atrophy of tissue in some parts, with a corresponding increase of connective tissue. Then the renal tissue sinks in at the affected parts, and there is a decided unevenness to the surface of the kidney. There is even a completely developed red or white contracted kidney, in which we find abundant amyloid, and which is, therefore, termed amyloid contracted kidney. In this form the parenchymatous and interstitial changes correspond precisely to those in ordinary contracted kidney, only the amyloid degeneration is added to them.

At present differences of opinion prevail as to the precise connection between amyloid and the inflammatory degenerative processes in the kidney. Probably we have an actual combination of both conditions, sometimes perhaps even co-effects of the same cause. For since genuine nephritis, as well as amyloid kidney, occurs, as we have seen, in syphilis, tuberculosis, and other diseases, it can not be remarkable that in these diseases both sequelæ, nephritis and amyloid, develop side by side, and that we may, therefore, find at the same time, beside the changes of an inflammatory large white kidney, of a secondary contraction, or of a genuine contracted kidney, a more or less extensive amyloid degeneration in the kidneys. On the other hand, it, of course, can not be questioned that the disturbance of circulation, which must arise in consequence of a marked amyloid of the vessels, is of influence on the nutrition of the renal tissue, and that, therefore, many changes in it, especially fatty degeneration of the epithelium, are, under some circumstances, the direct result of the amyloid disease.

**Clinical History.**—If we consider the great differences which the distribution of the amyloid in the kidneys shows, and its manifold combinations with inflammatory processes, it is clear from the outset that we can not set up a uniform picture of the symptoms of amyloid disease in general. To this we must add that the symptoms of amyloid disease, which is almost always a secondary condition, are also modified in various ways by the primary disease.

We must first state that many cases, where the amyloid in the kidneys is of comparatively slight extent, can not be recognized by any clinical symptom. The albuminuria in particular may be entirely absent, as has been repeatedly proved (Litten and others), which is perhaps due to the fact that in such cases the vasa recta and not the glomeruli are chiefly affected by the amyloid degeneration.

Except in these cases, however, the urine secreted from the amyloid kidneys shows marked changes, which, of course, present quite great variations according to the form of the individual case. The amount of urine is most frequently about normal, or somewhat diminished—in some cases much diminished—but in others it is decidedly increased, so that the patient may pass eighty to a hundred and twenty ounces (2500–3500 c. c.) in the twenty-four hours. We quite frequently see considerable variations in the amount of the urine in the same patient at different times. All these differences are easily explained if we remember how many circumstances may act on the amount of urine—the presence or absence of inflammatory changes in the kidney, the presence or absence of cardiac hypertrophy, co-existing perspiration, diarrhœa, œdema, fever, etc.

The color of the urine is almost always light yellow. Only exceptionally, in amyloid nephritis, does it contain an abundant sediment; usually it is entirely, or almost entirely, clear. The very considerable amount of albumen in the urine, which is often one or two per cent., is also characteristic of amyloid kidney. In many cases, of course, especially in amyloid contracted kidney, the amount of albumen is but slight. It sometimes, but by no means regularly, happens that the urine in amyloid kidney contains a comparatively large amount of paraglobuline beside the ordinary serum albumen (Senator).

The specific gravity of the urine varies very much according to the amount

of water and albumen in it. It may be increased (1015-1020) or diminished (1010-1003).

If we examine the urine under the microscope, we usually find only a few hyaline casts, and also most frequently a small number of white blood-corpuscles. In the combination of amyloid with more marked nephritic changes the sediment is more abundant, so that the urine is cloudy. The microscope then shows more numerous hyaline or moderately fatty casts, more abundant white blood-corpuscles, sometimes a little renal epithelium, and in quite rare cases even red blood-corpuscles. Amyloid reaction occurs in the casts, but it is very rare, and therefore of no value in diagnosis.

The other morbid symptoms which are observed in amyloid kidney depend either upon the change in the kidneys themselves, or upon co-existing amyloid degeneration in other organs; or, lastly, upon the primary disease. The symptoms of the latter are, of course, extremely varied, but in many cases they may be entirely subordinate.

In regard to the directly resulting symptoms of amyloid kidney, their occurrence is of interest, especially in comparison with the analogous conditions in acute nephritis. Dropsy of a moderate, or even a severe degree, is often present in amyloid kidney, but it may also be entirely absent. We must remember that an oedema independent of a renal affection may be produced by marantic venous thrombosis. Uræmic symptoms are distinctly rare in amyloid kidney, but they are sometimes observed, especially in their milder forms, such as vomiting. It is a very important point that a hypertrophy of the left ventricle is absent in most cases of amyloid kidney. This is because we have weak and cachectic individuals, in whom a cardiac hypertrophy can not develop for lack of an excess of nutritive material. Where there is no debility, a cardiac hypertrophy may doubtless develop, as we see especially in amyloid contracted kidney. At the autopsy we often find the heart, of course, in a condition of brown or simple atrophy.

Albuminuric retinitis hardly ever appears in pure amyloid kidney. In the amyloid contracted kidney it has sometimes been observed, however, in cases where there has probably been originally a pure contracted kidney, with amyloid coming on later. The secondary inflammations in the internal organs, such as renal pneumonia, and the hæmorrhages, like cerebral hæmorrhage, are also rare.

The patient's general condition is also dependent in part upon the renal disease, but usually upon the primary disease. The patient with amyloid kidney is usually correspondingly cachectic, and shows in high degree a pallid, anæmic color of the skin. In some cases, however, such as syphilis, bronchiectasis, or unilateral contraction of the lung, the condition of the nutrition may remain tolerably good for a long time.

The symptoms which point to a co-existing amyloid degeneration in other organs beside the kidneys are of great diagnostic significance. The symptoms in the liver (enlargement, abnormal firmness, and a hard, sharp lower edge to the organ), the spleen (enlargement and hardness), and intestines (diarrhoea) are clinically important in this respect. The explanation of the diarrhoea is, of course, usually difficult, since it may often depend upon tubercular intestinal ulcers as well as upon amyloid of the intestines.

We can scarcely make more general statements in regard to the whole course and the duration of amyloid kidney, since the form of the primary disease is to be especially considered in these cases. In regard to the time that it takes for an amyloid degeneration to develop in an existing primary disease, the degeneration is certainly present sometimes after a few months. Of course, it is hardly ever possible to determine its onset accurately, since the first beginnings of amyloid degeneration in the kidneys do not usually permit themselves to be recognized at

once by the appearance of albuminuria (*vide supra*). The duration of amyloid kidney varies very much according to the severity of the case; it may last only a few weeks or months until death, while other cases have certainly lasted for a year, especially in amyloid contracted kidney.

The **prognosis** of amyloid kidney is in most cases utterly unfavorable, which is due mainly to the incurability of the primary disease; but trustworthy observers have repeatedly proved that, when the primary disease is curable, as with syphilis and many chronic suppurations, an already developed amyloid kidney *can* be completely restored.

The **diagnosis** of amyloid kidney can be made with quite great certainty when the evident signs of a renal affection are added to those diseases which we know empirically often give rise to the development of amyloid degeneration. Whether in such cases we have a pure amyloid or a pure nephritis, or a combination of the two, can be decided with some certainty only from the condition of the urine: a clear urine, containing but few morphological elements, but rich in albumen, points to amyloid, while a large number of casts and red and white blood-corpuscles in the urine, point to the presence of inflammatory changes in the kidney. A very characteristic symptom of many cases of amyloid kidney, and one that is therefore of diagnostic value, is the rapid and frequent change in the amount of the urine and in the amount of albumen in it (Wagner). An accurate diagnosis of the anatomical changes, however, is hardly ever to be made with certainty, and at most can be made only by attention to the whole course of the disease.

A very material support for the diagnosis of amyloid kidney, and therefore one which should always be looked for, is the discovery of amyloid in other organs. We have briefly mentioned above the most important symptoms in the liver, the spleen, and the intestines referable to this point.

**Treatment.**—Only the treatment of the primary disease can, of course, be considered, both as a prophylactic and also as a causal indication. In many surgical cases, and also in the cases of amyloid in syphilis, there is a possibility of this (as by iodide of potassium); but otherwise we try to improve the primary disease as far as is possible.

In other respects the treatment is purely hygienic and symptomatic. We must try to strengthen the patient as much as possible by good food and the exhibition of preparations of iron and quinine. The use of iodide of iron is to be recommended. In a symptomatic point of view the same remedies are used as in other renal diseases.

## CHAPTER VI.

### PURULENT NEPHRITIS AND PERINEPHRITIS.

(*Renal Abscess.*)

**Ætiology.**—Although in the forms of nephritis so far described the occurrence of interstitial accumulations of granular matter has been repeatedly mentioned, none of them ever come to genuine suppuration—that is, to a purulent liquefaction of tissue, a true abscess-formation. The origin of a purulent nephritis is, rather, always associated with the entrance of perfectly definite morbid irritants into the kidneys. These are invariably organized and their special peculiarity is to excite a purulent inflammation.

There are two chief ways through which the morbid irritants may reach the kidneys—the arterial blood-current and the urinary passages. The first-mentioned

means of entrance is to be considered in all the cases of purulent nephritis which come on as one symptom of pyæmic processes and certain forms of ulcerative endocarditis (see page 112 on the point). Far more rarely purulent nephritis develops in this way as a complication in other diseases, such as dysentery. Purulent nephritis also occurs in actinomycosis (Israel).

The excitants of inflammation take the second path in those cases where a purulent nephritis follows an inflammation of the lower urinary passages, the pelvis of the kidney, the bladder, etc. Here the bacteria, which almost always enter directly into the urinary passages (the urethra and bladder) from without, pass gradually upward from the bladder through the ureters to the pelvis of the kidney; from this they enter the apertures of the collecting tubes and the uriniferous tubules of the kidney, everywhere exciting a purulent inflammation. We therefore term these forms of purulent nephritis—with regard to their origin—purulent pyelo-nephritis.

We must remark in conclusion that a purulent nephritis may arise in direct wounds of the kidney from infection of the wound; this is usually associated with a perinephritic suppuration (*vide infra*).

**Pathology.**—Purulent nephritis shows quite characteristic peculiarities and differences according to its mode of origin. (We omit traumatic abscesses here.)

The renal abscesses in pyæmia and analogous diseases are usually focal suppurations, which only exceptionally attain a great extent, but which are usually to be recognized with the naked eye as numerous little yellowish dots or lines, scattered over the whole kidney, about half a millimetre or a millimetre in diameter. On microscopic examination, these nodules prove to be genuine little abscesses, in whose territory the renal tissue proper is completely destroyed. In the middle of them we often find the originating colony of micrococci, the "micrococci embolus," seated in a central vessel. The conditions are still plainer if we examine the earlier stage of the process. We find vessels (the loops of the glomeruli, or the encircling capillaries), which are completely plugged with micrococci, and in whose vicinity the renal tissue is still perfectly normal. We further see analogous spots where the renal tissue is already necrosed in the vicinity of the colony of micrococci, and is infiltrated with emigrated cells. These nodules show, finally, a continuous transition to the completed abscess, which is often surrounded by a hyperæmic or even a hæmorrhagic areola.

In purulent pyelo-nephritis the renal abscesses appear somewhat different. The abscesses also have a characteristic striated appearance, corresponding to the distribution of the inflammation along the straight tubules. They often extend from the point of the renal papilla through the cortex to the surface of the organ, so that from the outside we see the abscesses, appearing through as yellowish points. The broader abscesses arise from the confluence of neighboring striæ. The microscope shows that the purulent inflammation arises from the vessels of the interstitial tissue, in whose territory the uriniferous tubules are of course destroyed. The clusters of micrococci form the most interesting feature. These settle originally in the uriniferous tubules and are the special cause of the necrosis of epithelium and the inflammation. Pyelo-nephritis, indeed, was one of the first diseases for which Klebs discovered a bacterial origin.

**Clinical Symptoms.**—We can speak very briefly here in regard to the clinical symptoms of purulent nephritis, since they can never be sharply separated from the symptoms of the primary disease. The pyæmic renal abscesses, and the abscesses in ulcerative endocarditis, hardly ever cause special clinical symptoms, so that their presence is first recognized on the autopsy-table. Since the abscesses do not usually communicate with the uriniferous tubules, there is usually not even a large amount of pus in the urine.

The clinical symptoms of pyelo-nephritis also depend less upon the nephritic abscesses than upon the previous and accompanying pyelitis and cystitis. We will therefore return to renal abscesses in the description of these diseases.

#### PERINEPHRITIC (PARANEPHRITIC) ABSCESS.

Perinephritic abscess is the name given to suppurations in the vicinity of the kidney, especially in its fatty capsule or in the peri-renal connective tissue. Apart from any traumatic origin for such abscesses, they develop most frequently as a result of purulent nephritis or purulent pyelitis. The escape of pus, which involves the surrounding tissue in the inflammation, may come from the ureter or pelvis of the kidney, or from the kidney. The special form of primary disease differs very much; it may be either simple purulent pyelitis, or pyelitis from renal calculi, or sometimes tubercular processes and new growths that finally suppurate, such as cancer, or echinococci. The peri-renal suppuration may also take its start from the other organs in the neighborhood. Thus cases have been seen in which the perinephritis followed a perityphlitic abscess, a hepatic abscess, or a psoas abscess after vertebral disease. Perinephritic suppuration may also be due to actinomycosis.

In many cases of this sort the accumulation of pus is so considerable that there is a protrusion in the lumbar region exactly like a tumor. This is at first only obscure; but later the skin becomes oedematous there, it constantly protrudes more and more, it assumes an inflammatory hyperæmic redness, until finally a definite fluctuation shows the advance of the abscess up to the skin. In other cases the inflammatory swelling extends forward into the iliac fossa; then there is also abnormal resistance and dullness above Poupart's ligament. The swelling may also extend upward toward the diaphragm, so that the diaphragm is crowded upward, giving rise to marked dyspnoea. The relations of the swelling to the descending colon are sometimes the same as in new growths of the kidney (compare Chapter VIII).

Beside the swelling, there is almost invariably a very great pain in the affected region, either spontaneous or on pressure. If the swelling presses on the large nerve-trunks in the vicinity, it produces severe shooting pains in the leg of the same side, and sometimes a numb feeling and paresis. The leg is then often kept in a position similar to that in coxitis.

The condition is almost always associated with fever, which shows the characteristic remitting or intermitting type of most suppurative fevers, and may be interrupted by occasional chills with a marked rise of temperature. The patient becomes very much debilitated and emaciated by the fever and the pain, and he may finally fall into a sad general condition. The urine contains pus only when the abscess communicates in some way with the urinary passages.

Recovery can take place only when the abscess is evacuated through some external channel. Except for operative procedures, the spontaneous escape of pus through the skin is the most favorable; this most frequently takes place in the lumbar region, or more rarely, like a psoas abscess, under Poupart's ligament. Sometimes persistent fistulæ are left after such a rupture. The rupture of the abscess into the intestine (the colon) has also been observed, with an evacuation of pus by the bowels, and also ruptures into the bladder, the pleural cavity, and the peritoneum. We need not here discuss in detail under what circumstances death may ensue; it comes on, in many cases, after the disease has lasted a considerable time.

The diagnosis is based chiefly upon the swelling, the tenderness, the fever, and a consideration of the ætiological factors. The disease may be confused with hydro-nephrosis, psoas abscess, or solid renal tumors. The result of an exploratory puncture is sometimes decisive in such cases.

The only treatment, apart from the fulfillment of any symptomatic indications, is surgical, and consists, if possible, in opening and draining the abscess. The success depends chiefly upon the patient's general condition, and the form of the primary disease. The details are to be found in the text-books of surgery.

## CHAPTER VII.

### DISTURBANCES OF CIRCULATION IN THE KIDNEYS.

1. **The Congested Kidney.**—Although local impediments to the flow of venous blood from the kidneys, as from thrombosis of the renal veins, hardly ever attain a clinical significance, the participation of the kidneys in a general venous stasis, as it is chiefly seen in heart disease (compare page 300), pulmonary emphysema, etc., is of great diagnostic importance, since we possess in the condition of the urine quite an accurate measure of the intensity as well as of the increase and decrease of the stasis.

The congested kidney is easily recognized anatomically. The organ is often somewhat enlarged, it feels firmer than normal, and shows, both on its surface and on section, a dark, bluish-red color—"cyanotic induration." The medullary substance is usually darker than the cortex. Under the microscope we see considerable dilatation and a tense fullness of the veins and capillaries. The parenchyma is normal, but in more advanced cases it may show a beginning fatty degeneration of the epithelium, which is a result of the defective arterial blood-supply. Interstitial changes are usually absent.

The clinical symptoms of congested kidney concern only the changes in the urine. The amount of urine diminishes, corresponding to the diminution of the arterial pressure and the diminished rapidity of the blood-current. Only twenty or twenty-five ounces (800-500 c. c.), or less, are secreted daily. The urine is also more concentrated and darker than normal, and often has an abundant sediment of uric acid or urates. If nutritive disturbances have begun in the epithelium of the glomeruli as a result of stasis, the urine is also albuminous, but the amount of albumen in pure congested kidney is always slight—about one tenth to one sixth of the volume. The urine often contains, besides, a few hyaline casts, and a few white and red blood-corpuscles, the latter pointing to little congestive hæmorrhages.

If the changes mentioned come on as one symptom of a general venous stasis, and are, accordingly, often associated with cyanosis, and dropsy, the diagnosis of congested kidney can be made with certainty. If we succeed in restoring the circulation by appropriate remedies, such as digitalis, the urine at once becomes more abundant and clearer and its albumen disappears. Otherwise the symptoms of the urine of passive congestion last until the patient's death.

2. **Embolic Infarction in the Kidneys.**—Since the renal infarction, although it has great pathological interest, is hardly ever of clinical significance, we will limit ourselves here to a brief description of the most essential points.

If one of the smaller renal arteries is plugged by an embolus in heart disease, the affected portion of the organ cut off from the circulation must perish, since all the renal arteries are terminal arteries. The epithelium undergoes the well-known changes of coagulation necrosis, disappearance of the nuclei of the cells, and disintegration, and the tissue becomes entirely or in part a hæmorrhagic infarction (compare page 300). In this way arise the characteristic wedge-shaped, red, hæmorrhagic infarctions in the kidney, or far more frequently the

yellowish-gray, anemic infarctions, often surrounded by a hæmorrhagic areola, the base of which is at the surface of the kidney; the base may reach a width of half a centimetre to a centimetre or more, while its apex extends a varying distance into the cortex, or even into the medullary substance. Later on the gradually disintegrated tissue of the infarction is absorbed, round cells emigrate from without into the region destroyed, and a shrunken connective-tissue cicatrix gradually develops in place of the former infarction. Many kidneys may have such a granular surface from numerous infarction cicatrices that they may be appropriately termed "embolic contracted kidneys."

The anatomical processes just briefly described cause in most cases no special clinical symptoms at all. Only in a few cases does a slight amount of blood in the urine seem to depend on the development of a hæmorrhagic infarction in the kidneys, so that when a cause for embolic processes, like heart disease, is present, we may sometimes entertain the suspicion of the development of a renal infarction during life. In a few cases the development of a large renal infarction may be accompanied by a sudden severe pain in the renal region.

The embolic processes in the kidney never demand special treatment.

## CHAPTER VIII.

### NEW GROWTHS IN THE KIDNEYS.

Of the primary forms of tumor occurring in the kidney, two especially claim our interest: cancer of the kidney and congenital sarcoma. The latter is of great importance in regard to the general theory of tumors, since it points definitely to the development of the new growth from scattered portions of embryonic tissue. Striped muscular fibers have been repeatedly found in tumors consisting otherwise of round or spindle cells, from which the name of "*rhabdomyoma*" has been chosen for these tumors. Since there are no muscular fibers in the kidney itself, their occurrence in the tumors points undeniably to disturbances of development. This theory obtains a further interesting confirmation from our own observation of the development of left-sided, and, probably, congenital renal sarcoma in two brothers. Both children died when between two and three years of age, and the autopsy gave almost precisely the same lesion in both: numerous metastases in the liver and lungs, beside a new growth almost as large as a child's head in place of the left kidney.

Renal cancer is also remarkably frequent, comparatively speaking, in children under four years of age, and about equally common in the two sexes, although, of course, we find renal cancer in persons of more advanced years. Usually only one kidney is affected, chiefly the left, as it seems, but the new growth has sometimes been found in both kidneys. In its character, renal cancer belongs either to the denser or to the softer, medullary form. It may permeate the whole kidney and change it to a large tumor, weighing fifteen or twenty pounds (five or ten kilogrammes). Softening and hæmorrhage very often take place within the tumor. The proliferation has been repeatedly observed to extend to the neighboring parts, especially the pelvis of the kidney, and metastases also form in other organs, as in the liver or the lungs.

The clinical symptoms of renal tumor are entirely absent, or of a very indefinite nature, in the first period of the disease. Dull pain in the renal region is repeatedly given as the first symptom, but, of course, this is hardly ever of definite significance. The diagnosis almost always first takes a definite direction by the

appearance of a palpable tumor. This develops in the lumbar and lower lateral abdominal region, constantly extending from this point upward and inward. As stated above, both carcinoma and sarcoma of the kidney may cause enormous tumors, especially in children, which may make the whole abdomen protrude to a marked degree. The tumor feels dense, and either smooth or rough, and it does not move with the respiration. The relation of the tumor to the descending colon in left-sided renal tumors is not unimportant in diagnosis. Since the latter is pressed forward by the growth of the tumor, and thus gets into a position between the new growth and the anterior abdominal wall, we can often succeed in making out by percussion, and sometimes even by palpation, that the affected portion of intestine, and sometimes even a loop of small intestine besides, is drawn forward over the tumor; the percussion may vary as the large intestine is empty or full. In right-sided renal tumors analogous conditions may also be present, but they are rarer. The liver is then sometimes pushed to the left.

In many cases of renal tumor the urine shows no abnormal conditions at all, since its secretion is performed compensatorily by the other healthy kidney. In carcinoma of the kidney it sometimes presents, however, one valuable sign for diagnosis—namely, an admixture of blood. This hæmaturia often comes on very early, even before there is any tumor to be felt. It is repeated either frequently or only rarely in different cases, and sometimes it is entirely absent. The hæmorrhage is associated with colicky pains only when large clots have to pass through the urinary passages. It is a remarkable fact that in a few cases the blood, as it seems, may come from stasis in the healthy kidney, which is very hyperæmic. Sometimes, but very rarely, small particles and shreds of tissue from the disintegrated new growth may be found in the urine.

The general symptoms are often very late at first, especially in children; but finally a general condition of marasmus almost always develops. A constant and great frequency of the pulse is often striking. We must also mention the peculiar symptoms several times observed, that in girls with congenital renal tumors there is an abnormally early development of the pubic and axillary hair, and sometimes a peculiar pigmentation of the skin (Kühn). We need not mention in detail the symptoms of compression of neighboring organs by the tumor, which may develop in different ways.

The diagnosis of renal tumor may be made with quite great certainty in many cases. The position of the tumor, its immobility, its relation to the large intestine, and, especially, our general experience as to the occurrence of renal tumors in children, lead us at once to think of the correct diagnosis. In older people renal hæmorrhages, which are otherwise inexplicable, must direct our suspicions toward the possibility of a renal cancer. Renal tumors may, of course, often be mistaken for retroperitoneal glandular tumors, ovarian tumors, large psoas abscesses, or splenic tumors. The differential diagnosis must accordingly be carefully considered in every case.

The prognosis is, of course, always unfavorable. The disease sometimes lasts only a few months, sometimes a year or two, rarely longer.

The treatment must in most cases be purely symptomatic. The only expectation of success lies in the operative removal of the new growth, the details of which are to be found in the later writings on renal surgery.

## CHAPTER IX.

PARASITES OF THE KIDNEYS AND OF THE URINARY PASSAGES.  
CHYLURIA.

**Echinococcus of the Kidney.\***—Echinococcus cysts have been repeatedly found in the kidney, although much more rarely than in the liver. Usually only one kidney is affected, and the parasite is generally situated in the renal substance itself, only exceptionally between it and the capsule of the kidney. The size of the echinococcus cysts may be very considerable, the diameter reaching to twenty centimetres or more.

Clinical symptoms usually first appear when the tumor can be felt through the abdominal walls. Subjective symptoms may even then be entirely wanting. Pain on pressure develops gradually later. The tumor usually has an approximately globular shape. Its relations to the neighboring organs, especially to the colon, are the same as we have learned to recognize in the preceding chapter, in the description of cancer of the kidney. The feeling of the so-called "hydatid thrill," from a sudden impulse on the tumor with the palm of the hand against it on palpation, is characteristic of echinococcus, but, unfortunately, it is but seldom manifest.

It happens rather frequently that the sac of the echinococcus bursts into the pelvis of the kidney. Then single echinococcus cysts, or at least bits of membrane, hooks, etc., are passed with the urine, usually with severe colicky pains, which are exactly like the renal colic from the passage of a calculus. Such attacks may be often repeated, and may form a very severe type of disease by obstructing the urinary passages—the bladder and urethra. In such cases the symptoms of a secondary pyelitis and cystitis are often added.

Perforations in other directions are much rarer. The rupture of a renal echinococcus into the lungs has sometimes been observed, the patient coughing up echinococcus cysts.

Sometimes, especially after injuries, the sac of the echinococcus inflames, suppurates, and thus leads to a general pyæmic condition.

The diagnosis of renal echinococcus is possible only when a tumor can be made out belonging to the kidney, and when portions of echinococcus are passed with the urine, or through an exploratory puncture. They are most frequently confounded with hydronephrosis (*vide infra*), and, in women, with ovarian tumors.

The prognosis is not wholly unfavorable. Permanent recovery has been repeatedly observed, especially after the rupture, or single or repeated evacuations of the sac of the echinococcus; but, of course, echinococcus of the kidney may also be attended with numerous dangers, such as suppuration of the sac. The whole course of the disease is always very tedious.

A radical treatment is possible only by surgical means. Symptomatically, ice and local blood-letting are used when there are symptoms of local inflammation; and morphine, warm baths, and sometimes mechanical aids, like the catheter, when there are symptoms of colic.

2. **Distoma Hæmatobium** (see Fig. 113) is a parasite, occurring frequently in Egypt and Abyssinia; it is one of the fluke-worms (*hematodes*), and has its seat in the branches of the portal vein, the splenic vein, the vesical plexus, etc., and is nourished by the blood. Its eggs are often deposited in great numbers in the mucous membrane of the pelvis of the kidney, the ureters, and the bladder, and

\* In regard to the general natural history of the echinococcus, compare page 494.

there cause very intense inflammation, ulceration with subsequent stricture, deposit of concretions, etc. Many cases of the so-called tropical hæmaturia are caused by the distoma. The diagnosis of the disease can be made with certainty by finding the eggs in the urine.

FIG. 113.—*Distoma hæmatobium* (from LEUCKART). *a.* Male and female, the latter in the canalis gynecophorus of the former. Ten diameters. *b.* Egg with a terminal spine. *c.* Egg with a lateral spine. 150 diameters.

3. **Strongylus or Eustrongylus Gigas** (*palisade worm*) is a parasite occurring in the pelvis of the kidney in many animals—the dog, the wolf, the marten, and very rarely in man. In size and color it is not unlike an ordinary earth-worm. It may produce symptoms of severe pyelitis, with hæmorrhages, and colicky pains.

4. **Filaria Sanguinis Chyluria.**—The blood filaria of man, belonging to the round-worms, has obtained a special clinical interest, since it is recognized, from the investigations of Wucherer in Bahia in 1868, and of Lewis in the East Indies in 1870, as the cause of the tropical chyluria and some allied diseases, such as lymph scrotum, elephantiasis Arabum, and chylous ascites.

The full-grown filaria, "*filaria Bancrofti*," a very thin worm, about three or four inches long, has been found only a few times in man. Its seat is in the larger lymphatics, where it gives rise to chronic stasis of the lymph with its consequences—chronic hyperplasia of the connective tissue, etc. In the affection which here especially interests us, chyluria, the parasites are probably situated in the main branches of the thoracic duct—at any rate, in such a place that a stasis of the lymph ensues in the lymphatics of the bladder, or perhaps, in some cases, of the pelvis of the kidney and the other urinary passages. If the distended lymph-sac ruptures, the lymph or chyle is poured out into the urinary passages and is evacuated with the urine. Since this process may be often repeated, the intermittent course of chyluria is thus explained. The individual attacks of the disease may come on during years at intervals of weeks or months. They are often associated with pain and febrile symptoms.

The condition of the urine, which in many cases may look almost exactly like milk, is most characteristic. A creamy layer of fat forms upon the surface. If we shake the urine with ether, the greater part of the fat can be removed, and the urine rendered clear. The fat in the urine may amount to two or three per cent. The chyluria is often associated with a hæmaturia coming from the ruptured veins. The urine then looks bloody red, and shows under the microscope many red blood-corpuscles beside the fat-drops. Large clots often form in the urine.

The embryos of filaria, found in the urine in very many cases, although not in all, form the most important diagnostic feature in the urine. These (see Fig. 114) are objects two to three tenths of a millimetre long, with a diameter about that of a red blood-corpuscle. They are usually imbedded in a very sheath, which often projects at the end of the animal, and show a c

ously vibrating motion. They have also been found in the blood of the patient, as well as in the urine, and, strange to say, especially during the night.

FIG. 114.—(From SCHEUBE.) Embryos of filaria.

The course of the filaria disease may vary considerably. Many patients reach an advanced age; in others, severe general symptoms, like anæmia and emaciation, finally come on. The different forms in which the disease occurs—chyluria, elephantiasis, etc.—are combined in manifold ways.

The region of the geographical distribution of the disease lies almost wholly in hot countries. It has so far been most frequently observed in Brazil, the Antilles, the East Indies, China, Japan, Egypt, Cape Colony, and Australia. Nothing definite is yet known of the precise mode of invasion of the parasites. According to Manson's investigations, mosquitoes play an important part here.

In regard to treatment, apart from any surgical interference, we may try picronitrate of potassium, three to ten grains (grm. 0.2–0.5), in pills or capsules, several times a day (Scheube).

## CHAPTER X.

### MOVABLE KIDNEY (FLOATING KIDNEY, REN MOBILIS).

**Etiology.**—Although under normal conditions the kidney is fixed firmly in its position by its fatty capsule, over which the peritoneum is tightly drawn, and by the diaphragm, there is not infrequently a pathological condition, in which the kidney shows quite a high degree of displacement and mobility. The causes of this anomaly are not always quite clear, and there are probably different factors which may give rise to movable kidney.

First, perhaps, a congenital predisposition is often to be considered; this may be based chiefly upon an abnormally loose character of the tissue surrounding the kidney, and also upon an abnormal length of the renal artery; but in later life it is chiefly the factors that lead to a marked distention and laxity of the abdominal cavity, which further the development of a movable kidney. Frequent pregnancies are especially unfavorable in this respect, which explains the fact that floating kidney is very much commoner in women than in men. Severe and persistent bodily labor may also give rise to floating kidney; in some cases, too, injuries which affect the abdomen, and especially the region of the kidney, also play a part. Too tight lacing, and the wearing of corsets, have been repeatedly accused of gradually causing a mobility of the kidney. Finally, a loss in the general nutrition, by which the fatty capsule of the kidney undergoes a reduction, sometimes seems to favor the occurrence of movable kidney.

We have just mentioned the frequent occurrence of floating kidney in women

but some cases have also been observed in men, and even in children. It is remarkable that the right kidney shows the anomaly in question much oftener than the left, which is possibly connected with the fact that the right kidney may be more easily displaced by the respiratory movements of the liver. Litten has lately pointed out that we often find the right kidney dislocated upward in simple gastrectasia, arising from immoderate distention of the stomach, relaxation of the muscular coat of the stomach as a result of chronic gastric catarrh, etc. In such cases the distended stomach and sometimes the duodenum push up the liver, and with it the right kidney. Movable kidney can be confirmed in the cadaver only when the kidney is found in an abnormal position—for instance, in front of the vertebral column.

**Clinical Symptoms** are not necessarily present in every case of movable kidney. If we examine old women with special regard to this point, we not very rarely find movable kidneys without any symptoms caused by them. In other cases, however, the floating kidney gives rise to a whole set of symptoms which are inexplicable except by the discovery of their cause. Drawing and pressing pains in the abdomen are the most frequent; these may shoot into the epigastrium or into the sacral and lumbar region, and may sometimes assume almost a colicky character. They are also frequently associated with nausea and even vomiting. All these disagreeable sensations usually increase still more as the patient moves, in walking or riding, while they are slightest or even disappear entirely when the patient lies down.

In many cases of floating kidney more severe attacks come on periodically, often at the time of the menses; they have been termed by Dietl "incarceration symptoms." They consist of the sudden onset of pain, chills which may increase almost to a rigor, vomiting, and symptoms of general collapse. Diuresis is usually diminished during this period, and increases only when the attack ceases—that is, three or four days later. The special cause of these symptoms is to be found partly in circumscribed inflammatory changes in the vicinity of the kidney, but chiefly in a sudden urinary stasis from bending or twisting the ureter. There then arises an acute hydronephrosis whose attendant symptoms disappear when micturition has again become possible. In some cases floating kidney seems to cause persistent hydronephrosis, with secondary pyelitis.

We find quite frequently in women with floating kidney a line of general nervous "hysterical" symptoms—headache, backache, mental irritability, paræsthesiæ, etc. It is often hard to decide whether these symptoms are due to floating kidney or are only co-ordinate with it. They often arise, at any rate, only as a result of the mental condition, for the mere idea of possessing a "floating kidney" may be enough in nervously disposed women to provoke a host of subjective sensations. Hence we must be cautious in informing the patient of the diagnosis.

Movable kidney also seems able sometimes to produce certain resultant conditions by pressure on neighboring organs. Thus Bartels has claimed that many cases of dilatation of the stomach are due to a compression of the descending part of the duodenum by the movable kidney. In an analogous way, jaundice may arise from pressure on the gall-ducts, constipation from pressure on the colon, œdema of the legs from pressure on the inferior vena cava, and finally it has been stated that floating kidney in women may be the cause of abortion. All these accidents, at any rate, are only rarely to be considered.

The **diagnosis** of floating kidney can be made only by its objective discovery. It is rather a theoretical assumption, which is only rarely of value in practice, that we can recognize the displacement of the kidney from its normal position by the sinking in of the affected lumbar region (almost always the right).

by the abnormal clearness of the percussion-note there. The only certain proof is feeling the kidney as a movable tumor of the proper size and shape beneath the edge of the right ribs or toward the umbilicus or the inguinal region. Occasionally we can succeed in feeling the pulsation of the renal artery. Palpation of the movable kidney, however, is not always equally easy, and generally demands a certain amount of practice. Bimanual palpation and counterpressure in the lumbar region with the left hand is very advisable. If we can reach the kidney with the fingers, we can push it about and often bring it back into its proper place.

In general, the diagnosis is not very difficult in patients whose abdominal walls are lax, if the attention be directed to the possibility of floating kidney. Of course a positive result is alone decisive, while a negative result, or finding it only once, proves nothing. In many cases, of course, floating kidney is confused with other sorts of tumors, with pedunculated ovarian cysts, fecal tumors, enlargements of the gall-bladder, or echinococci.

The prognosis is so far favorable that the patient's life is never threatened by an uncomplicated floating kidney. The symptoms, are of course, very obstinate, and may resist any therapeutic attempts for years. In advanced age they often cease of themselves.

**Treatment.**—If there are severe disturbances or "incarceration symptoms" on the part of a floating kidney, a quiet dorsal decubitus is to be prescribed; and if the kidney does not return to its proper place of itself, we should try artificial reposition, which can be performed in many cases, and which is then attended with success. If we can not relieve the symptoms in this way, prolonged warm baths, warm poultices, and opium must be used as indicated. Various bandages provided with pads and supports are recommended to guard against a new displacement of the kidney; these, of course, sometimes do good service, but they are often useless. At all events, they should be tried. The hope of "removing the laxity of tissue" by a "tonic treatment," iron preparations, cold rubbing, etc., must be illusory; nevertheless, these remedies are very much recommended in practice, since they often act very favorably, especially on the general nervous symptoms, as mental remedies. Certain general hygienic measures, especially the avoidance of any great bodily movements, and care for easy dejections, are also of service.

In cases with very severe, distressing symptoms, surgeons who are fond of operations have repeatedly stitched the kidney to the parietes, sometimes with success, sometimes, too, without the desired result. At any rate, the indication for operation is furnished only when the symptoms are very marked, and when all other remedies have been unsuccessful.

#### APPENDIX.

##### THE DISEASES OF THE SUPRA-RENAL CAPSULES AND ADDISON'S DISEASE (BRONZED SKIN).

In the year 1855 the English physician Addison published for the first time a list of cases in which, besides the symptoms of a general bodily weakness and anæmia, a peculiar dark pigmentation of the skin had gradually developed. Since disease of the supra-renal capsule was found at the autopsy in all cases, Addison concluded that this was the immediate cause of the bronze coloring of the skin. Observations similar to Addison's were soon made in greater numbers, so that the fact itself can not be doubted; but even at present nothing definite is known as to the special cause of the disease or the theory of this remarkable con-

nection between disease of the supra-renal capsules and pigmentation of the skin.

Attempts have been made in different quarters to obtain an explanation from experiments on animals; but up to the present time these attempts have remained quite fruitless, and even lately Nothnagel, in spite of having destroyed both supra-renal capsules in a large number of rabbits, has not succeeded a single time with certainty in provoking the symptoms of the disease artificially. The anatomical lesions in man are up to the present time not calculated to add clearness to the case, since they seem to contradict one another in various points. In the first place, some observations must be mentioned in which the supra-renal capsules were found perfectly normal in spite of an existing pigmentation of the skin. Such cases, however, prove little, since it of course can not be put in question that a staining of the skin may sometimes develop from some other reason besides disease of the supra-renal capsules. On the other hand, it has been asserted that extensive changes are sometimes found in the supra-renal capsules on autopsy without the existence of the symptoms of bronzed skin during the patient's life; but these cases are also open to the objection that the disease has perhaps not been extensive and intense enough to cause the bronze coloring of the skin. The contradictions just mentioned, however, have led to many other attempts at an explanation of Addison's disease, of which one especially deserves consideration. According to this, the symptoms met with are produced not by the disease of the supra-renal capsules themselves but by the invasion of the solar plexus and the semilunar ganglia of the sympathetic by the morbid process (Risel, Burger, and others). According to this theory, the symptoms of Addison's disease may arise when the aforesaid nervous parts are diseased independently, or by the extension of a pathological process from some other neighboring organ. A number of anatomical lesions are cited to favor this view, but it is not certainly proven, and the internal connection between the symptoms is by no means clear by this hypothesis.

**Pathological Anatomy and Ætiology of Addison's Disease.**—Addison himself has pointed with emphasis to the fact that the special form of disease in the supra-renal capsules is by no means always the same. At any rate, the disease named from him is not to be regarded as a definite anatomical affection, but rather as a particular group of symptoms. By far the most frequently it is tuberculosis of the supra-renal capsules which lies at the bottom of Addison's disease. The capsules then are either enlarged and studded with caseous tubercular new growths, or they are in part cicatricially contracted. Other tubercular affections are almost always present in the body at the same time, especially caseation of the mesenteric lymph-glands and pulmonary tuberculosis. Other morbid processes besides tuberculosis may also be found in the supra-renal capsules: simple chronic inflammations, enlargement of the organ (which Virchow has called "struma of the supra-renal capsules"), hæmorrhages, new growths such as cancer, and even echinococci. It is self-evident, from what has been said above, that in every case we must consider some implication of the neighboring sympathetic ganglia, by compression, cicatricial contraction, or chronic inflammation. Both supra-renal capsules are almost always diseased at the same time, rarely only one is affected.

Of the lesions in other organs we must also mention that Peyer's patches and the solitary follicles of the intestine are as a rule swollen. The spleen is somewhat enlarged in some cases, but not in others. There is no striking pigmentation of the internal organs. The changes in the skin and in certain mucous membranes will be mentioned below.

Considering the variety of the anatomical causes there can be no question of a

uniform aetiology of the disease. Among the causal factors, those most frequently reported are defective nutrition, care and anxiety, and finally traumatic action on the abdomen. The majority of cases are met with in the male sex and in middle life. Addison's disease, however, must be regarded as a rare affection, of which but few cases are observed even in the larger clinics.

**Symptomatology.**—The purest type of Addison's disease appears in those cases where the symptoms are apparently primary in their development, and do not come on in the course of some other disease, such as phthisis or cancer.

The first symptoms of the disease are usually of a general nature, and are referable to a gradually increasing anæmia and to general weakness and physical lassitude. The anæmia shows itself objectively through the pallor of the skin and the diminution in the number of red blood-corpuscles, but without other definite anomalies of the blood that can be made out. A number of symptoms appear besides, which are due secondarily to the anæmia, especially to the anæmia of the brain. Among them are mental lassitude and loss of energy, frequent headaches, attacks of vertigo and faintness, and tinnitus aurium. The patient's general nutrition often suffers very considerably; but it must be added that in Addison's disease, as in other anæmias, the fatty layer, especially over the abdomen, often remains remarkably well developed.

Besides the anæmic symptoms, there frequently are disturbances of the stomach. The appetite is poor, and there is very often vomiting. The latter may sometimes be almost unrestrainable, and then it is one of the most distressing symptoms of the disease. It is usually due not to an anatomical change in the stomach, but probably to the anæmia of the brain, or to other nervous influences. Cardialgic symptoms are also frequent. The bowels are sluggish as a rule, but there is sometimes diarrhœa. We sometimes hear functional murmurs in the heart, but as a rule its sounds are low and pure. The pulse is usually moderately accelerated. The liver and spleen present no constant changes. Albuminuria is only exceptionally found, and is due to complications, such as amyloid kidney.

The special characteristic symptom, which alone renders the diagnosis possible, is the gradual onset of a peculiar pigmentation of the skin. This usually shows itself first in the face and on the backs of the hands, and also in those parts which normally present a greater pigmentation (the areola of the nipples, the axillæ, and the genitals), or which are exposed to greater pressure by the clothing, as the hips and shoulders. It is especially noteworthy that dark pigmented spots usually develop on the mucous membrane of the lips and mouth. The intensity of the coloring differs in different cases. It usually increases as the general condition grows worse. In the most intense cases the whole skin may become dark brown or black, like that of a mulatto or negro. Sometimes, however, the pigmentation remains limited to separate large or small spots, and in other parts of the skin there may then be even a marked loss of pigment. The nails and the sclera always remain white, and frequently the palms of the hands and the soles of the feet also. The pigmentation of the skin usually increases during the whole disease; only exceptionally does the skin become light again in the later stages.

The special cause of the accumulation of pigment in the skin is wholly unknown. We find on microscopic examination of the skin that the pigment lies not only in the cells of the rete Malpighii, but also in the corium, especially along its blood-vessels. It is probably formed from the blood-pigment, and is carried by wandering cells from the cutis into the epithelial layers of the skin (Demiéville, Nothnagel).

The course of Addison's disease is almost always chronic, and may last for years, but cases have been described with a more acute course. The disease some-

times begins with violent initial febrile symptoms, vomiting and diarrhoea. The disease then has a comparatively rapid termination after a few months, or a second chronic stage may follow the first acute one.

The final termination of Addison's disease is always unfavorable. Temporary remissions are often observed, but the disease always becomes worse again after them. Death usually ensues gradually amid the signs of increasing general uræmia and weakness. In some cases severe nervous symptoms also come on toward the end of the disease—coma, delirium, or epileptiform attacks. Such conditions, which, according to Jaksch, may depend upon acetonuria, may sometimes develop quite rapidly and unexpectedly.

**Treatment.**—There can be no question of a specific treatment of Addison's disease, especially considering the differences in the primary diseases and in the complications. Tonic remedies, strengthening diet, iron, quinine, and arsenic, are most indicated, although iodide and bromide of potassium, electricity, etc., have been tried by some physicians. Otherwise the treatment is purely symptomatic; the vomiting, diarrhoea, and nervous attacks demand special measures. We know by experience that great caution is to be used in prescribing cathartics, since patients have repeatedly been observed to grow considerably worse after them.

## SECTION II.

### *DISEASES OF THE PELVIS OF THE KIDNEY AND OF THE BLADDER.*

#### CHAPTER I.

##### **INFLAMMATION OF THE PELVIS OF THE KIDNEY. PYELITIS.**

**Ætiology.**—Isolated primary pyelitis hardly ever occurs as an independent disease. Pyelitis is rather in most cases either a complication or a result of other diseases, and in such cases often claims but little clinical interest.

We sometimes find a rather moderate pyelitis in the bodies of persons who have died of severe general infectious diseases, typhoid fever, smallpox diphtheria, or pyæmia. The affection depends, in all probability, upon the elimination by the kidneys of substances that excite inflammation, and is thus to be regarded as analogous to the renal changes which often coexist. Toxic substances, such as cantharides and copaiba, which pass through the kidneys, may also cause pyelitis as well as other disturbances.

Pyelitis very often arises from a direct extension of inflammation from the neighboring organs. In many cases of acute and chronic nephritis the pelvis of the kidney takes part in the inflammation to a greater or less degree; but an ascending extension of the inflammation from primary diseases of the urethra or bladder is still more common. Any urethritis or cystitis may, if it lasts long, advance upward to the ureters and the pelvis of the kidney, so that in severe cases we often find an inflammation of the whole urinary tract, a pyelo-cystitis, and even a "ureteritis." We have already stated (compare page 868) that the inflammation may extend still farther to the kidneys themselves, and this extension will be repeatedly spoken of.

Another frequent cause of pyelitis is the presence of foreign bodies in the pelvis of the kidney, which act as direct mechanical irritants. Among these are,

in the first place, renal calculi (*vide infra*), and also retained coagula, parasites (see page 874), etc. The pyelitis arising as a result of retention of urine in the pelvis of the kidney (*vide infra*, hydronephrosis), does not belong here directly, since it first develops from a decomposition of the urine.

Whether there is a primary independent pyelitis, arising in ways other than those so far mentioned, is doubtful, as we have said. The occurrence of a primary pyelitis after exposure to cold especially lacks confirmation. The pyelitis coming on in women in childbed, or following different sorts of diseases of the sexual organs, may in all cases be referred to an infection of the pelvic mucous membrane from the bladder or from the kidneys.

**Pathological Anatomy.**—In simple catarrhal inflammation the mucous membrane of the pelvis of the kidney is reddened, swollen, and covered with an abundant secretion, which contains varying amounts of pus-corpuscles and epithelium. In severer inflammations we often find quite numerous little hæmorrhages in the mucous membrane, and sometimes little gray nodules, which correspond to the swollen lymph-follicles.

In severe cases, which are seen almost solely as a complication of a more extensive affection of the urinary passages, such as pyelocystitis, we have a purulent, ulcerative inflammation, which may even assume a diphtheritic character. In these cases the kidneys are almost always coincidently involved—pyelonephritis. If the nephritic abscesses break into the pelvis of the kidney, there arises an ulcerative destruction of the renal tissue, so that the pelvis of the kidney is filled with pus and bounded by extensive ulcers, which often penetrate deeply into the substance of the kidney—pyonephrosis. The usually striated, pyelonephritic abscesses reaching to the surface of the kidney have already been described in the previous section (see page 869), where their bacterial origin has also been mentioned.

The condition differs when the kidney is involved, as in many cases of chronic pyelitis. This appears most frequently as a result of retention of urine, and hence it is usually associated with a dilatation of the pelvis of the kidney. In those cases we sometimes find pronounced processes of contraction in the kidneys—that is, a partial atrophy of the renal tissue, increase of the interstitial connective tissue, and evident cicatricial depressions on the surface—in a word, a secondary contracted kidney, arising as a result of pyelitis, which differs from genuine contraction of the kidney only in its aetiology.

**Clinical Symptoms.**—Since in most cases pyelitis develops only as one symptom of a more extensive morbid process, its clinical symptoms are usually but slightly prominent in the whole course of the disease. In what follows, therefore, we can not give any complete description of the clinical course of pyelitis, but we must mention only those symptoms from which, when there is an affection of the urinary passages, we can conclude that the pelvis of the kidney takes part in the morbid process.

The most essential sign which the urine presents in all inflammatory affections of the urinary passages, the presence of mucus and pus, will be described more fully in the chapter on cystitis (*vide infra*). In pyelitis, also, the muco-purulent secretion of the pelvic mucous membrane must mix with the urine, and in every severe purulent inflammation the amount of pus in the urine must be quite considerable. We can never decide with certainty, from the mere presence of pus in the urine, as to the place where the pus mixes with the urine, whether in the pelvis of the kidney or in the bladder, or even in the urethra. Only when the urine contains other characteristic morphological elements besides the pus-corpuscles can we decide upon the portion of the urinary tract which must be especially affected. Among these morphological constituents is, first of all, the epithelium, which in the

pelvis of the kidney shows in part another shape than in the bladder. If we find in the urine, then, the triangular, long caudate pelvic epithelium (see Fig. 115), with its cells sometimes laid over one another in the form of tiles, we may assume that the pelvis of the kidney is involved in the inflammation. Of course, the reverse of this law does not obtain; for, even in severe purulent pyelitis and pyelo-nephritis, we often fail entirely to find the caudate epithelium in the urine. We must also add that similar forms of epithelium are also found in the bladder, so that great caution is always to be enjoined in estimating the diagnostic value of the epithelium found. Blood is only rarely found in the urine in simple pyelitis, but it is common in pyelitis calculosa (see the following chapter). The reaction of the urine in pyelitis is usually acid, but it is not correct to assume that there is in this a comprehensive mark of distinction between pyelitis and cystitis, in which the urine is often alkaline.

FIG. 115.—Pelvic epithelium.

Another symptom to be referred directly to the pyelitis, is the local pain in the region of the kidney, which sometimes passes from this point down along the ureters to the bladder. This symptom has not, therefore, a great diagnostic value, because only its presence is in favor of pyelitis, while its absence proves nothing against the existence of the disease.

All the other symptoms may be directly dependent upon the pyelitis, but they may usually be referred in great degree to the other co-existing affections. First among these is fever, which either shows an irregularly remitting course, or appears in single high elevations of temperature, usually associated with rigors. The fever, however, seldom shows this latter pyæmic character except in the severe purulent forms, where we usually also have the formation of renal abscesses—that is, a pyelo-nephritis. Besides the fever there are often in severe cases, general nervous symptoms, such as headache, delirium, and sopor, which are to be referred partly to the general pyæmic infection of the body and partly, perhaps, to the absorption of ammonia from the urine decomposing in the blood—the “ammoniaemia” of Treitz and Jaksch.

The whole course of pyelitis differs so much according to the primary disease present that nothing of general application can be said about it. The milder forms, which often pass off rapidly, are found most commonly in childbed, and sometimes in acute infectious diseases, poisonings, and as a result of mild cystitis. The severe forms occur chiefly as cysto-pyelitis and pyelo-nephritis, as a result of strictures of the urinary tract (*vide infra*), of severe cystitis in diseases of the spinal cord, and in other severe diseases of the kidney and of the pelvis of the kidney, such as new growths, and parasites. They usually form then a very tedious and often incurable affection, which lasts until the patient's death.

The signs of pyelitis which are important in diagnosis have already been mentioned above. The main point is always to pay careful attention to the ætiology of the case, and, next to that, to the changes in the urine. If the whole condition points to a severe affection of the urinary tract, we can often decide correctly on a pyelitis or a pyelo-nephritis without the presence of direct signs of these diseases, because we know by experience that such an extension of the affection is the rule in all severe and long-continued cases.

The implication of the kidneys is sometimes shown directly by the presence of casts in the urine in addition to the pus-corpuscles. In the cases above mentioned, where a chronic cysto-pyelitis is complicated with pyelo-nephritis, the condition of the urine is the same in many respects as in the acute pyelitis of the affected kidney.

It is abundant, usually has a low specific gravity, and contains, besides the pus-corpuscles, a few short hyaline casts.

**Treatment.**—The treatment of pyelitis coincides mainly with the treatment of the primary disease, and therefore it needs no detailed description here. Ordinarily only the accompanying cystitis (*vide infra*) is accessible to a direct local treatment, and here an important prophylactic factor is discovered, since by a timely treatment of the cystitis we can certainly hinder the advance of the inflammation to the pelvis of the kidney.

Among the internal remedies to which we ascribe a favorable influence on the mucous membrane of the urinary tract, and which are therefore used in like manner both in pyelitis and in cystitis, we may mention the astringents, tannin, alum, and acetate of lead. Balsams, such as copaiba, are sometimes prescribed, and also antiseptic substances, such as salicylic acid and chlorate of potassium. The details in regard to all these remedies will be found in the treatment of cystitis. The copious ingestion of fluids sometimes acts favorably, especially the use of certain mineral waters, among which the waters of Carlsbad, Vichy, Ems, Neuenahr, and Wildungen have obtained the most reputation. A methodical milk cure is also greatly to be recommended, especially when there are symptoms of irritation, such as pain on micturition.

Local applications to the region of the kidneys, warm poultices, or exceptionally local bloodletting, are indicated only when there is severe pain, where, of course, narcotics must also be used under some circumstances. In this respect warm baths also do good service at times.

## CHAPTER II.

### NEPHROLITHIASIS.

(*Renal Calculus. Renal Gravel. Pyelitis Calculosa.*)

**Occurrence, Chemical Composition, and Etiology of Renal Concretions.**—The precipitated concretions of the urinary constituents which form in the pelvis of the kidney, and which, under some circumstances, may be passed from it with the urine, are designated, according to their size and nature, as renal sand, a fine pulverized precipitate; renal gravel, gravel-like, granular concretions about the size of the ordinary coarse grains of sand, which can usually pass through the ureters without special difficulty; or renal calculi, the larger concretions. The latter are about the size of a pea or bean, but larger stones are occasionally seen which may even resemble actual casts of the pelvis of the kidney. We usually find a calculus only in one kidney, although both kidneys may be affected.

In regard to the chemical nature of renal concretions, they consist most frequently of uric acid. They then have a brown-red or blackish color, and have a crystalline breakage, which in large stones is usually plainly laminated; and, on the whole, a smooth although irregularly-shaped surface. More rarely the renal concretions consist of calcic oxalate. The oxalate calculi are extremely hard, have a dark-brown color and a rough surface, often furnished with many prickles, from which reason they are often called "mulberry calculi." Their breakage sometimes has a radiated but never a laminated arrangement. Stones are also frequently seen, which consist of alternating layers of uric acid and calcic oxalate, or which have a nucleus of uric acid and a coating of calcic oxalate. The phosphatic calculi are another variety of renal concretions. We only very rarely

have to do, however, with stones which consist exclusively of basic calcic phosphate or ammonio-magnesian phosphate, but we usually have secondary deposits of layers of phosphate which are precipitated on uric acid or mulberry calculi in urine which has become alkaline. The phosphatic calculi have a grayish-white color, and are comparatively soft. The largest examples of them are found, not in the pelvis of the kidney, but in the bladder. The cystine and xanthine calculi are the rarest of all.

But little is definitely known as to the exact causes for the origin of all these concretions. We must suppose for the deposition of uric acid an abnormally great acidity of the urine, but we are not in a position to state by what circumstances (the patient's food and manner of life, acid fermentation of the urine within the urinary tract?) this may be provoked. It is a very probable theory that some solid body usually affords the nucleus and the first cause for the formation of at least the larger stones, among these bodies being mucous coagula, shreds of epithelium, and perhaps bacteria. The oxalate, cystine, and xanthine calculi are also deposited from acid urine, but scarcely anything is known as to the precise conditions to be here considered. We can point only to the fact that with the close chemical alliance between uric acid and oxalic acid the origin of the latter from uric acid seems possible, and the frequent co-existence of the two substances in the calculi therefore seems plausible. We have already indicated above that the cause of the deposition of phosphatic concretions can be found only in the existence of an alkaline reaction in the urine.

In regard to the predisposing causes of calculus formation we must mention, first of all, that they are often found in children, and next in frequency in advanced life. Men show a greater disposition to renal calculi than women. Heredity also seems to play a certain part, since the disease has been repeatedly observed in different members of the same family. The many relations which have been imagined between the formation of calculi and certain conditions in the manner of life and in the food taken, all lack accurate foundation. In regard to this the chief blame is laid upon an excessive meat-diet, drinking copiously of new sour wines, and drinking water containing lime. In regard to the occurrence of uric-acid concretions in gouty patients, compare the chapter on arthritis uratica.

**The Anatomical Changes caused by Renal Calculi.**—The most frequent change which the presence of concretions in the pelvis of the kidney excites is pyelitis. This may exhibit all degrees, from a simple catarrhal inflammation to a diphtheritic or severe purulent inflammation of the pelvic mucous membrane. As a result of the mechanical irritation, there are quite frequently large or small hæmorrhages.

If a severe purulent pyelitis has developed, this may bring with it all the sequelæ with which we have previously become acquainted. In severe cases the process may involve the kidneys, and there arises a pyelo-nephritis, with a purulent breaking down of the renal tissue, and, under some circumstances, even a perinephritis, with extensive suppuration into the vicinity of the kidney, and with occasionally perforation into the neighboring organs. If the renal calculi have previously passed outward, they are not found at the autopsy, although they form the special starting point of the disease. Sometimes, however, the pus-cavity is entirely filled with calculi.

A second important sequel of a renal calculus which sometimes develops is hydronephrosis (*vide infra*). It arises when a large stone blocks the pelvis of the kidney into the ureter, or when a smaller one is lodged in the ureter and completely shuts off the passage of the urine. In such cases there may also arise a pressure necrosis and perforation.

without saying that inflammation and hydronephrosis or pyonephrosis may be combined with each other.

**Clinical Symptoms.**—If there is merely the formation of renal sand or renal gravel in the urinary tract, this condition is sometimes associated with no symptoms at all. The little granules are washed away by the urine and evacuated, and at most they may give rise to slight pain in the region of the kidney. Larger stones, however, may sometimes be wholly, or almost wholly, without symptoms, if from their position and their smooth surface they can cause no special bad results.

The characteristic clinical symptoms of nephrolithiasis do not appear until the results of mechanical irritation of the pelvis of the kidney arise, or until there is an incarceration of a calculus in the ureter. It is the latter circumstance which, after the analogy of gall-stones, causes the most important symptom in the diagnosis of renal calculi—the pains, the so-called renal colic. Such an attack of colic sometimes comes on quite suddenly and unexpectedly; in other cases it is produced by some exciting cause—jumping, running, walking, or riding. The pain often attains an uncommonly severe intensity; it shoots from the lumbar region along the course of the ureters, but sometimes extends still farther, to the testicles, the thighs, or the back. In severe attacks there may be a general state of collapse with a small rapid pulse, cold sweat, and attacks of fainting. The temperature may be somewhat raised. We often see nausea and repeated vomiting. The urine is sometimes entirely normal, inasmuch as it comes exclusively from the other free kidney; but oliguria, or even complete anuria, with its consequences, invariably sets in if both ureters be stopped. Even when one kidney remains normal, the evacuation of urine may be inhibited by a reflex spasm of the bladder. Sometimes the urine passed contains pus and blood. The duration of renal colic depends upon the duration of the incarceration; it may last for a few hours or several days. The attack often ends with the passage of the stone outward into the bladder.

The other symptoms occurring in nephrolithiasis refer mainly to the results of the mechanical irritation of the pelvis of the kidney. The urine then shows an admixture of pus, and contains pelvic epithelium and often blood. The frequent appearance of blood in the urine, which usually has its cause in purely mechanical lesions of the mucous membrane, is a characteristic symptom of pyelitis calculosa. If we find, as sometimes happens, the urine at many times perfectly clear and normal, but at other times containing pus, we may suspect an occasional blocking of the ureter coming from the diseased kidney by a renal calculus.

The symptoms are much more severe if the trouble goes on to a severe purulent pyelitis and pyelo-nephritis. We need not describe the details again here—the pain, fever, swelling, and perforation internally or externally—since they agree completely with what has been said before (see the previous chapter and Chapter VI in the previous section). A special chapter is devoted below to the symptomatology of hydronephrosis.

The whole course of nephrolithiasis is, as a rule, very tedious. Since the disposition to the formation of calculi usually persists, and since also the sequelæ which have once developed may last for a long time, a very chronic state often develops, which, in varying ways and with manifold exacerbations and remissions, is composed of attacks of colic, hæmorrhages, and symptoms of pyelocystitis.

In many cases, of course, complete recovery may finally ensue. The calculi present are passed, new ones are not formed, the pyelitis that has arisen disappears, and, of course, all the morbid symptoms cease; but, on the other hand, nephrolithiasis has also a number of dangers in itself, which threaten life very seriously.

These are, besides the rare occurrence of uræmia, first of all the development of pyelo-nephritis and of still more extensive suppurations, with a general decline in strength, pyæmic states, etc. There is also a possible danger in such chronic suppurations that there may be the appearance of a general amyloid degeneration of the internal organs.

Among the complications occurring in other organs, only one circumstance has especial interest: that gall-stones and renal calculi are found quite frequently in the same individual. We, of course, can not well speak of a complication with vesical calculi, since a great part at least of the vesical calculi are originally formed in the pelvis of the kidney, and undergo merely a further growth in the bladder.

**Diagnosis.**—The diagnosis is made perfectly certain only by finding the special *corpora delicti* in the urine. For this purpose the urine must always be examined as soon as possible after its passage, and it is best to pour it through a fine sieve. In many cases, however, we can diagnosticate nephrolithiasis quite certainly, without the direct evidence of concretions, from the characteristic symptoms, especially from the periodical renal hæmorrhages and from the attacks of colic. Of course it may be confused with renal cancer, parasites of the kidney such as echinococci, and similar affections, but this does not happen very often, because renal calculus is a far commoner affection than the diseases just mentioned. Finally, we must state that these diseases may comparatively often be combined with nephrolithiasis.

**Treatment.**—Since the uric-acid concretions are by far the commonest, the methods of treatment most in use for nephrolithiasis refer first to these; but they are to be used in like manner in the allied oxalate calculi.

If the tendency to the formation of urinary gravel be confirmed in a patient, or if the severer symptoms of nephrolithiasis have already appeared, we must first give a number of general dietetic directions, which check the formation of uric acid in general, and aid the solubility of the uric acid already formed as far as possible. Without entering too much on theoretical reasoning, we will give in what follows the measures which have been proven practically and quite generally acknowledged. In the first place, the patient must avoid any immoderate indulgence in food in general, and particularly too great indulgence in meat. We should recommend for him a diet mainly, though not exclusively, vegetable, with a moderate supply of meat; milk is also a proper food. Alcoholic beverages should be taken only in slight amount, and acid foods and drinks, except lemonade, should not be taken at all. It is a good plan to control the supply of food by weighing the patient regularly, in order to avoid any further addition to the weight in all persons in a state of normal nutrition, and to obtain a loss of weight in the corpulent. We should also aid the using up of tissue by regular physical exercise and muscular work, gymnastics, sawing wood, or gardening; and, finally, the urine must be diluted by an abundant supply of fluid, and its soluble power be thus increased.

This latter indication will usually correspond at the same time with those which diminish the acid reaction of the urine by a supply of alkalies and thus hinder the deposition of uric acid as far as possible. From this comes the very extensive use of the alkaline mineral waters in nephrolithiasis. The simplest plan is to dissolve some alkaline salt in a large amount of plain water, soda water, or lemonade, and let the patient drink it. Among these salts we may mention sodic phosphate, one to four drachms (grm. 5-15) a day, or better, sodic carbonate, one to two drachms (grm. 5-10), or carbonate of lithium, which has lately been especially recommended, two to five grains (grm. 0.1-0.3) several times a day. Of course, the special mineral waters enjoy a greater reputation; these may be used in con-

formity with the treatment at home, or especially at the appropriate springs. The following springs enjoy the greatest reputation in this respect: Carlsbad, Vichy, Salzbrunn, Fachinger, Tarasp, Neuenahr, Ems, and Wildungen.

The symptomatic treatment is also very important. In so far as this relates to the accompanying pelvic and vesical catarrh, we may refer to the appropriate chapters in this book, while the surgical methods of treatment in the severer sequelæ—hydronephrosis, pyonephrosis, or perinephritic abscess—are to be found in the special treatises. Against renal hæmorrhages some internal remedies, such as ergotine or tannin, have been recommended, but their action is quite doubtful. The treatment of the attacks of colic is of greater practical significance. The chief remedies are the narcotics, opium, and morphine, internally, or, with very severe pain, better subcutaneously. Warm baths, warm poultices, or narcotic embrocations, such as chloroform liniment, also frequently give relief. Local blood-letting is only rarely indicated. An abundant supply of fluid is always advisable, in order to aid the washing out of the incarcerated stone by an increased secretion of urine.

As we have stated, what has thus far been said obtains chiefly in the treatment of uric-acid and oxalic-acid calculi. We know no special prescriptions to be considered for the occasional cystine calculi. When there are phosphatic calculi, however, which can be deposited only from alkaline urine, the use of acids has been recommended, especially of lactic acid, seven to fifteen grains (grm. 0.5-1), internally in an aqueous solution. The main thing, of course, is always the treatment of the catarrh of the urinary tract, which usually lies at the bottom of the calculus formation.

### CHAPTER III.

#### TUBERCULOSIS OF THE GENITO-URINARY APPARATUS.

**Ætiology and Pathological Anatomy.**—It does not seem remarkable that, with the presence of many tubercular processes in the body, tubercle bacilli should quite easily reach the kidneys by way of the blood-current, and there give rise to an eruption of tubercle. Accordingly, we quite frequently find a few or many miliary tubercles in the kidneys in acute miliary tuberculosis, in pulmonary tuberculosis, etc., which are distributed over the whole kidney, or sometimes only in the territory of one arterial branch.

While miliary tuberculosis of the kidney, however, is without any clinical significance, there is also an extensive local tuberculosis of the kidney, as well as of the urinary tract and the sexual organs. Such affections sometimes occur as a result of pronounced pre-existing tuberculosis of other organs, especially the lungs, or they arise as an apparently independent disease, which is termed genito-urinary tuberculosis. In such cases the infection with the tubercular poison often seems to take place by means of the blood from some previously existing—perhaps concealed—tubercular foci in the body, such as glands, tubercular bone or joint disease, etc. In other cases, the tubercle bacilli perhaps enter the urinary tract from without, but the point of the first anatomical lesion need not, apparently, always be the same. The kidneys often seem to be first diseased, in other cases the bladder, and quite frequently, as it seems, the prostate, and sometimes perhaps the vesiculæ seminales or the testicles. From the organ first affected the process then extends continuously or by leaps to the neighboring parts. If the cases come to autopsy, the tuberculosis is often so extensive that we can no longer make out

with certainty the place where it first began. In women the urinary apparatus is only very rarely affected by tuberculosis, while uterine and ovarian tuberculosis represents a localization of the tubercular poison of clinical importance (compare the chapter on tuberculosis of the lungs).

In the kidneys the tubercular infiltration develops either chiefly from the pelvis of the kidney or in the renal substance itself. Yellow cheesy nodules arise, which finally break down and thus lead to an actual "nephro-phthisis." If the disease arise from the pelvis, the infiltrated renal papillæ are usually first affected, from which the whole pelvis of the kidney is changed into an ulcerating surface covered with necrotic tissue and cheesy detritus. In very advanced cases almost the whole kidney is destroyed. The process is usually bilateral, but it is often more advanced on one side than on the other.

If the process invade the ureters, their walls are also infiltrated with tubercular deposits, and hence they are thickened, while the mucous membrane is often changed in great part to a necrotic ulcerating surface. Precisely analogous conditions are found in the bladder, and in some cases even in the urethra; while in the prostate, the vesiculæ seminales, and the testicles there is more frequently the formation of cheesy tubercular nodules, and more rarely disintegration and perforation.

**Clinical Symptoms.**—The picture of genito-urinary tuberculosis corresponds in most of its details completely to that of a severe chronic pyelo-cystitis. The occasional local symptoms are pain in the region of the kidneys and bladder. This may sometimes assume great severity, like colic, if the ureter become plugged by a broken-down, crumbling mass; yet in other cases the pain is but slight during the whole disease.

The urine shows the most important changes. It almost invariably contains an abundant sediment, consisting of pus-corpuscles and detritus. Its amount usually remains normal for a long time; its reaction is faintly acid, but in severe cases it may become alkaline through complication with an alkaline fermentation of the urine. The discovery of shreds of tissue in the urine, elastic fibers and connective tissue, is sometimes possible, and is of diagnostic value because it is direct evidence of an ulcerative process. The discovery of tubercle bacilli in the purulent urinary sediment (Rosenstein and others) is, however, far more important. This is performed by the same method as in the sputum; it succeeds in almost all cases, and is an infallible and absolutely decisive sign in diagnosis. Admixtures of blood in the urine are also seen in genito-urinary tuberculosis, but they may often be entirely absent. In one of our cases a slight hæmaturia was the first symptom which called the patient's attention to the trouble with the bladder.

The local objective examination of the kidneys usually gives a negative result. Only in a few cases have we been able to feel the diseased kidney as a tumor through the abdominal walls. This is usually due less to the tubercular infiltration of the kidney itself than to the dilatation of the pelvis of the kidney from hydro-nephrosis. We can sometimes feel the thickened walls of the bladder. The local examination of the prostate and the testicles is far more important in diagnosis. Especially in the latter we often feel the hardening corresponding to the tubercular infiltration, and manifesting itself chiefly in the epididymis, while the hardening and enlargement of the prostate can usually be easily detected by rectal palpation.

Among the general symptoms we must mention, first of all, fever, which is only exceptionally absent, and usually, in the severe cases, shows a pronounced remitting, hectic character. The other general symptoms are the same as in most of the other tubercular diseases—anæmia, emaciation, loss of

sing

bodily weakness, etc. We have a special sign in the occasional co-existence of other tubercular diseases in the body, the lungs, the intestines, the bones, etc., but these may also be wholly absent, so that we have to do with a purely local genito-urinary tuberculosis.

The course of the disease is steadily progressive. Recovery does not occur, at least not in any cases where the disease has attained any extent. The disease lasts from a few months to a year or two, but sometimes much longer. The fatal termination usually ensues from the increasing general weakness, more rarely under the symptoms of ammoniæmia, or sometimes from a miliary tuberculosis or some other tubercular disease, such as pulmonary tuberculosis, tubercular meningitis, etc.

**Diagnosis.**—The diagnosis of genito-urinary tuberculosis is now usually no longer difficult in fully developed cases, since it can be made with complete certainty by the discovery of the tubercle bacilli joined to the presence of pus in the urine. Of course this gives no information as to the more special extent of the process. In order to judge of this, we must add the local symptoms and the physical examination of the different organs. We are aided in the confirmation of our first suspicion of a tubercular disease chiefly by the consideration of the general condition and the habit of the patient, the discovery of a hereditary taint, or at least the approximate possibility of tubercular infection, and also the discovery of other tubercular affections, especially in the testicles, the hectic fever, and the tedious course, upon which nothing has a favorable influence. At any rate we must make it a rule, in every case of persistent pyuria which can not be otherwise explained, to examine the purulent sediment for tubercle bacilli. We may then often be able to recognize with certainty the milder and incipient cases of this not very rare affection.

**Treatment.**—Since we do not know at present any efficient remedy to combat the tubercular process, the treatment has merely the task of improving the patient's general condition as far as possible, and also of undertaking a local symptomatic treatment in the same way as in ordinary pyelitis and cystitis (*q. v.*). Of internal remedies we have most frequently used chlorate of potassium and turpentine, and have sometimes seen good results, especially from the latter. The internal exhibition of creosote sometimes seems to us to act well. In vesical tuberculosis it is well to wash out the bladder. As an operative procedure we may remove tubercular testicles and epididymes, but we must remember that in such cases there is usually co-existing disease of other parts of the genito-urinary apparatus, such as the prostate, etc.

## CHAPTER IV.

### HYDRONEPHROSIS.

(*Dilatation of the Pelvis of the Kidney.*)

**Ætiology.**—If a contraction arises in any part of the urinary tract and checks the flow of urine, there is a stasis of the urine in the portion behind the stenosis, which gradually leads to a constantly increasing dilatation of the tract as a result of the pressure of the retained fluid. If the obstacle be situated in a ureter, the pelvis of the kidney, as well as the part of the ureter, dilates, and there arises a so-called hydronephrosis. If, however, the obstacle have its seat in the urethra, the bladder and both ureters gradually dilate, and there finally arises a bilateral hydronephrosis.

A closure of the ureter arises most frequently in adults from impacted renal calculi, and also from new growths in the vicinity, in the uterus or ovaries, which compress the ureter from without. So great a pressure may also be exerted on the ureters by the gravid uterus as to be followed by a hydronephrosis, which is usually bilateral. Cicatricial strictures, valve-formations and bends, also are found in the ureter, and form an obstacle to the flow of urine. Finally, in cancer of the bladder the lower opening of the ureter may be contracted or entirely closed.

Constrictions of the urethra, which finally lead to a bilateral hydronephrosis, arise most frequently from strictures as a result of gonorrhœa, and also from enlargements of the prostate. In a rare cases a phimosis may even form the obstacle.

In general, it is evident that gradual constrictions of the urinary tract and periodic obstructions, as from calculi, interrupted by free intervals, lead to more marked degrees of hydronephrosis than rapid and complete obstructions. Under the first-named circumstances the renal secretion persists much longer and is more abundant than in the latter case, when it usually soon ceases. Nevertheless, even then there still follows a further slow distention of the pelvis of the kidney, since its mucous membrane continues to secrete.

It is worthy of note that hydronephrosis may also be congenital, and then it is usually due to congenital defects of development in the ureters or other urinary passages. In later life hydronephrosis is in general more frequently observed in women than in men.

**Pathological Anatomy.**—The pathological anatomy of hydronephrosis is on the whole very simple. We have a dilatation of the pelvis of the kidney, which is associated with a pressure atrophy of the renal tissue. The papillæ are flattened, the uriniferous tubules and the glomeruli are gradually more and more obliterated, and finally the whole kidney may be changed to a connective-tissue sac filled with fluid. The size of such a hydronephrotic sac may sometimes be so large as to contain ten or twenty quarts (litres) of fluid. The latter consists, of course, at first of urine, but the farther the atrophy of the kidney advances, the more it contains merely the secretion of the mucous membrane. Inflammatory conditions are found in hydronephrosis only when they have existed previously, as in pyelitis calculosa, or when excitants of inflammation in addition have reached the pelvis of the kidney.

**Clinical Symptoms.**—Since the whole type of the disease is, of course, dependent in many respects upon the nature of the primary disease, we have here to describe only those symptoms which point particularly to the development of hydronephrosis. Such a condition often causes no special clinical symptoms at all, so that we can at most suspect its existence from the presence of an ætiological cause.

The appearance of a visible and palpable tumor is the first definite point in the diagnosis of hydronephrosis. This first shows itself in the region of the affected kidney, but then it gradually enlarges toward the hypochondrium and the median line of the body, and it may finally show very considerable dimensions. The tumor is not movable on respiration. Its resistance is usually quite considerable, but sometimes a marked feeling of fluctuation may be present. On percussion, the tumor gives a dull note, from which the tympanitic note of the colon in front of the tumor is sometimes distinct (see page 873). It is an important diagnostic sign if the tumor show variations in its size at times, since it decreases in size with a co-existing increase in diuresis, and increases again when the amount of urine becomes smaller.

In doubtful cas

uncture of the tumor may also be of signifi-

cance in diagnosis. It of course favors the existence of hydronephrosis if urinary constituents, especially urea, can be found in the fluid evacuated; but if the hydronephrosis be of long standing, its contents, as we have said, will be simply sero-mucous, and then chemical examination gives no definite data for distinguishing hydronephrosis from ovarian tumors, or other cystic tumors of the kidney. In regard to the procedure first devised by Simon, which is also important in regard to palliative therapeutics—namely, catheterization of the ureter in women after having previously dilated the urethra artificially, and in this way confirming the diagnosis—the details may be found in the special works on surgery.

The secretion of urine in unilateral hydronephrosis may be completely normal if the other healthy kidney act vicariously. In stricture of the urethra, and also in bilateral constrictions of the ureters, however, there is, of course, an obstacle for the passage of urine, so that the amount of urine may be abnormally small. There may be at times complete anuria, and even uræmic symptoms. The composition of the urine depends entirely upon the form of the primary disease. If only the healthy kidney secrete, the urine passed is normal. If there be at the same time pyelitis or cystitis, the urine may contain pus or blood. If the urine can also come from the diseased kidney at one time and not at another, the urine also exhibits a varying composition, as we have said before (page 886).

In many cases of hydronephrosis quite severe local symptoms are present; there are frequently severe pains in the tumor, which shoot chiefly toward the thigh. Of course, these local symptoms are sometimes only slight. In regard to the symptoms on the part of other organs, gastric disturbances appear to be of the most frequent occurrence; among them are nausea, loss of appetite, vomiting, and eructations. In some cases the bowels are constipated, in others there is obstinate diarrhœa.

The whole course of the disease is always chronic. There are often variations in its course, but no general statements can be given, because the conditions vary in the different cases according to the form of the primary disease. Most cases of hydronephrosis end fatally, either in consequence of the primary disease or in consequence of secondary pyelo-nephritic or perinephritic inflammations, of uræmia, etc. Recovery takes place in rare cases, especially if one kidney be perfectly normal, and there be no incurable primary disease. Recovery may ensue spontaneously from perforation or obliteration, or it may be brought about artificially from operative procedures.

In the **diagnosis** of hydronephrosis, the points especially to be considered have already been mentioned. The diagnosis is usually not easy, especially if the ætiological factors be unknown; and the disease is often confused with other renal tumors and echinococci of the kidneys, with ovarian tumors, and even with splenic and hepatic tumors.

**Treatment.**—Except for the symptomatic treatment of the pain and any accompanying pyelo-cystitis, an efficient treatment of hydronephrosis can be attempted only by surgical means. Puncture, incision, extirpation of the kidney, and the establishment of a renal fistula, are the methods of operation most in use—the details of which are to be found in the special surgical treatises.

---

## CHAPTER V.

## CYSTITIS.

(Vesical Catarrh.)

**Ætiology.**—In most cases of vesical catarrh the agents of inflammation reach the bladder from without through the urethra. The most unequivocal experiment in this regard is, unfortunately, often made by the physician himself, when he excites a cystitis by the use of an insufficiently purified and disinfected catheter or bougie. The development of the vesical catarrh is generally aided in such cases by the fact that there is usually a defective evacuation of urine, from stricture of the urethra or paralysis of the detrusor, and that there is at the same time retention of urine, in which the bacteria can develop undisturbed. The agents of inflammation may also enter from the urethra into the bladder in incontinence of urine. On account of the imperfect closure of the sphincter, a stagnating column of urine, directly connected with the contents of the bladder, forms in the urethra, and to this column the air and the bacteria that excite decomposition of the urine have direct access. In this way many cases of cystitis arise in patients with nervous disease who have paralysis of the bladder, and also many of the frequent cases of cystitis arise in this way in persons who are severely ill and stupid from some other disease, such as typhoid fever.

Cystitis often follows diseases of the neighboring urinary tract. Gonorrhœal urethritis is the most common, and this invades the bladder directly and leads to a gonorrhœal cystitis. In women, the agents of inflammation may quite easily enter the bladder from the vagina through the short female urethra. Thus arise especially the frequent cases of cystitis in childbed. In some cases communications may develop between the bladder and certain neighboring organs, as in vesico-rectal or vesico-vaginal fistulae, by which again access to the bladder is open to the agents of inflammation.

Another group of cases is due to the presence of foreign bodies, which irritate the vesical mucous membrane mechanically. Among these is, first of all, the cystitis which so often accompanies stone in the bladder. It must be stated, however, that many cases of the vesical catarrh which here exists are not directly dependent upon the calculi, but are first excited by examination with catheters and sounds.

In distinction from the methods of the origin of cystitis so far described, the production of inflammation by way of the blood-supply is much rarer. Certain chemical substances, already mentioned (page 837), which are eliminated by the kidneys and provoke an inflammation of the urinary tract, are the most important in this respect. Cantharides shows the most intense action of this sort, and it may cause an actual croupous cystitis. Slight irritative states of the bladder also frequently appear after taking certain foods and drinks, as after drinking new beer. Infectious substances only rarely come under consideration in this regard. Most of the cases of cystitis in severe acute infectious diseases are secondary complications (*vide supra*). It can not be doubted that in some cases an apparently idiopathic primary cystitis appears after exposure to cold, but it is very rare. In such cases we usually have to do with acute exacerbations of an old chronic cystitis—for example, of gonorrhœal origin.

It has been stated in the previous chapters how frequently cystitis is only one symptom of a more extensive disease of the urinary tract. As cystitis may further invade the pelvis of the kidney through the ureters, so, on the other hand, any pyelitis of primary origin may extend downward and involve the bladder.

**Pathological Anatomy.**—The pathological anatomy of cystitis presents the same conditions as the inflammation of any other mucous membrane. In simple

catarrhal cystitis the mucous membrane is swollen and covered with pus, and is often studded with hæmorrhages. In old chronic cystitis the mucous membrane often takes on a slaty, grayish-black color as a result of the hæmorrhages. The severer forms of cystitis, such as are often observed in diseases of the spinal cord, are termed vesical diphtheria. These cases come to a necrotic destruction of the superficial layers of the mucous membrane, ulcerations, etc. In such severe cases submucous and pericystitic abscesses sometimes develop, which may perforate into the surrounding parts in various ways. The incrustation of the mucous membrane with urinary salts, especially with ammonio-magnesian phosphate, is also frequently found in chronic cystitis, and is worthy of mention.

**Clinical Symptoms.**—The local symptoms in the bladder are sometimes quite severe in cystitis, but in other cases they are only slight. In general, they show a greater intensity in acute cases than in chronic cystitis. The pain in the region of the bladder is rarely entirely continuous; it usually comes on only on micturition, but it is often very distressing then, and shoots to the opening of the urethra. Since the inflamed vesical mucous membrane shows an increased irritability, and since the morbidly altered urine (*vide infra*) also exerts an abnormal irritation on the mucous membrane, there is very often an increased desire to micturate. The patient has to empty the bladder much oftener than normal, and in severe cases there is an almost constant, painful "vesical tenesmus," from which, at any attempt to micturate, only a very small amount of urine is passed, with severe burning. As a result of the increased irritability of the vesical mucous membrane, there sometimes comes on a very troublesome reflex spasm of the sphincter, by which the symptoms are increased.

Only the character of the urine is decisive in the diagnosis. This is secreted in a perfectly normal amount and character, in case there is no complication on the part of the kidneys; but in the bladder it is mixed with the products of the diseased mucous membrane, and it is here exposed to the action of the bacteria in a way that will presently be described. The abnormal admixtures in the urine consist chiefly of pus-corpuscles and bladder epithelium, and sometimes of some of the mucus produced by the mucous membrane. The specific action of the bacteria, which have reached the bladder from without, consists of the so-called alkaline fermentation of the urine—that is, in the fermentative change of urea into carbonate of ammonia. This process is associated entirely with the presence of certain micro-organisms, the "*micrococci ureæ*," and the retention of urine as such never leads to an alkaline fermentation. As Lépine and Roux have shown, we can produce a very severe cystitis, and even nephritis, by injecting very small amounts of a pure culture of *micrococcus ureæ* (Cohn) into the bladder of a guinea-pig. The stagnation is only a factor, which greatly aids the whole process since the activity of the bacteria, as we have said, can develop much better here than if the bladder were to a certain degree constantly purified and washed out by the urine that is always coming afresh. As soon as a part of the urea is changed to carbonate of ammonia, the acid reaction of the urine must be less. The urine has a faintly acid or neutral reaction, and sometimes it is even already decidedly alkaline when passed. The latter, however, is only rarely the case, but it is often simulated by the fact that the urine is not examined until it has stood for some time. Since during this time the alkaline fermentation which has once begun makes rapid progress, the cystitic urine that has stood is very often alkaline. Many crystals of ammonio-magnesian phosphate and urate of ammonia then form in it; the former are easily recognized by their "coffin-lid shape," and the latter by their "thorn-apple shape" (see Fig. 116).

If we then briefly put together what has been said, the urine is passed in about the normal amount in cystitis. It usually looks clear, and has an abundant sedi-

ment, which can often be recognized as purulent with the naked eye, and in which, microscopically, we can find pus-corpuscles, often bladder epithelium, and constantly innumerable bacteria—usually short rods in vigorous motion. The alkaline fermentation may usually be recognized by the strong ammoniacal odor,

FIG. 115.—Crystals of triple phosphate and ammonic urate. (From FENKES.)

and also, as we have said, by the reaction of the urine. In the severe diphtheritic forms of cystitis we find entire shreds of necrotic tissue in the urine. If there are hæmorrhages in the bladder, the urine often contains red blood-corpuscles and sometimes even large blood-clots. The mucus in the urine appears in milder cases as a cloudy opacity—"nubecula." The viscid masses which can be drawn out into threads, and which are usually abundant in the urine in severe cystitis, are not the special product of the mucous membrane, mucine, but they arise from the pus-corpuscles and the epithelium dissolved in the alkaline urine, and hence give the reactions for albumen. It goes without saying (compare page 824) that every cystitic urine is albuminous from its mixture with pus-serum.

The presence of slimy threads in the urine—the so-called "clap-threads" (*Tripperfäden*)—is characteristic of gonorrhœal cystitis.

There can be no doubt that the decomposing alkaline urine acts as a chemical excitant of inflammation on the vesical mucous membrane. Hence cystitis often arises perhaps in this way, that the bacteria which have entered the bladder first excite only an alkaline fermentation, and that then the mucous membrane is affected by the irritation of the ammonia salts that are formed. It is, however, at present hard to decide, and it is also without special practical interest, whether the bacteria as such can not directly excite inflammation.

The other morbid symptoms associated with cystitis usually depend only in part upon the disease itself and in part upon some existing primary disease. The most important symptom is the fever, which is often to be referred directly to the cystitis. In severer cases it may be very intense, and often assumes a pyæmic intermittent character, especially if there have arisen pericystitic suppurations or if the cystitis has extended to the pelvis of the kidney and the kidneys (see page 881). An acute cystitis may also begin with a chill and high fever. If the escape of the purulent urine, however, always remains undisturbed, the fever may be entirely absent in spite of the existence of cystitis.

Sometimes in severe cystitis with a marked alkaline fermentation certain nervous symptoms appear, such as headache, vertigo, stupor, and nausea. The idea has been advanced that in these cases we have to do with an auto-intoxication of the body, since ammonia and perhaps other products of decomposition, like sulphuretted hydrogen (?), are absorbed from the bladder into the blood (ammoniaemia), and in this way excite the symptoms of poisoning mentioned.

According to the course of the disease we distinguish an acute and a chronic cystitis. The former, which may come on, for example, after catheterization, in gonorrhœa, etc., often passes off favorably after a few days. The amount of mucus and pus in the urine remains slight. Chronic cystitis is observed especially as a complication in other diseases of the urinary tract, like stricture, in chronic diseases of the spinal cord with paralysis of the bladder, etc. It is very often

incurable because the primary disease is incapable of improvement and the cause of the disease therefore persists. The longer a cystitis lasts, the nearer is the possibility of the development of more severe and dangerous complications, especially the development of a pyelo-nephritis, and the formation of pericystitic suppurations. In this way cystitis, especially in chronic nervous diseases, may become the immediate cause of death.

**Treatment.**—The dangers last mentioned must urgently impress upon us the prophylaxis of cystitis. Fortunately, a good deal can be done in this respect, in the first place, by the avoidance of all unnecessary use of bougies and catheters, by the greatest care for cleanliness in the use of all instruments of this sort, and by the timely treatment of all those conditions which may lead to cystitis.

The treatment of cystitis is, in the milder and acute cases, hygienic and medicinal, but in the severer cases only a careful local treatment can be useful.

In any severe, and especially in any acute cystitis, the greatest bodily rest (if possible rest in bed) is urgently desirable, since otherwise an increase of the symptoms and a prolongation of the course of the disease is the almost inevitable result. The diet must be mild and unirritating. Spiced food and alcoholic drinks are to be avoided, but we should recommend an abundant supply of fluid, by which the urine is diluted and the bladder washed out. We have the patient drink plenty of ordinary water, tea, or a suitable mineral-water, like Wildunger, Selters, or Fachingen. A diet mainly of milk is very good; by it the cystitic symptoms often very rapidly cease.

Among internal remedies those are to be considered which are eliminated with the urine, and are thus able to act on the diseased mucous membrane, or directly upon the agents of inflammation. One of the most efficient drugs, which never does harm with necessary caution, is chlorate of potassium, of whose favorable influence on vesical catarrh we have often convinced ourselves. It is prescribed in an aqueous solution, forty to seventy-five grains a day (grm. 3-5), and should never be taken on an empty stomach. Salicylic acid is sometimes used with good results in doses of half a drachm to a drachm (grm. 2-4) a day in ten-grain (grm. 0.5) capsules. The two remedies mentioned have largely replaced tannin, which was formerly in great favor. At present a decoction of *uva ursi* is still more frequently prescribed, 10 or 15 to 150, whose active principle, arbutine, in doses of forty-five to sixty grains a day (grm. 3-4) in an aqueous solution, seems worthy of further trial (Lewin and others). In more advanced stages of vesical catarrh, if the initial symptoms of irritation have ceased, the resinous drugs are to be used, of which oil of turpentine and balsam of copaiba especially sometimes show a very good action. Both are best given in gelatine capsules.

If there are severe local symptoms, we prescribe warm compresses and poultices to the region of the bladder. In robust persons with acute cystitis, local blood-letting, three to six leeches to the perineum, sometimes has a decidedly favorable symptomatic action in such a case. In other respects narcotics, especially subcutaneous injections of morphine, are the best remedy where there is severe pain and tenesmus. Camphor, extract of belladonna, etc., are much more uncertain in their action. The frequent use of protracted warm baths may, however, be greatly recommended.

In chronic cystitis all the remedies previously mentioned are also to be considered; but they are usually not sufficient alone, and at any rate they are far less effective than a methodical local treatment. This consists in washing out the bladder regularly every day by the aid of an elastic catheter, to which a T-tube is fastened by means of rubber tubing, one arm being connected with an irrigator and the other with the escape-tube. We thus let a moderate amount of fluid, eight or ten ounces (200-300 c. c.), run into the bladder and run out again, fre-

quently repeating the process, until it comes away perfectly clear. For this purpose we use either pure warm water, or, better, a dilute solution of plumbic acetate (1 to 1000), permanganate of potassium (1 to 1000), boric and salicylic water, and the like. By such a treatment many cases of chronic vesical catarrh may recover, and others may at least be kept constantly in check.

Attention to the causal indication is sometimes very important also in chronic vesical catarrh—for example, the treatment of any strictures, the removal of calculi, or the improvement of paralytic states of the bladder.

In pericystitic suppuration surgical treatment is only rarely possible. We must, therefore, confine ourselves to purely symptomatic procedures.

---

## CHAPTER VI.

### NEW GROWTHS IN THE BLADDER.

**PRIMARY** new growths in the bladder are quite rare. The commonest is the so-called villous cancer (which is properly a papillary fibroma), which may attain the size of a walnut, and is usually situated in the lower portion of the bladder near the entrance of the urethra. Since the tumor is usually very vascular, there are often hæmorrhages into the bladder, and repeated hæmaturia is therefore one of the commonest symptoms of vesical papilloma. In this affection the blood-clots often assume a peculiar long, worm-like shape, from their passage through the urethra. Severe symptoms on micturition sometimes appear, since portions of the tumor may lie in front of the opening of the urethra. A definite diagnosis of a villous tumor is possible only when single portions of the tumor are thrown off, and are found in the urine passed. Examination of the bladder by the catheter may also give information as to the presence and seat of the tumor.

Primary carcinoma of the bladder is rare. It is usually spread diffusely over the wall of the bladder, and leads to so considerable a thickening of it that we can often feel the bladder from without through the abdominal walls. Otherwise the symptoms are the same as in severe chronic cystitis. The urine contains much pus, and is sometimes bloody. The general cancerous cachexia developed rather late in the cases which we have seen, of which one was in a man still quite young. The diagnosis is not always easy. Except from attention to the general course of the disease and any vesical tumor that may be felt, it must aim to be based chiefly upon the discovery of particles of cancer in the urine.

A secondary invasion of the bladder by carcinomatous new growths from the uterus, rectum, and vagina is quite frequently observed.

The treatment can usually be only symptomatic, since surgical procedures are possible only in rare cases.

## CHAPTER VII.

**ENURESIS NOCTURNA.***(Nocturnal incontinence of Urine.)*

ENURESIS nocturna is a nervous affection of the bladder by no means rare in children of both sexes, and therefore quite important in its practical relations. Of course, in small children there is no sharp boundary to be drawn between normal and pathological conditions; but it is decidedly pathological if larger children, from four to ten years of age and even older, pass their urine in bed more or less frequently during sleep, in spite of well-developed reasoning powers and professedly the best intentions. This anomaly may extend to the years of puberty and even beyond it, and then it frequently produces a very depressing mental affection for the patient. Special causes for it are not to be discovered in most cases. We are compelled to assume either an abnormal weakness of the sphincter, which is probably sometimes congenital, or an abnormal irritability of the detrusor. At any rate, in wetting the bed at night the process of micturition comes on in a purely reflex way, but it is often accompanied by certain ideas in dreams referable to micturition. It does not hold in all cases that the sleep is especially deep. Many patients, of course, first notice the trouble in the morning, but others almost always wake directly after. The involuntary micturition usually occurs in the first hours after going to sleep, but sometimes it is later, and even first toward morning. By day micturition is often perfectly normal; but in many cases there is even then a noticeable weakness of the bladder, so that the child has to make water oftener than usual, and sometimes wets its clothes even by day.

Although, as we have said, we can usually find no special cause for the trouble, still, in some cases, certain morbid changes in the urinary organs may give rise to the incontinence. We should, therefore, in every case at least think of the possibility of stone in the bladder, of congenital phimosis and adhesions of the prepuce to the glans penis, of ascarides, and of inflammatory conditions, and make a special examination of these points. We must also bear in mind polyuria caused by diabetes or renal disease, and finally, of course, in the diagnosis of a purely nervous nocturnal incontinence of urine, we must exclude the existence of any actual anatomical spinal affection.

In all the cases just mentioned, the treatment must of course refer first to the primary disease; but in the ordinary nocturnal incontinence the treatment must first take into consideration the prevention of the appearance of nocturnal micturition as far as possible. The child must take only a very little fluid in the evening, and he should be made to empty his bladder immediately before going to sleep, and once again later. He should not be covered up too warmly, and, if possible, he should not lie on his back during sleep. Tying a brush to the back is therefore a well-known domestic remedy. A somewhat strict mental treatment is often effective, since thus the attention to the process is increased, although unconsciously, and the child often learns to wake up at the right time. The use of the rod is of course on the whole only rarely admissible. On the contrary, we often have to protect the child against unreasoning parents.

Internal remedies, especially belladonna and tincture of nux vomica, which were formerly recommended, rarely avail. Iron preparations are indicated only in anæmic children. Electrical treatment, however, is often, if not always, very effective. We put the broad anode over the lumbar cord, and the smaller kathode over the region of the bladder or on the perineum, and let quite a strong constant current pass through for two or three minutes. Then we pass the wire

end of a conducting cord, which we make the kathode, into the mouth of the urethra for one or two centimetres, and let quite a strong and somewhat painful faradic current act for one or two minutes (Seeligmüller). The sittings must at first be repeated daily. It is also a very good plan to let the whole body be well rubbed with cold water before going to sleep.

The prognosis of these forms of incontinence, which have no organic disease at the bottom of them, is almost always favorable, since in the worst case the anomalous condition usually disappears gradually of itself with increasing years.

[Belladonna, strychnia or nux vomica, or a combination of the two, are often of unquestionable service. If the enuresis is only nocturnal, belladonna alone may be used, either in a single dose at bedtime or three times a day. If the enuresis is diurnal also, the two drugs should be combined and given three or four times a day.]

## DISEASES OF THE ORGANS OF LOCOMOTION.

### CHAPTER I.

#### ACUTE ARTICULAR RHEUMATISM.

**Ætiology.**—Acute articular rheumatism is an infectious disease. This is shown by all the clinical and anatomical peculiarities of the disease; and, although the specific organic pathogenetic poison can not yet be demonstrated, still this view of the disease, which was first brought forward by Hüter, is the only one which enables us properly to understand its symptoms and course.

Like many other infectious diseases, acute articular rheumatism is often indisputably endemic and epidemic. According to Hirsch, the disease is most prevalent in the temperate zones, being much rarer in cold and tropical latitudes; but even in Europe it is by no means uniform in its frequency, and certain districts of England, Belgium, and Russia are said to be almost exempt from it. It is also possible to observe epidemic influences with regard to the frequency of its appearance, as already intimated. Here in Leipsic, where articular rheumatism is one of the most frequent of acute diseases, we have observed for years that at certain times there are only a few cases, while at others there is a striking increase in their number. Usually attacks are most prevalent in the winter and spring months, but again it is sometimes in summer that the disease is especially common.

Among the exciting causes of the disease, taking cold is always mentioned as of first importance; and in fact it can not be denied that the influence of cold does often seem to contribute to the occurrence of the disease.

This result, however, seldom follows a single severe exposure, but it rather follows persistent causes, and in particular the long-continued influence of wet and cold, as in certain occupations—for example, washing and scrubbing, or inhabiting unhealthy damp dwellings, and the like. This explains why those who follow certain callings are especially subject to articular rheumatism; thus servant-girls and coachmen are frequently victims to the disease. And yet it is possible to regard all these injurious influences as being merely indirect causes, inasmuch as they favor the development or action of the specific micro-organisms; and, furthermore, it is by no means exceptional to see a case of articular rheumatism where no history of exposure to cold can be obtained.

Sex exerts no special influence upon the frequency of the disease. As to age, acute articular rheumatism is most frequent in young adults between fifteen and thirty-five years of age. In later life, and particularly in old age, it is much rarer. In children six years old or more the disease is not especially infrequent, but in younger children it occurs only exceptionally. We may be permitted to mention a single interesting case which we met with here in Leipsic, where a child who died when only a few days old, and whose mother at the time of its

birth was suffering from a severe attack of acute articular rheumatism, was found to have multiple purulent arthritis.

Much has been said with regard to the relations of acute articular rheumatism to other acute diseases. We must, therefore, call particular attention to the fact that the joint diseases, whether simple or multiple, which occur after scarlet fever, gonorrhœa, or in connection with puerperal and septic diseases, as well as recent cases of secondary syphilis, have nothing to do with genuine acute rheumatism. In cases of this sort the trouble in the joints is merely a special localization of the general disease; and, indeed, the circumstance that the joints are a favorite point of attack for infectious diseases may be brought forward as another proof that acute articular rheumatism is of infectious origin. There is, however, a single affection, namely, chronic endocarditis, about which the facts are different. This disease is etiologically identical with acute endocarditis, and therefore with acute rheumatism (*vide infra*). At least this is true in many cases, although probably not in all. It may be regarded as a proof of this connection between the two diseases that patients with chronic cardiac disease are especially liable to attacks of acute articular rheumatism. Here, therefore, we have a genuine articular rheumatism as a symptom of more general disease. It may be regarded in some sense as a fresh acute exacerbation of this disease, localized mainly in the joints.

A very noteworthy fact is that acute articular rheumatism can not be numbered among those infectious diseases which usually occur but once in the same individual. This disease, on the contrary, resembles pneumonia and erysipelas, in that it is very apt to occur repeatedly in the same person. Acute rheumatism, therefore, even when it ends favorably and leaves behind it no evident lesions, seems to render the patient more liable to the disease than he was before.

**Symptomatology.**—The chief symptom of acute articular rheumatism is an acute febrile synovitis, which almost always affects several joints. The synovitis is associated with the usual local phenomena of swelling and tenderness in the parts affected. Often this articular affection is the first symptom, and, indeed, it may be the only symptom of the disease. It is, however, by no means exceptional for the arthritic trouble to be preceded by certain prodromal or initiatory symptoms, as is true of other infectious diseases. These prodromata consist either of a slight general malaise, or of certain local symptoms. It is not rare to have sore throat, or, as we have repeatedly had opportunity to observe, laryngitis. These premonitory symptoms are, however, generally insignificant, and may, as we have said, be entirely absent.

The articular disturbance is almost always very rapid in its development. Some of the larger joints are usually first affected, and perhaps those of the lower extremities somewhat oftener than those of the upper. It is extremely exceptional for all the joints that are affected to be attacked at one and the same time. It is somewhat characteristic of acute articular rheumatism that it "jumps from one joint to another." To-day this joint will be affected and to-morrow that, while the joint first attacked may still remain diseased or undergo rapid recovery. Thus, there may be either a few joints affected or many, in varying sequence, and they may sometimes be affected rapidly and at other times more slowly. In many of the milder cases the disease is an extremely temporary one, while in others it may attach itself most persistently to some one or more joints.

There is usually fever in addition to the arthritis; but it is not usually very high, seldom exceeding 103° (39.5° C.). The fever, on the whole, corresponds with the arthritic phenomena, and does not present a curve which is at all typical, but one which is irregularly remittent. We have scarcely ever seen the disease begin with an initial rigor, nor are the so-called "general febrile symptoms" of headache, stupor, and subjective feeling of heat as a rule at all marked in acute rheumatism.

This indicates that the constitutional infection does not as a rule attain great severity. The skin is noticeably inclined to perspiration, but the perspiration is not at all a result of any sudden fall in temperature such as is seen in other diseases.

The course of the disease is marked by alternate ameliorations and aggravations of the local symptoms and of the fever, and lasts, particularly if it is not treated, one or more weeks, or a still longer period. Then, as a rule, the symptoms gradually abate and convalescence begins; but it generally is tedious and frequently interrupted by relapses. In other cases, however, the disease contrasts strongly with this simple course, for articular rheumatism is notoriously subject to numerous complications and peculiarities in its course. The protean character of the disease will be evident upon a perusal of the following description of the symptoms referable to the different organs of the body.

**Symptoms referable to the Different Organs, and Peculiarities in the Course of the Disease.** 1. JOINTS AND SHEATHS OF THE TENDONS.—The favorable termination of most cases of acute articular rheumatism prevents us from often examining the anatomical changes in the affected joints; but there can be no doubt that in most instances the trouble is merely a simple serous synovitis—that is, an inflammation of the synovial membrane, with an exudation into the cavity of the joint composed mainly of serum with but little admixture of fibrine and pus. The synovial membrane itself, in the cases which do come to autopsy, is usually very little affected. It is somewhat injected, opaque, and thickened. Necrosis of the cartilages is seen only in severe cases, or in those which have lasted a rather long while. From a clinical standpoint, the articular disturbance is noticeable chiefly for the pain which it causes the patient upon every movement of the joint and any pressure upon it. The painfulness is often in striking contrast with the slight apparent change in the structure of the joint, for a joint which is extremely sensitive may appear to be scarcely at all diseased. Usually, however, the joints exhibit the signs of synovitis. The effusion into the joint produces an evident swelling, which can be seen particularly well in the knees, but also in the joints of the ankle, wrist, shoulder, and elbow, and sometimes even in the smaller joints of the fingers and toes, particularly the great toe. It is rather exceptional to detect swelling of the hip-joint. It should be remembered, however, that the swelling in the region of the joint, particularly the ankle or wrist, is often less the result of a synovial effusion than of an inflammatory periarticular œdema. This œdema, for example, may extend over almost the whole posterior surface of the hand. The joints are by no means invariably the only parts attacked. Not infrequently there are analogous inflammatory changes visible in the sheaths of the tendons, the bursæ, and perhaps, in many cases, even the fasciæ and muscles. The skin over the affected joints often has an inflammatory blush, which is usually pale red and spotted, and can be best seen at the ankle, knee, and wrist. It has been maintained that the cutaneous sensibility is diminished over the joints affected, but we regard this as a mistake.

As might be expected, the number of joints attacked and the sequence in which they are attacked differ greatly in different cases; but almost invariably a number of joints suffer, so that any monarticular arthritis should not be regarded as rheumatic except after careful deliberation (*vide infra*, diagnosis). It should be said that, in mild cases, there may be only two or three joints affected, these being usually some of the larger joints of the extremities; and of these, one may be so much worse than the others that their participation in the trouble can be ascertained only by careful questioning and examination. In severe cases, on the other hand, the number of joints attacked is often very great. Such patients become extremely helpless, because any movement is possible, if at all, only under the

penalty of very severe suffering. The patient usually lies with bended knees and feet curved so as to be concave on the plantar surface, and screams with pain at any attempt to change his position. The joints of the trunk sometimes participate in the disease, but hardly ever except in the severe cases. The articulations of the vertebrae, the sterno-clavicular joint, the articulation of the lower jaw, and the symphysis pubis, are particularly apt to be affected. The fugitive character of the arthritis has been spoken of as characteristic of acute articular rheumatism, and, indeed, it is not infrequently the case that comparatively large swellings of the joints soon abate and yield to new disturbances in other joints; but, on the other hand, the disease may persist very obstinately in a single joint. In this case one joint, or rarely several, are attacked with marked severity, either from the start or subsequently to milder affections of other joints, and often remain for weeks swollen or painful long after all other symptoms have vanished.

2. CARDIAC SYMPTOMS.—The condition of the heart in acute articular rheumatism is next in importance to that of the joints. The physician should therefore, in every case, even the mildest, maintain a continuous watch over this organ. In 1836 Bouillaud made careful auscultatory investigations in this disease, and was thus the first to discover that the course of acute articular rheumatism is, with noticeable frequency, accompanied by endocarditis, and sometimes even by pericarditis. Complications of this sort may occur in any case, whether mild or severe, or may be absent in any case, even the worst. They may develop at the beginning or later on in the course of the disease. Their development is often unattended by any subjective symptoms, so that they can be recognized only by careful physical examination. In many cases, however, the onset of cardiac disease is marked by a fresh exacerbation of the fever, or possibly by palpitation, or by painful sensations in the præcordia, or by dyspnoea.

We will consider first rheumatic endocarditis. This is almost always the benign verrucous variety (see page 278).

It is far more prone to attack the mitral than the aortic valves, and is accordingly usually betrayed by a blowing systolic murmur at the heart's apex. Uncertainty may be cast upon the diagnosis by the fact that functional murmurs are not very infrequent at the apex of the heart in cases of acute articular rheumatism. We once observed a case of "hyperpyretic rheumatism" (*vide infra*) where there was an evident murmur of this sort during life, and yet at the autopsy we were able to assure ourselves of the complete integrity of the cardiac valves. Even an expert may for a time be in doubt as to the significance of many cardiac murmurs, and this explains in part the conflicting statements as to the frequency of cardiac complications in acute rheumatism. In general, one may say that such complications occur in 25 to 33 per cent. of the cases. The ultimate results of this endocarditis we do not need to describe over again in this connection (see the chapters on acute and chronic endocarditis). Complete recovery is possible. Often, however, the lesion gives rise to a chronic endocarditis—that is, to a cardiac valvular disease, which lasts through life.

The close connection between endocarditis and the arthritis must formerly have seemed very puzzling, despite the many hypotheses made to explain it. If, however, we regard acute articular rheumatism as an infectious disease, this obscurity vanishes. Acute articular rheumatism is plainly not a merely local disease, but the result of a general infection. The specific pathogenetic matter is not only present in the joints affected, but it also circulates in the blood. It is therefore easy to understand why the valves of the heart should be affected, as it is the case in so many infectious diseases (see page 276). The micro-organisms in question produce a valvular endocarditis, therefore, is not strictly a "complication,"

Rheumatic pericarditis is not infrequent, although less common than endocarditis. The only certain way to recognize it is by a characteristic friction-sound; and even when this is heard there may be a doubt as to its significance, inasmuch as functional murmurs are not infrequently heard at the base of the heart. The pericarditis is of a sero-fibrinous nature. Sometimes it is of slight severity; but it may be extremely severe, with a large effusion and the most urgent dyspnoea (see page 323). In rare instances this pericarditis proves fatal. Usually, however, recovery ensues, although in severe cases there may be obliteration of the pericardial sac, with the consequences described on page 326.

With regard to the origin of the pericarditis, it may be said that it would not be impossible for the pericardium to be directly infected by the blood. We have reason, however, to believe that in most cases the infection proceeds from the endocardium, and probably in the great majority of cases from the aortic valves (see page 298). It is not always possible to prove that an endocarditis precedes the pericarditis, but yet this does not overthrow the opinion we have expressed, inasmuch as many cases of acute endocarditis do not betray themselves by any audible murmurs.

We should also mention that there may be functional cardiac derangement without any grave anatomical lesion. We have already spoken of the functional murmurs. There may also be a rapid and irregular pulse, and, in rare instances, attacks of angina pectoris of apparently purely nervous origin.

3. SEROUS AND MUCOUS MEMBRANES.—The pleura and peritoneum, as well as the pericardium, may be affected in articular rheumatism; so that it was formerly often maintained that acute articular rheumatism is a disease of the serous membranes of the body in general, inclusive of the joints. Rheumatic pleurisy is much rarer than either endocarditis or pericarditis; and rheumatic peritonitis is rarer still. The pleurisy, at least in most instances, is propagated directly from an inflamed pericardium; and in the same way the peritoneum may become infected from the pleura by way of the diaphragm. Few of these severe cases, presenting a simultaneous inflammation of several serous membranes, occur, now that the salicylic-acid treatment has been introduced. We do not say that it is absolutely impossible for a pleurisy or a peritonitis to occur in rheumatism without inflammation in any other serous cavity, but such an occurrence is extremely rare.

The mucous membranes are seldom greatly affected in acute articular rheumatism. As has already been stated, a catarrh of the pharynx or larynx sometimes occurs in the beginning of the disease. Bronchitis is often spoken of by the older authors; but it is probably in many cases not due directly to the rheumatism, but it is a complication, just as in any disease attended by great prostration. The stomach and intestinal canal are seldom especially affected.

4. SKIN.—Cutaneous phenomena are not infrequent in the course of acute articular rheumatism. A prominent symptom of the disease is the tendency to profuse perspiration. The perspiration often has a strongly acid odor and reaction. Many patients exhibit an abundant crop of sudamina, the back in particular being sometimes entirely covered. Sometimes there are other cutaneous eruptions. In a whole series of cases we observed erythema nodosum. This affected the lower extremities more than the upper. Urticaria is not very infrequent, while herpes labialis has been very rare in our experience. It is well known that arthritic affections and the so-called "haemorrhagic diseases" are in many ways related to each other; and it is therefore an interesting fact that extensive haemorrhagic disturbance of the skin also occurs in connection with acute articular rheumatism, as we have repeatedly had opportunity to observe. We have seen several cases of haemorrhagic urticaria: wheals appear upon the

skin, and a hæmorrhage takes place into their centers and spreads gradually. There may also be simple cutaneous ecchymoses. These may in severe cases be merely one symptom of a general hæmorrhagic diathesis, with hæmorrhages from mucous membranes. The occurrence of these symptoms again points most clearly to the infectious character of acute articular rheumatism.

5. THE MUSCLES AND NERVOUS SYSTEM.—The condition of the muscles is very important in many cases of acute polyarthritis. They are often quite painful on pressure, and apparently somewhat swollen about a joint that has been long affected. The muscular atrophies and muscular paralyses that often remain after the arthritis is well are especially important.

According to a general law, there are certain definite trophic relations between a joint and the muscles belonging to it, whereby almost every severe and persistent disease of the joint is necessarily followed by an atrophy of the affected muscles. The extensors of the joint are often most affected by this atrophy. This atrophy has long been recognized, and was formerly regarded, particularly by surgeons, as merely the result of inactivity of the muscles—"atrophy from disuse"; but this view is certainly erroneous. We do not know its precise cause, but it is without doubt the result of the disease of the joint, and may therefore be termed "muscular atrophy of arthritic origin." If an attack of acute articular rheumatism affects any one joint for a long period there is a secondary atrophy of the corresponding muscles. This is seen most often, and in its most typical form, where there is obstinate trouble in the shoulder-joint, the deltoid becoming extremely atrophied. This atrophy of the muscles may contribute largely to the sum-total of functional derangement. We have repeatedly seen cases where the patient could hardly lift his arm at all, although the inflammation of the shoulder-joint had passed away, and that without leaving any ankylosis. It is therefore entirely justifiable to speak of a rheumatic paralysis. We have seen similar muscular paralyses after acute articular rheumatism in the rest of the muscles of the upper arm, also in the quadriceps extensor, and once in the serratus magnus. The explanation given by Chareot, that the cause of the atrophy is a "reflex" implication of the trophic centers in the cord which starts from the joint, seems to us hardly satisfactory. There are probably local disturbances of nutrition, and sometimes apparently a direct extension of the inflammatory process from the joint to the neighboring muscles. It is noteworthy that the atrophied muscles respond promptly to the faradic current, and never exhibit the reaction of degeneration.

Chorea (*vide supra*, page 780) may be a sequel of acute articular rheumatism, and it is one of the nervous symptoms which may arise in connection with it. This complication is seen most frequently in children. Endocarditis may accompany it, but it does not always do so.

There are certain peculiar cases of acute articular rheumatism which excite the greatest interest. In these, very severe cerebral symptoms are developed, often most acutely. They are therefore called "cerebral rheumatism"; or, as they are almost always characterized by an extraordinarily high temperature, another name is "hyperpyretic articular rheumatism." In these cases the disease may exhibit severe nervous symptoms from the start, particularly delirium; or it may at first run an apparently favorable course, and not change for the worse until after several days, or even at a later period. The change may be quite abrupt. The temperature rises to 104° or 106° (40°-41° C.). There are great uneasiness, delirium, and sometimes also signs of motor irritation, such as general convulsions, or tonic spasm of the extremities, or trismus. The face grows pale and cyanotic, the pulse small and extremely rapid. With slight interruptions, the temperature continues to rise, and attains 107.5° to 109.5° (42°-43° C.). This great rise is most apt to

occur just before death, and there may be a still further increase of temperature after death occurs. As has been implied, the termination is usually unfavorable. It is only in exceptional cases that recovery takes place.

It has been stated that cerebral rheumatism attacks mainly hard drinkers and other individuals whose nervous system has been previously impaired; but our own experience does not confirm this view. No case is absolutely secure from the occurrence of hyperpyrexia; but it is a very rare phenomenon, occurring perhaps once in several hundred cases. On post-mortem examination, the brain seldom shows any change in these cases of cerebral rheumatism. We are therefore obliged to regard the condition as the result of an unusually severe infection, affecting chiefly the intellectual, motor, and thermal centers. Cases have also been reported where there have been actual anatomical lesions of the brain—in particular, purulent meningitis. Probably, however, most of these cases were falsely diagnosed, the observer having confounded articular rheumatism with epidemic meningitis, pyæmia, and similar diseases. Of course, if there be endocarditis, cerebral embolism is possible. Mental derangements deserve a brief mention. They rarely occur during the course of the disease, but are somewhat more frequent after it has terminated. We may have either melancholia attended with marked excitement or anxiety, or a more general insanity. The prognosis is usually favorable.

6. OTHER VISCERA.—Other parts of the body than the heart, the serous membranes, and the brain, are seldom much affected in articular rheumatism. Lobar pneumonia occurs only in especially severe cases, but in such it may attain quite a considerable development and occasion great dyspnoea. It usually requires quite a long while to recover from it. Lobular inhalation-pneumonia may also occur in severe cases. Acute nephritis has certainly sometimes occurred, but it is extremely rare. The spleen may be somewhat swollen, but it is not the rule to find a splenic tumor, such as is present in other acute infectious diseases.

7. GENERAL SYMPTOMS.—In many cases the general condition of the patient is but little affected, but in others the disease seems to exert a peculiar influence upon the constitution. This may show itself in a striking anæmia; and we have observed this repeatedly where there was no cardiac complication. Another much more dangerous but extremely rare complication has already been briefly referred to, namely, the occurrence of a general hæmorrhagic diathesis. This is almost always associated with high fever and great prostration, and is usually fatal.

**Course, Duration, and Prognosis.**—Acute articular rheumatism may be described as generally a benign disease, for it usually terminates in recovery. It is only in a very few cases that an unfavorable termination takes place immediately, whether as the result of pericarditis or other severe cardiac complication, or from hyperpyrexia, or the development of a general hæmorrhagic diathesis. The entire duration of the disease varies greatly according to its severity. There are mild cases, which terminate in a few days; and, on the other hand, the disease may be very tedious, lasting for weeks and months, and finally merging into chronic articular rheumatism. Quite often the violent symptoms experienced at first disappear quite rapidly, but only to be replaced by such milder ones as pain and stiffness of the joints—these latter persisting for a long while. It is a general rule, that the severity and persistency of the case correspond with the number of joints affected; but to this rule there are numerous exceptions. The disease may persist with great obstinacy in a single joint. It need hardly be said that the duration of the disease is greatly modified by the occurrence of complications, cardiac or otherwise, and such sequelæ as muscular atrophy, ankylosis of the joints, or chorea. The most important of all sequelæ is cardiac disease, and this must always be

considered in giving a prognosis; for, although the disease as such does in most instances terminate in recovery, yet too often it gives rise to a tedious and usually incurable disease of the heart. It is, however, true that complete recovery from the acute endocarditis seen in articular rheumatism is possible, but in a large majority of cases recovery is not complete, and the acute passes into a chronic endocarditis. In these cases the cardiac symptoms may be developed directly, so that the patient at once begins to complain of palpitation and shortness of breath; or he may seem to regain his health completely, and a murmur which the physician alone can detect may be the only sign of the incurable injury which the body has suffered. The patient may feel perfectly well for years after, and then at last begin to suffer from the failure of compensation (see page 283 *et seq.*).

**Diagnosis.**—Most cases of articular rheumatism can be easily recognized, for the acute occurrence of pain and swelling in several joints is sufficiently characteristic of the disease. It should nevertheless be borne in mind that articular swelling may also take place in the course of other diseases, and that mistakes in diagnosis are by no means impossible. Where there are grave constitutional symptoms with fever from the start, we should not forget the possibility of pyæmia, or of acute osteomyelitis, since these affections occasionally give rise to the swelling of several joints. In such cases, however, careful attention to the further course of the disease will generally enable us to see that we can not be dealing with a simple acute articular rheumatism. Again, after childbirth there may be swelling of the joints, of septic origin, and therefore entirely independent of any genuine rheumatic infection.

If a single joint be attacked, the diagnosis of articular rheumatism must be made with extreme caution. These monarticular inflammations often prove to be something entirely different, namely, fungous disease of the joint, or an osteomyelitis. The arthritis which follows gonorrhœa is also sometimes monarticular (affecting especially the knee-joint), or at any rate it is confined to the lower extremities; and, in conclusion, it should be stated that it is not very rare to observe pain and swelling in various muscles and joints at the commencement of the secondary stage of syphilis, simulating an acute articular rheumatism.

Sometimes the diagnosis is doubtful in those cases which present cutaneous ecchymoses (purpura and peliosis) and erythema nodosum, because we may be unable to determine which should be regarded as the primary symptoms and which the secondary; but in these cases, after all, it is often merely a question of nomenclature, and the best way is to follow the rule that the greater should include the less.

Genuine gout (*q. v.*) can usually be readily diagnosticated from articular rheumatism by its localization in the toe, and by the gastric and other symptoms which attend it.

Finally, we must mention that acute multiple neuritis (*q. v.*), beginning with fever and severe pain in the extremities, may sometimes, if we are not sufficiently careful, be mistaken for polyarthritis.

**Treatment.**—Acute articular rheumatism is one of the few diseases for which we possess an undoubtedly specific and universally accepted remedy. Kolbe suggested its use, and since 1876 it has been largely employed upon the recommendation of Stricker, Buss, and others, for articular rheumatism. This remedy is salicylic acid. Although this medicine does not in all cases produce its surprisingly favorable results with equal rapidity and completeness, yet it almost invariably does produce a decided and beneficial effect upon the disease. We might even say that this influence is so constant that where salicylic acid proves entirely inefficient in a fresh case, such failure throws doubt upon the correctness of diagnosis. Thus, where there is monarticular arthritis dependent upon

cause, the remedy has hardly any beneficial influence. The same is true with regard to affections of the joints connected with gonorrhœa, pyæmia, and similar troubles. In genuine acute articular rheumatism, on the other hand, the salicylic acid treatment is so superior to any other that it is the first duty of the physician in every case to give this remedy a fair trial.

There are but two preparations of salicylic acid used in rheumatism—the pure acid and its sodium salt, salicylate of sodium. Each of these two remedies has its peculiar advantages, but the specific influence of each is about the same. Salicylic acid should never be prescribed in solution, but always in capsules, usually containing ten grains (grm. 0.50). In this way the salicylic acid can be taken by almost any patient quite easily, especially if a little water or milk be drunk after each dose. Adults should receive ten grains every hour until about one or two drachms (grm. 5–8) have been administered. Usually there will by this time be a very decided abatement of the articular pain and swelling, while on the other hand there will also usually be such toxic “salicylic symptoms” (*vide infra*) as to forbid its further use. The salicylate of sodium is best exhibited in single large doses of a drachm to a drachm and a half (grm. 4–6), each dose being given with about an ounce (grm. 20–30) of peppermint water. The quite disagreeable taste of the medicine is only exaggerated by the addition of such things as syrup or fluid extract of licorice, added for the sake of elegance; but the simple solution in peppermint water is quite well taken, at least by most patients. It is a very good plan to give salicylate of sodium in a glass of Hungarian wine, or in strong black coffee without sugar. The advantage of the salicylate over the pure acid consists in its being possible to give a larger dose at one time, so that it need not be taken more than two or three times a day. In general, the amount given in twenty-four hours should not exceed two and a half drachms (grm. 10); one and a half to two drachms (grm. 6–8) may suffice. For children the dose is, of course, smaller, say five grains of salicylic acid (grm. 0.30), or half a drachm to a drachm (grm. 2–4) of the sodium salt.

Which of these two preparations shall be employed is, as has been stated, of little consequence. We ourselves usually prescribe, at first, capsules of salicylic acid to be taken hourly, as being most agreeable to the patient; but if our first visit be made in the evening, we prescribe a single large dose of a drachm to a drachm and a half (grm. 4–6) of salicylate of sodium, so that the patient may not be disturbed every hour through the night in order to take medicine. It is often possible to give the two remedies in alternation. This is a good way later on in the disease, when the patient has already acquired a distaste for the medicine. In such cases also it may be desirable to give the salicylate of sodium as an enema. About two and a half drachms should be given, in two ounces of water (grm. 10 and 60). There is no doubt that the specific effects can be obtained in this manner.

The benign influence of this remedy upon the disease is apparent in many fresh cases as early as ten to eighteen hours after treatment begins; and it is often astonishing to see how soon a patient, who before lay helpless and complaining, becomes free from pain and able to move his limbs. It must be confessed, however, that, apart from its taste, salicylic acid may produce disagreeable incidental effects. In the first place, there may be nausea with epigastric distress, and even vomiting. Tinnitus aurium may be exceedingly troublesome, and may be attended with marked vertigo. In somewhat rarer instances the mind is especially affected. Young girls in particular are often peculiarly excited; but the frame of mind is, however, in general a cheerful one. After large doses there may be an actual “salicylic delirium.” It should also be said that respiration may be affected, becoming very deep and rapid (salicylic dyspnoea). All these incidental

effects, and particularly the nausea and ringing in the ears, render difficult the employment of the remedy in those large doses which alone are of any benefit. This is the more unfortunate, as it is often very desirable to employ salicylic acid persistently.

Although it is not exceptional to have the symptoms almost entirely vanish at the end of one or two days, yet it is only in the minority of cases that the entire process ends with this release from pain. There is very often, sooner or later, a relapse, with fresh pain or even fresh swelling in one or more joints. It has been recommended to continue the salicylic acid in smaller doses for some time, in order to avert such relapses; but of late we have abandoned this method, for the reason that these small doses do not prevent the return of the disorder, but are calculated to give the patient a strong dislike to the remedy, and lessen his confidence in it. We therefore recommend to stop the medicine entirely as soon as the pain ceases, and to guard the patient as much as possible from relapses by preventing his catching cold (*vide infra*). If there be fresh pain, we should at once resume the acid or its salt in large doses, and thus we will very frequently be able to cut short the relapse at once.

[One other salicylic compound deserves mention—the oil of wintergreen; this has been used largely by Kinnicutt, who finds it efficacious, easy to take, and not likely to produce the unpleasant symptoms which sometimes follow the compounds in more general use. It is given in doses of  $\mathfrak{M}$  x-xv every two hours, either in milk, on sugar, or in capsules.

The salicylic treatment markedly diminishes the pain and fever, shortens the time spent in bed by four or five days, does not shorten the time spent in hospital, and seems to have little or no influence on the cardiac complications. The full alkaline treatment does not curtail the pain and fever in the same degree, but does seem to afford some protection against the heart affection, and to shorten the stay in hospital several days.

A combination of the salicylic and alkaline treatments seems therefore rational, and it has been adopted by the editor for some years. Citrate of potash is given in sufficient doses to produce and maintain alkalinity of the urine. The salicylic compound is given at first in full doses, which are diminished in size and frequency with the control of the articular symptoms, but are not omitted entirely until recovery is practically complete. The editor is inclined to believe that relapse is less common if the system be kept somewhat under the influence of the drug. Salicin is often perfectly well borne when the sodium salt causes gastric irritability, and the oil of wintergreen is another form which has advantages in some cases.]

Despite the admirable qualities of salicylic acid, it must be confessed that we can not always bring about a rapid and complete cure of the disease by this remedy. There are cases where, although at first evident improvement follows its use, relapses continually recur, or the disease fastens itself obstinately in single joints. In such, the continued use of salicylic acid proves almost unavailing, and indeed the patient can hardly be persuaded to take it. In these cases, and also when the salicylic preparations are ill borne or cause unpleasant attendant symptoms, antipyrine is the best substitute. Many physicians therefore often prescribe it from the first in place of salicylic acid, although we think the action of the latter upon acute articular rheumatism is greater than that of antipyrine. We should give antipyrine in doses of fifteen grains (grm. 1) several times a day in water or wine. Its attendant symptoms (sweating, nausea, and sometimes an eruption like measles) are usually without special significance, and its influence on the articular pains is often so favorable that the remedy is of much value in the treatment of protracted rheumatism. Antifebrine, in doses of four to seven gr (grm. 0.25-0.50), seems also to have a certain favorable action in joint affec

but it is distinctly inferior to antipyrine. Sahli has recommended salol (salicylic acid, phenyl ether), which deserves more confidence; it is given in fifteen-grain (grm. 1) powders several times a day (five to eight powders a day). We are often compelled, especially in articular rheumatism which has frequent relapses, to try in turn the different remedies mentioned.

There are still other internal remedies which should be tried, but their effects are rarely satisfactory. Most important among these are iodide of potassium and the preparations of colchicum (tincture of colchicum, twenty-five to forty drops several times a day). Numerous other remedies have been recommended, and they were formerly largely employed, but at present they are almost abandoned. Among these are large doses of the alkalis (such as bicarbonate of soda), trimethylamine, veratrine, and quinine. Local treatment of the diseased joints is far more important and effective in such cases. Properly executed massage deserves special mention, as its effects are often very brilliant. Electricity also may have a beneficial effect, particularly the galvanic current. We would caution against the too early use of warm baths, as these often aggravate the pain instead of mitigating it. Steam baths are sometimes very beneficial, but they may also do harm, and they should therefore be given only when the acute inflammatory symptoms have entirely vanished, leaving behind only stiffness and tenderness in the joints.

The application of an ice-bag in genuine articular rheumatism is seldom necessary, but it may sometimes be desirable where there are violent and obstinate symptoms of acute inflammation. Warm, moist applications are useless, if not harmful, in acute cases. In the advanced stages of subacute cases a wet pack may afford some relief. Painting the skin over the joints with tincture of iodine produces no effect in acute cases, and even in the chronic ones it is probably mainly a subjective remedy. Some observers report that injections of carbolic acid beneath the skin of the affected joints greatly relieve the pain. A Pravaz's syringe (thirteen minims) of a one-per-cent. solution may be injected one to three times a day. We have had no personal experience with this remedy. In all severe cases careful attention should be given from the start to maintaining a correct position of the diseased joints, because of the possibility of ankylosis. Before salicylic acid was introduced, "the treatment of articular rheumatism with splints" was largely and very advantageously employed. The use of salicylic acid has greatly diminished the necessity of such procedure, but even now it is sometimes required. It is often possible to give the patient great relief by applying a suitable paste-board or wooden splint to an affected extremity.

General hygienic and dietetic treatment should not be undervalued. An equable temperature should be carefully maintained in the sick-room, inasmuch as cold, or draughts, or moisture have very often been found to exert an evil influence upon the disease and excite fresh pain. The patient should therefore be kept warm, and it is sometimes advantageous to wrap up the affected joints in cotton batting. It is of great importance that even in the mildest cases the patient should be strictly confined to bed, and he should by no means get up too soon. If possible, we keep our own patients in bed for a week after the pain has ceased. Getting up too early will very often bring on a relapse. With regard to diet, milk is the best food. We may also allow soup, eggs, and a little meat. In France, great weight is laid upon an exclusive milk diet; but this would seem to us an extreme view.

We do not need to speak at length about the treatment of the complications and sequelae, since we should merely repeat what has already been said in the appropriate chapters of this work. There has been much said on both sides as to the influence of salicylic acid in preventing complications, particularly cardiac

complications. This much is certain, that cardiac complications are not absolutely prevented by the salicylic treatment, and that they too frequently occur while it is being employed; but we do believe that this treatment decidedly shortens the course of the disease as a whole, in many instances, and thus lessens the liability to endocarditis. If, however, a cardiac complication have made its appearance, salicylic acid does not apparently exert any appreciable influence upon it. Another important question is in regard to the efficiency of salicylic acid in the graver forms of articular rheumatism, particularly in cerebral rheumatism. It may be stated, in the first place, that in Leipsic cerebral rheumatism has apparently become much less frequent since the salicylic treatment was introduced. At any rate, not a single case of hyperpyrexia occurred in the clinique in that city out of many hundred cases treated, where the salicylic acid was properly employed from the first. We had an opportunity to observe a case in which hyperpyretic symptoms had already appeared when we first saw it, and which had not been treated with salicylic acid. Here large doses of that remedy produced no effect. We should nevertheless be inclined to employ it, first of all, in such cases; and the energetic use of cool baths would probably be the most speedy way of modifying the dangerously high temperature. Stimulants, in particular camphor, are also required in these severe cases.

In the severe hæmorrhagic varieties of rheumatism we should also give salicylic acid a trial. The milder hæmorrhagic cases (hæmorrhagic urticaria) do well under ordinary methods of treatment.

If the acute affection merge into a chronic condition of stiffness and swelling of certain joints, such as the wrist or shoulder, we must employ the same remedies as in chronic articular rheumatism. Massage furnishes the best results. Warm baths may also be ordered in such cases (see the following chapter). The patient might be sent to Teplitz or Wiesbaden. The subsequent muscular atrophies and paralyses recover most rapidly under electricity.

Prophylaxis requires, first of all, that one should avoid cold or wet, and other "rheumatogenous influences." Persons who have already had one attack of articular rheumatism must be especially careful, inasmuch as they are more than ever liable to the disease, as has already been said. It is not inconsistent, however, with the exercise of due caution, to endeavor to lessen the sensitiveness of the skin by such procedures as cold sponging, followed by friction.

## CHAPTER II.

### CHRONIC ARTICULAR RHEUMATISM (CHRONIC POLYARTHRITIS) AND ARTHRITIS DEFORMANS.

**Ætiology.**—The two diseases known as "chronic articular rheumatism" and "arthritis deformans" are considered together here, because it is impossible to draw a sharp distinction between them. It is, indeed, not unlikely that the above names are sometimes applied to diseases which differ essentially from each other; but as we do not yet understand the nature or the ætiology of many chronic diseases of the joints, we must provisionally be guided by the external changes they produce. We shall therefore embrace all chronic inflammatory processes affecting the joints under the name of chronic arthritis. Traumatic arthritis it is not intended to include, much less those chronic affections of the joints which are evidently of tubercular origin, and which have ordinarily been termed fungous arthritis. These belong to the domain of surgery. We would also exclude chronic

syphilitic diseases of the joints, about which, indeed, there is still less known than about the tubercular affections; besides, they are rare. Chronic articular affections from gonorrhœa are probably more frequent.

The ætiology of those cases of chronic arthritis where the disease is a direct sequel of acute articular rheumatism is evident enough. It is hardly possible to doubt that the same specific poison which excited the acute arthritis maintains possession of the joints, and produces the chronic inflammatory changes. Cases of this sort especially deserve the name of chronic articular rheumatism. They are not very infrequent, and may be of slight or great severity. The worst cases produce macroscopic changes which fully justify the other appellation of arthritis deformans.

It is also possible that many cases which are chronic from the start have the same ætiological origin—that is, are due to the same pathogenic agents. This might be inferred from analogy with numerous other diseases, and it is rendered still more probable by the fact that the same exciting causes which promote acute articular rheumatism often play a conspicuous part in chronic arthritis. Such causes are exposure to cold and wet, and working in cold or draughty places, or dwelling in newly built and damp houses. This explains why those who follow certain callings—for instance, washerwomen—are more apt to suffer from the disease than others, and why arthritis deformans has, with some justice, been called a disease of the poor, in contrast with the gout of the wealthy. Many of the laity, and even some physicians, believe that gout and arthritis deformans are in some way related, but this view is erroneous.

It is very questionable whether all cases of chronic multiple arthritis are referable to the causes already enumerated. Such other influences, however, as are concerned in its production are not at all understood. Various authorities have maintained that arthritis deformans is the result of a primary disease of the nervous centers, and in particular of the spinal cord. We regard this statement as entirely unwarranted. It originated at a time when there was a tendency to ascribe all sorts of ills to disease of the "trophic centers," but there is no doubt that this tendency was carried very much too far. We may state in this connection that a careful microscopic examination of the spinal cord in one case of very severe arthritis deformans yielded an entirely negative result.

[Some striking cases are reported by Blake, which go to show that the arthritic changes may set up chronic, though slight, suppuration, in analogy, perhaps, with the synovitis of gonorrhœa. Careful examination should consequently be made of all the mucous membranes, especially in cases which seem to have no connection with true rheumatism.]

*Predisposing Influences.*—Chronic arthritis is mainly a disease of advanced years. Certain monarticular varieties, about whose ætiology, it must be confessed, we know little as yet, have been termed arthritis senilis—in particular the *malum coxae senile*. Even the common and, in a certain sense, typical form of arthritis deformans (*vide infra*) is not apt to occur in people under thirty-five years of age. This rule, however, has exceptions, and we have ourselves seen a few perfectly characteristic cases of arthritis deformans in children between ten and fifteen years of age. Women are much oftener attacked than men. It is often said that trouble, anxiety, and other emotional influences favor the outbreak of the disease; but the proof of this is lacking. The disease does not often seem to be hereditary.

*Pathology.*—The process is described as simple chronic arthritis so long as it is confined mainly to the synovial membrane of the joint and the periarticular connective tissue. These parts often undergo decided inflammatory thickening; the synovial membrane becomes cloudy; and the amount of synovial fluid is more or less increased—that is, we have chronic dropsy of the joint. Sometimes different

parts of the synovial membrane are connected by adhesions, which considerably interfere with the movements of the joint. There may even be complete ankylosis: for example, in the shoulder or knee.

Chronic synovitis may pass imperceptibly into arthritis deformans. In this, not only the capsules of the joint, but the articular cartilages and the articular extremities of the bones, are so much affected as to produce the most striking deformity. These changes almost always originate in the articular cartilages. The cartilage is roughened and worn away: its free borders and surfaces undergo proliferation and then disintegration, or become polished on the surface, while deeper in the newly formed layers of cartilage undergo ossification. The underlying bone undergoes inflammation and degeneration. Sometimes, also, the periosteum near the joints undergoes ossific periostitis. On microscopic examination, we find fibrous disintegration of the matrix of the cartilage, and proliferation and subdivision of the cartilage-cells, at the same time that there is destruction of the newly formed cells by simple or fatty degeneration. Analogous processes of proliferation and destruction also affect the bony structures. The synovial membrane is invariably affected in cases of any severity. Usually the most striking change is a great proliferation of the joint villi, which may cover the walls of the cavity like great fringes.

Of course the normal structure of the joint is at last completely destroyed by these various processes. The articular extremities of the bones waste away more and more, and take new relative positions, as the parts which impinge upon each other are worn away. Externally, the joint usually becomes larger and larger: and this is the more evident because the surrounding muscles undergo great atrophy. Often there is no synovial fluid whatever (*arthritis sicca*), but sometimes there is a considerable effusion—for instance, in the knee-joint.

**Clinical History.**—The symptoms of chronic arthritis are usually quite simple and uniform. They are almost exclusively referable to the local disturbances and their results.

Except in the cases which are preceded by acute articular rheumatism, the disease usually begins quite gradually and insidiously. The first subjective symptoms are stiffness and pain in the joints, the latter being aggravated by pressure or movement. The stiffness is most noticeable when the joint has remained quiet for some time previous, and is therefore ordinarily greatest on waking up in the morning. The pain often shoots from the joints upward and downward, and is of a burning character, or less often neuralgic. Even in advanced cases the pain usually occurs only when the affected joints are moved, although then it may be very severe. When the body is entirely at rest there is little or no pain. Motion is impaired very early. This is due at first to the pain, and to a certain reflex inhibition and ataxia of the muscles; to which are later added the purely mechanical hindrances and the ever-increasing atrophy of the muscles.

The objective changes in the affected joints begin to appear soon after the symptoms just mentioned, at least in cases of any severity. The joints seem enlarged and thickened. If we attempt to move them, we not only cause pain and meet with mechanical obstruction, but we may hear and feel the cracking and grating produced by the rubbing of the denuded and uneven surfaces upon each other. This is often noticed by the patient himself. As the disease gradually progresses, there are usually developed certain characteristic deformities, which are apt to be most strikingly exhibited in the hands (see Fig. 117). The metacarpophalangeal joints are thickened and swollen, and are made all the more prominent because the interossei upon the back of the hand are atrophied. The bases of the first phalanges are directed obliquely toward one side, so that the fingers assume more and more the appearance of subluxation. They are bent over

toward the back of the hand, and are also displaced toward the ulnar side, so that they often actually come to rest one upon the other. The palm of the hand is frequently deeply hollowed out. Often the phalangeal joints are also distorted, so

FIG. 117.—Appearance of the hand in a case of protracted arthritis deformans.

that, for example, there will be an obtuse angle on the dorsal surface of the fingers between the first and second phalanx, while the terminal phalanx is apt to be flexed, although the second phalanx preserves a position of extension. Despite these changes, many patients, if only the thumb remains tolerably movable, are able to use their hands for quite delicate work, although at the expense of much time and effort. The feet exhibit analogous deformities, but seldom to the same extent as the hands. The knees and elbows are likewise enlarged. At the hip-joint, subluxation is not infrequent, the head of the femur slipping upward. The motion of the shoulder-joint, and as a consequence the use of the arms, is gradually more and more impaired. If the joints of the lower extremities are affected, of course it becomes painful and difficult either to get up or to walk. It may finally be necessary for the patient to have the help of some other person, or of crutches.

There are monarticular and polyarticular forms of the disease—the name indicating that one or several joints are affected. The monarticular form is usually regarded as a surgical trouble, and is most often located in the hip-joint (*malum coxae senile*), or more rarely in the knee- and shoulder-joints. The polyarticular form is the characteristic one. In most of the typical cases it begins in the small joints of the hand and fingers. At a later period the larger joints are also invaded, one after the other, the invasion taking place symmetrically on both sides of the body, although the disturbance is not infrequently greater on one side than on the other. In severe cases the joints of the spinal column are also involved. This impairs particularly the movement of the head. The articulation of the lower jaw is usually very little affected, if at all.

In less frequent instances the arthritis is confined principally to the lower extremities, while the upper escape intact for a long while, or even permanently. It is very possible that such cases often have a different etiology from ordinary arthritis deformans; and the same is true of the cases which are confined mainly to the vertebral column, and are termed spondylitis deformans. A remarkable and, as it seems to us, unique disorder may be mentioned in passing. It leads very gradually and painlessly to a complete ankylosis of the entire spinal column and the hip-joints, so that head, trunk, and thighs are firmly united and completely stiffened, while all the other joints retain their normal mobility. It need scarcely be said that this necessarily causes a peculiar modification of the carriage and gait of the sufferer. We have ourselves seen two cases of this peculiar affection which resembled each other very closely.

There is hardly any affection of parts of the body other than the joints in arthritis deformans. The muscles should be excepted, for they always undergo that muscular atrophy which we have already described (*vide* page 905) as the result of joint disease. This atrophy is most marked in the interossei, the shoulder muscles, and in the muscles of the calf and thigh. Sometimes the skin over the wrist and other affected joints appears peculiarly wrinkled and flabby. The internal organs almost always perform their functions in a perfectly normal manner. Appetite and digestion remain good, although there is often some tendency to constipation. Rarely there is valvular disease of the heart, but usually only in such cases as originate in an acute articular rheumatism. Once in a while it is seen in cases chronic from the start. This last fact is not without interest from an aetiological point of view. Sometimes there are certain nervous symptoms to be observed, such as headache, congestion, or mental depression, but these are probably not the direct result of the disease, but arise indirectly in a way to be easily imagined.

*General Course of the Disease.*—Arthritis deformans is an extremely chronic trouble. It may last even ten or twenty years, or more. Sometimes there is an apparent arrest of the process extending over months, or even longer. Sometimes the progress of the disease is marked by remissions and exacerbations, affecting either the general or the local manifestations. In general, however, the disease continually advances.

The prognosis is therefore unfavorable. Recovery, if it ever occurs, is extremely rare, and is possible only in the early stages. For the encouragement of the patient, it may be said that under proper care and treatment the disease often runs so gradual a course that the general condition remains at least bearable for a very long while, although there may be considerable local disturbance. The disease is not directly dangerous to life. The eventual fatal termination ensues either from general debility, or because of some intercurrent disease.

The prognosis is somewhat more favorable in the milder cases of "chronic articular rheumatism," where the anatomical changes are less severe, and are completely limited to the synovial membrane. Even here, however, recovery is by no means frequent, and it is always to be feared that grave deformities of the joints will gradually be developed.

*Treatment.*—With regard to regimen, it is requisite in the first place to avoid all unfavorable external influences. If possible, the dwelling should be dry and warm; and it may often seem advisable to make a change of climate. The patient must dress warmly, without, however, undermining his powers of resistance too much, as he will be in danger of doing. The diet must be abundant and nutritious.

Internal remedies may be tried, with the hope of modifying the disease, but our chief reliance must be upon local treatment of the joints. Among internal remedies, the most important are iodine and arsenic. Iodine may be given in the form of tincture (a few drops in mucilage several times a day), or a better form is in combination with potassium. As yet, we ourselves have not seen any great benefit from iodine, but we have in repeated instances witnessed a quite striking result from the use of arsenic. It is best administered in pills containing one thirtieth to one fifteenth of a grain (grm. 0.002–0.004) of arsenious acid, one pill two or three times a day. If this remedy prove beneficial, it must be continued for at least months, perhaps with occasional brief intermissions. Salicylic acid and antipyrine have no permanent effect, and are useful only when there is an acute exacerbation of the disease. The preparations of colchicum may be tried, but they will seldom be found efficient. Iron, quinine, and cod-liver oil are sometimes indicated by the general condition.

First among local methods of

age, although the good it

accomplishes is, of course, apt to be evanescent. It will, however, do much to hasten the absorption of inflammatory exudations, and also to loosen up the joints, invigorate the muscles, and improve the general health. The Swedish movement cure will be found of great benefit in all cases if begun early and methodically persevered in. It preserves the mobility of the joints as long as anything can. Electricity also has a palliative influence. The galvanic current is applied to the affected joints, and the faradic current to the atrophied muscles.

Baths are universally employed in chronic arthritis. Their value should not be overestimated, but it is, notwithstanding, undeniable in many cases. Simple warm baths, or salt baths (two to ten pounds of salt for each bath), are practicable in almost any household. As health-resorts in arthritis deformans, experience shows the following to be most desirable: The different warm baths, such as Teplitz, Wildbad, Ragatz, and Baden in Switzerland; the warm chloride-of-sodium baths in Wiesbaden; the acidulated baths of Oeynhausen and Nauheim; and the mud baths of Elster, Marienbad, Franzensbad, and Schmiedeberg. Steam baths are admissible only in the early stages of the disease, and for patients whose general condition is still vigorous. Even then they should be employed cautiously.

[The mineral springs within the limits of our own country chiefly to be recommended are Sharon and Richfield, in New York State, the Sulphur Springs of Virginia, and the Hot Springs of Arkansas. At the two former, particularly, there is every provision for comfort as well as for the use of the waters.]

We have repeatedly seen quite excellent results follow the employment of hot sand-baths. These also can be easily used at home, particularly if applied merely to the hands or feet. They are employed more elaborately in Köstritz and Blasewitz. These hot sand-baths seem to do good, not only from the temperature, but also from the uniform and persistent compression which they exert.

Stimulating or narcotic remedies may be rubbed into the joints, but they are beneficial only because of the massage which accompanies their employment. In practice it is not always possible to omit their use. The application of tincture of iodine is usually entirely without effect. As to morphine and other narcotics, the disease is so chronic that it is desirable to employ them as little as possible. A considerable number of those who suffer from chronic arthritis become opium-eaters.

We may say, therefore, that the use of the various remedies which have been suggested will enable us to oppose some obstacles to the progress of the disease. Persistent treatment will, in many cases, be rewarded by at least temporary improvement.

### CHAPTER III.

#### ACUTE AND CHRONIC MUSCULAR RHEUMATISM.

(*Myositis, or Myalgia, Rheumatica.*)

**Definition and Ætiology.**—Certain acute affections may originate primarily in the muscles. These are to all appearance inflammatory in their character, and not infrequently result from taking cold, or other causes similar to those which produce acute articular rheumatism. These affections are classed as "acute muscular rheumatism," or rheumatic myositis. It is possible that this disease is also an infectious one, but the question remains entirely undecided. The analogy which this trouble bears to acute articular rheumatism is not complete. It is seldom

that the two processes are seen in combination; and, furthermore, acute myositis is not "polymuscular," but is usually confined to one muscle, or to a single group of muscles; and it is never followed by acute endocarditis. The two diseases, therefore, are alike only in certain symptoms (pain and impairment of motion), and in the fact that they are often, although not always, ascribable to wet or cold, and the like. There are many cases where pain suddenly occurs in the muscles ("myalgia") without any attendant objective change. These cases can not be called genuine acute myositis. Indeed, it is sometimes difficult to know how to regard them. In practice they are often termed muscular rheumatism, especially when they are referable to exposure; and it is possible that many such cases are really a very mild form of the genuine inflammatory disease. On the other hand, however, there must often be some different process going on. Thus, traumatic pain in the muscles is the result of some excessive strain, and in many instances is apparently due to laceration of some of the muscular fibers. This is generally occasioned by too violent muscular exertion. Any physician who sees many patients from the laboring classes meets with an abundance of cases of this sort.\*

The limitations of acute muscular rheumatism are obscure; but still more so are those of "chronic muscular rheumatism." This disease is also a frequent one, and only imperfectly understood. It does not bear a close analogy to chronic articular rheumatism, except in this point, that chronic muscular rheumatism seems to be quite often occasioned by meteorological influences. While the anatomical changes in chronic articular rheumatism are almost always striking, similar lesions are very exceptional in chronic muscular rheumatism. On the contrary, the name is usually applied to cases where there is pain in various muscles all over the body, but where there is no discoverable objective disturbance. Older authorities used to speak of "rheumatic induration" of the muscles, but this or any other actual anatomical change is very exceptional.

These facts justify a doubt as to whether all cases of chronic muscular rheumatism actually deserve their name. It is certainly quite appropriate in those not infrequent cases which are due to "rheumatogenous influences," and which are so evidently aggravated upon every exposure to cold, or every period of bad weather, that the patient often asserts that he carries in his legs the best of thermometers. Such is the "old rheumatism" of those who have passed a large part of their lives in the open air, regardless of wind or weather. There are other cases, the character of which is different. In them the muscular pain is associated with a general neurasthenic condition, or with corpulence (when it is, perhaps, the result of circulatory disturbance), or possibly with chronic poisoning. An important instance is the "rheumatic pain" sometimes complained of by toppers, which we are inclined to ascribe not to changes in the muscles but to nutritive disturbances of the nerves. For these and similar disorders there are no special names, and the practicing physician often terms them all "muscular rheumatism," a diagnosis with which the patient is usually quite contented.

**Clinical History.**—Genuine acute muscular rheumatism is usually, as has been said, limited to some one definite group of muscles. The affected muscles often seem somewhat swollen and infiltrated, are very sensitive to pressure, and, if not quite useless, are nearly so, greatly impairing the motion of the corresponding member of the body. All these symptoms are best illustrated in acute myositis of the deltoid (omalgia). The whole shoulder is swollen, the muscle is very painful,

\* Some time ago I saw an organ-player who had to work the pedals for many hours a day; he had an extremely painful affection of the leg  
- associated with swelling, which could be regarded only as an acute myositis.

and the upper arm is almost incapable of voluntary motion, although, if caution be exercised, passive movement can be made without causing any pain.

The various forms of acute muscular rheumatism have received names descriptive of the locality of the affection. We have:

1. *Omalgia*, as already mentioned.
2. Acute rheumatic myositis of the cervical muscles, *myalgia cervicalis*, or rheumatic torticollis. Here the muscles of the back of the neck and throat are very painful. The head is usually held to one side, and, in severe cases, is almost perfectly immovable.
3. *Lumbago*, or *myalgia lumbalis*. This is the most frequent form of acute muscular rheumatism. The common people in Germany have termed it "witch's shot" (*Hexenschuss*), on account of its sudden onset. The entire lumbar region is very sensitive; and any motion of the trunk, such as stooping or turning, is extremely difficult and painful. The disease is more frequent in men than in women. Certain persons seem to be especially predisposed to it. It should also be stated that lumbago is not always of a rheumatic character, but of traumatic origin, as from lifting a heavy weight, or from sudden stooping. [It is very common in the traumatic neuroses, where it was once regarded as indicative of spinal injury.—K.]

4. Rheumatism of the thoracic muscles, and particularly of the intercostals. This may cause great discomfort, as it renders breathing, coughing, and sneezing very painful. It is comparatively rare; and caution should be exercised in diagnosing it to avoid confusion with pleurisy and periostitis of the ribs. Very often, also, thoracic disturbance is regarded as rheumatic when it is really traumatic, being the result of stretching or laceration of the fibers of the pectoral or other muscles.

5. Rheumatism of the head also, probably, belongs in this category, although the affection is seldom confined to the muscles of the scalp, but involves also the fasciæ, and may even be almost confined to them. It is not infrequently excited by exposure to cold. The pain is quite violent, and greatly increased by any movement of the scalp. Of course, the diagnosis requires the previous exclusion of the various forms of headache described on pages 530 and 591.

The duration of acute muscular rheumatism is brief. Usually the pain abates in a few days; but a tendency to relapse persists for some time. In chronic muscular rheumatism there are usually no objective changes to be detected. The pain is seldom located permanently in any one place, but it is felt first here and then there. It is usually increased during bad weather, and is less severe when the weather is warm. The pains are often described as "wandering." Motion is seldom much impaired. Sometimes, however, there may be a certain stiffness of the muscles, most marked after a period of rest.

The diagnosis of chronic muscular rheumatism rests, therefore, mainly upon the rational signs. Hence it is often impossible to avoid the suspicion of malingering, particularly where certain applicants for hospital care are concerned. We should not, however, be too uncharitable, since without doubt there are cases where quite severe pain is felt, now in one set of muscles and now in another, without any anatomical basis for such pain being discoverable. Nor should we ever forget that other diseases may have pain for their first symptom. It is not at all exceptional for the lancinating pains of locomotor ataxia to be for a long time regarded as "lumbago." Lumbago may be confounded with insidiously developing diseases of the vertebrae, or with various hypogastric disorders (particularly in women). We should therefore never omit to make a careful physical examination.

**Treatment.**—Acute muscular rheumatism has this in common with acute

articular rheumatism, that it is usually very favorably affected by salicylic acid. In cases of genuine acute rheumatic myositis the employment of this remedy in the manner already described, for twelve to twenty-four hours, will often give surprising relief. We also see good results from antipyrine. Local treatment of the affected muscles may also be followed by great and speedy improvement. Massage is particularly valuable. It is not infrequently the case that a single properly conducted massage will cause a violent lumbago or omalgia to disappear almost completely, and like favorable results are witnessed where there is traumatic pain of the muscles. Most of the external applications which are so frequently prescribed for rheumatism—such as spirits of camphor or chloroform liniment—accomplish less through the cutaneous irritation they produce than by the massage incident to their employment. Next in value comes electricity. Both the constant and the faradic current may be employed. Simple counterirritation by means of mustard poultices or hot compresses will often prove palliative, but it is less effective than the remedies previously mentioned. Great benefit often follows excessive perspiration. The best means to this end is a steam bath. This is so favorite a remedy that patients often take it of their own accord.

In chronic muscular rheumatism the benefit of salicylic acid and antipyrine is merely temporary, and therefore is to be sought, if at all, only when there is an acute exacerbation. Massage and electricity are more effective, and, if persevered in for some time, will often accomplish good results even in obstinate cases. Treatment by baths is frequently prescribed with advantage. Steam baths are often beneficial, but their use requires great caution where the patient is corpulent and has a tendency to congestion or cardiac failure. There is also value in mud baths, pine-needle baths, and in the baths given at Teplitz, Wiesbaden, and other places.

In many cases of chronic muscular rheumatism constitutional treatment is of great importance. Particularly where the patient is overfed, and intemperate in the use of alcohol, much benefit will often be accomplished by a proper regulation of the ingesta and the prescription of a sufficient amount of muscular exercise. Such patients may also be helped by a cautiously conducted cold-water treatment.

[In acute cases with localized pain I have found a thick flaxseed poultice, applied as hot as it can be borne, renewed once or twice, and followed by the application of a thick layer of cotton, useful.

A dry cup or two is also often productive of great relief. In chronic cases, plasters and the iodide of potash are often of benefit.

Muscular rheumatism is a common and often very troublesome affection in those whose occupation calls for decided muscular exertion. A muscle is strained, pain settles in and is apt to recur in the part; and, while the general health is sufficiently good, the man is compelled to remain idle. Quack advertisements dwell so much upon pain in the back as a symptom of Bright's disease, that we are frequently consulted by those who, suffering from muscular pain and soreness, think themselves the subjects of serious disease of the kidneys.]

## APPENDIX.

### ACUTE POLYMYOSITIS.

From some very recent observations (E. Wagner, Unverricht, and others) we have obtained knowledge of a disease which consists essentially of an acute inflammation of most, or even of all, the muscles of the body. The disease occurs chiefly in young or middle-aged persons. Without a <sup>begin to have</sup> a consid-  
pains in the arms, legs, and trunk, which more

erable disturbance of motion. The general disturbance is at first slight, but it increases later, especially if, as usually happens, there be fever. A marked oedematous swelling is soon very noticeable; it is first seen on the extensor side of the extremities, and later in the face and trunk. The oedema is stiff and painful, and it may be very considerable. As soon as the muscles of deglutition and respiration are affected the whole condition becomes distinctly worse. It becomes harder and harder to take food, and there is severe dyspnoea. Bronchitis and lobular pneumonia soon develop, which become the more distressing, since expectoration is more and more impaired, and finally becomes impossible. The spleen as a rule seems swollen. There is usually a marked tendency to sweating.

In the cases thus far published death always ensues after a few weeks, with symptoms of extreme dyspnoea and cyanosis. We do not yet know certainly whether there are also milder cases which recover.

In the cases observed thus far there was on examination a true acute inflammation of the muscles. Not only do the muscular fibers show all forms of degeneration and destruction, but also in the interstitial connective tissue we find true inflammatory foci (accumulation of nuclei about the vessels, etc.). In a case which we recently examined these changes were apparently to be found in all the muscles, even in the tongue, the ocular muscles, etc. In genuine polymyositis the peripheral nerves are found to be perfectly normal, but it is, of course, possible that on future investigation relations may be established between polymyositis and multiple neuritis (*vide supra*).

The diagnosis of polymyositis will probably soon be comparatively easy, when the disease becomes better known. The distinction from trichinosis must be the most difficult; here we must first of all consider the ætiology. Polymyositis is to be distinguished by the pronounced oedema from multiple neuritis, which in other respects closely resembles it.

Experience is still limited in regard to the treatment of the disease. We would first recommend the exhibition of salicylic preparations, antipyrine, and similar remedies. Toward the close of the disease narcotics usually become unavoidable.

## CHAPTER IV.

### RACHITIS.

(*Rickets*.)

**Ætiology.**—The first accurate description and the now universal name of "rachitis" (from *ράχis*, the spinal column) is to be ascribed to the Englishman Glisson, who published a comprehensive monograph upon this disease in 1650. It was his opinion that it first appeared in England in the beginning of the seventeenth century; and for this reason rachitis is still often called by Germans "the English disease."

Although the clinical and anatomical phenomena of rachitis have been often and accurately investigated since that time, its true cause still remains entirely unknown. It is certain only that its development is promoted by all unfavorable external circumstances affecting the nourishment and health of the child. It is therefore more frequent among the poor than the wealthy, in the damp and crowded quarters of large cities than in the country, and among artificially fed, and therefore weakly and anæmic children, than such as receive the mother's milk. Nevertheless, the essential cause of the disease is not to be sought among

these various influences, for rickets undoubtedly does occur, although rarely, in children whose circumstances seem in every respect most favorable.

Guerin, Friedleben, E. Voit, Wagner, Baginsky, and many others have made very exhaustive experimental researches with regard to the development of rachitis. It has been found possible to produce certain changes in the bones of growing animals by giving them as little lime as possible in their ingesta, or by administering very large amounts of lactic acid, with the purpose of dissolving the calcium salts, or by giving small quantities of phosphorus. The changes thus caused have been, with more or less correctness, regarded as analogous to those of rachitis. These investigations are of great interest with regard to the physiology of bony structures in general, but in our opinion they throw little light upon the clinical question which here concerns us. It is indeed natural enough to suppose that rachitis in childhood may be due to an insufficient proportion of lime in the food; or to a defective absorption of the lime-salts, on account of intestinal catarrh; or to an abnormally abundant production of lactic acid, or even of carbonic acid, which may dissolve the lime-salts in the system; but every one of these theories is contradicted by the facts of experience; for it is wholly improper to assume that the food of children with rachitis contains less lime than the food of healthy children, and the hypothesis of a mere poverty in lime of the bony tissues is by no means adequate to explain the whole complicated rachitic process. In our opinion everything seems to indicate that some special, specific, ætiological factor is requisite for the development of rachitis. This factor, however, is as yet entirely unknown to us. The thought had occurred to many that the disease bears some relation to congenital syphilis; but this assumption has long since been proven to be entirely without foundation. It is also claimed that heredity plays an important part in rachitis. The proof of this is lacking. It is, however noteworthy that quite often several children of the same family are attacked by the disease.

Rickets is most common in children of two or three years old. According to Kassowitz, the disease usually begins in the first months of life, while the severe symptoms, of course, appear only at the age of two or three years. Congenital rachitic changes (foetal rachitis) have been repeatedly observed, but the cases of so-called *rachitis tarda*, where the disease is said to develop in children of eight or ten years of age and over, are at least extremely rare.

Sex exercises no great influence upon the occurrence of the disease.

**Pathology.**—Rachitis consists in a peculiar disturbance of the processes connected with the growth of the bones. As a result of an increased absorption of the already formed bony tissue, and especially as a result of an insufficient or an almost wholly deficient deposition of lime-salts, the bones become or remain abnormally flexible and soft, so that they can easily be cut with a knife.

Upon minute examination, we find both the periosteum and the marrow much reddened and congested. If we try to detach the thickened periosteum from the bone, not infrequently a few bits of bone adhere to the membrane. The most striking changes, however, are exposed upon making a longitudinal section of the bone. They are located at the base of the epiphyses, because here is the place where the normal, and therefore the abnormal, processes of ossification are most active. Under normal circumstances, the epiphyseal cartilage of the bones in childhood is separated from the main shaft by two narrow layers: first, an outer one, nearest the epiphyseal cartilage, of a bluish color, and one or two millimetres thick; this is the proliferative layer, or hyperplastic zone, where the cartilage-cells become divided and arrange themselves in rows. Secondly, an inner, dull yellow layer, only about half a millimetre thick, known as the ossific layer, or zone of calcification, in which the real process of ossification takes place. That is,

blood-vessels grow into it, osteoblasts develop, lime is deposited, and medullary spaces are hollowed out. In healthy bone these two layers are parallel to each other, and are limited by perfectly straight lines. In rachitic bone, on the other hand, they are both much enlarged, and their naturally sharp boundaries are replaced by an irregular serrated edge, so that the two zones encroach mutually upon each other. These changes affect both layers, but are most marked in the proliferative layer. Upon microscopical examination, the details of which can not be given here, we can see most plainly the complete confusion, if we may be permitted to use the expression, into which the growth of the bone has fallen. The proliferation of the cartilage-cells has increased beyond all bounds, and the scanty matrix of the cartilage displays a fibrous character. In the bony layer are seen irregularly scattered foci, which are already undergoing incomplete calcification, or marrow formation, breaking down the cartilage. The latter is due to an invasion of the vessels, which are always affected in an active new growth, pierce the cartilage like lacunar spaces, and are surrounded by a so-called osteoid tissue.

The periosteum presents analogous changes. The innermost osteoblastic layer of the periosteum is thickened; but the newly formed tissue does not become completely calcified, but remains in large part soft and spongy. Finally an increased absorption of bone takes place inside the bones. The bony partitions disappear, and the cortical layer of bone often becomes much smaller.

These various processes furnish a direct explanation of the macroscopic changes presented by rachitic bones. The proliferative process causes marked swelling of the epiphyses of the long bones, and thickening of the flat bones of the skull. The abnormal softness of the bones is due to the increased absorption of bone, their insufficient calcification, and it in turn causes various deformities, which are, for the most part, very characteristic (*vide infra*). If recovery takes place, the whole bone becomes firm at last, but often remains permanently deformed.

The deficient development of rachitic bones can also be recognized upon chemical examination. While normal bones in a dry state contain about sixty-three to sixty-five per cent. of lime, rachitic bones have only about twenty to thirty per cent.

**Clinical History.**—Rachitis often begins so insidiously that it can hardly be detected. Attention is not called to the disease until the deformity of the bones becomes very obvious, or it is noticed that the child does not learn to walk as early as other children, or, having already learned, is no longer able to do so. At last the anxiety of the parents is excited; and, on seeking medical advice, they find their fears only too well grounded.

In other cases, certain prodromata precede the development of the characteristic changes in the bones, which are especially mentioned by Oppenheimer. There is often a peculiar form of diarrhoea, which is said to occur only in the first half of the day, being entirely absent at other times. The discharges are scanty and almost colorless. Not infrequently the diarrhoea is attended by fever, and it is said that the spleen is almost invariably swollen. The children are pale, but not emaciated. The first characteristic changes in the cartilages of the ribs and elsewhere are said to appear within two or three weeks of these first symptoms. In other cases, Oppenheimer observed that the development of rachitis was preceded by attacks of screaming at night, likewise associated with intermittent elevations of temperature and splenic tumor; or, again, there were simple febrile attacks at night, which passed away in the morning with profuse perspiration.

These facts indicate that the entire organism is considerably affected by rachitis. It would seem reasonable to suppose that the disorder is caused by some specific infection. That this infection is malarial, as Oppenheimer thought, is more than improbable.

The diagnosis of rachitis can not be definitely established until the characteristic changes in the bones have been developed. These anomalies vary, of course, in their severity and extent in different cases. We append a list of the most important:

The head is often noticeable for its great size and somewhat square shape; the fontanelles remain open until the second or third year of life; their edges seem soft and yielding; the thinness and softness of the occiput is sometimes very striking, so that it can be pressed in like parchment. This phenomenon (the *craniotabes* of Elsässer) appears to be due to the pressure exerted upon the occiput when the child is lying on its back. There is often a peculiar change in the shape of the jaws, particularly of the lower jaw. This is not rounded, but angular, being sharply bent in the neighborhood of the canine teeth; so that the incisors stand in a perfectly straight line, besides being somewhat inclined inward. Fleischmann was the first to describe this condition, and referred it to the action of the mylohyoid and masseter muscles upon the soft bone. Dentition in rachitic children is usually tardy and tedious.

The thorax presents, even in the mildest cases, very characteristic and noticeable changes. There is a swelling at the junction of the cartilages with the ribs, which can be felt and seen through the skin, and produces what is called the "rosary of rickets." In severe cases the lateral portions of the thorax are often drawn inward, particularly at the parts which correspond with the insertion of the diaphragm. This change is due mainly to the action of the diaphragm during inspiration upon the abnormally soft and therefore yielding ribs. The changes are greatest when the respiratory efforts, and particularly abdominal respiration, are exaggerated because of bronchitis, pneumonia, or some other disease of the air-passages. In such cases the entrance of air into the lungs is impeded, so that it is possible that the external atmospheric pressure also contributes to produce the deformity of the thorax. Deep hollows may finally be developed on each side of the chest, while the sternum becomes unusually prominent, giving the whole chest that shape which has been termed pigeon-breast, or *pectus carinatum*. When once this deformity has been developed, of course it in turn contributes to render respiration difficult.

The clavicles are sometimes distorted, and may even be partially fractured (*vide infra*). The spinal column is usually unaffected if the child remains quiet in bed; but if it sits up, or is carried about, or tries to walk, the traction and pressure thus exerted often produce curvature of the spinal column (rachitic scoliosis and kyphosis). These deformities may become extreme. Changes in the bones of the pelvis are of no special clinical importance at this period of the patient's life; but in later life the consequent shortening of the antero-posterior diameter of the pelvis may, as is well known, prove a great obstacle to childbirth.

The extremities not only present swelling of the epiphyses, but are liable to curvature. This latter change is most marked in the lower limbs, inasmuch as they have to support the weight of the body. The swelling is especially well developed at the lower ends of the bones of the forearm and of the tibia and fibula. The curvature is almost invariably greatest, and therefore most easily recognized, in the tibia, which becomes convex outward, giving the rachitic child its "bow-legs." Similar curvature of the femur is less often seen, although it may be obvious enough in severe cases. The same is true of the humerus. The deformity of the lower limbs causes that waddling gait which can be so often seen on the streets of any large city. Sometimes the limbs present a sharp bend, the result of partial fracture. These "green-stick fractures of rachitis" are invariably referable to some slight traumatism, and are most often seen in the lower third of the tibia, although sometimes visible in the clavicles, ribs, and bones of the lower arm. The

infraction usually takes place upon one—generally the concave—side, so that it is often compared to the partial fracture of a quill or an osier rod.

*Symptoms in Other Parts of the Body.*—Apart from the changes in the bones, a rachitic child may seem to be perfectly well. Even the general nutrition may be unimpaired. As a rule, however, rickets is associated with anaemia and impaired nutrition. The child seems pale, thin, and feeble, and may present swollen lymph-glands and other "scrofulous" symptoms. Sometimes there is a tendency to profuse perspiration, especially from the scalp. Very frequently there is chronic intestinal catarrh, and sometimes there is chronic bronchitis or lobular pneumonia. The liver and spleen are often, but not invariably, enlarged. It should also be stated that spasm of the glottis and convulsions are frequently observed in rachitic children. Possibly they are due to the effect of the disease upon the skull.

The faeces and urine have been repeatedly subjected to careful chemical examination, in the hope of gaining some information as to the pathogenesis of the disease. The results have thus far been rather contradictory. Much emphasis has been laid upon the fact that the faeces contain a comparatively large amount of lime. This has been ascribed to a deficient absorption of the lime-salts from the intestinal canal. The amount of lime in the urine, on the other hand, seems to be diminished rather than increased.

The disease almost invariably runs a chronic course. Usually months, or even years, pass before the process ends. Its termination is to be recognized by closure of the fontanelles, increase in the length of the bones, and, above all, by the fact that the patient becomes stronger and makes attempts to walk. Unfortunately, many results of the disease persist through life. The legs are crooked, the thorax deformed, the spinal column curved, and the pelvis narrowed. Even in the most favorable cases persons who have once had rachitis usually remain somewhat smaller than those who are perfectly healthy.

Some authorities describe an "acute rachitis," in which painful swelling of the epiphyses is said to be developed in the course of a few weeks. At the same time the child becomes emaciated, and may also suffer from diarrhoea or ulcerative stomatitis. Recovery takes place in a few months. How far cases of this sort are related to genuine rickets has not yet been determined.

Rachitis does not involve direct danger to life, although many rachitic children fall victims to the attendant intestinal catarrh, or to such complications as catarrhal pneumonia or tuberculosis. The prognosis is, therefore, not unfavorable where the outward circumstances of the child permit of good care and nourishment. The remote influences of the thoracic, spinal, and pelvic deformities can be readily inferred.

The diagnosis of rachitis is but seldom difficult if the characteristic changes in the bones exist. In case cranial changes exist, we should guard against confounding rickets with hydrocephalus, but we can usually avoid error. The rachitic child holds its head erect, and is free from mental or other functional nervous disturbances.

**Treatment.**—The most experienced specialists agree that the first aim in treating most cases of rachitis is to improve the general nutrition. It is often possible to bring about recovery simply by means of proper diet (milk, the yolk of eggs, and perhaps meat), good air (in the country), and baths (brine, malt, and medicated baths). Digestive disturbances should be corrected by such remedies as hydrochloric acid or tincture of rhubarb; and iron should be administered if the patient be anaemic.

It is very important that the child should be placed upon a good mattress, and should neither attempt to walk too early, nor be needlessly taken up and carried

about. The best way to avoid the development of deformities in the bones is to avoid all such unfavorable mechanical influences.

Attempts have also been made to check the disease by specific remedies. Upon theoretical grounds, lime has been very frequently prescribed in the form of phosphate of calcium, of which fifteen to forty-five grains may be given in powder several times a day; or in the form of lime-water, of which one or two teaspoonfuls are added to the milk which the child drinks. The benefit of these remedies is seldom very obvious. Kassowitz has given a fresh impetus to the employment of phosphorus. To support his belief he brings forward numerous clinical observations as well as facts obtained from experiment. We may either dissolve the phosphorus in cod-liver oil (0·01–100), giving one or two small teaspoonfuls of this solution every day, or we may write for the following mixture, which is more elegant, but is also more apt to spoil:

℞ Phosphori..... 0·01;  
 Olei amygdalæ expressi..... 10·0.  
 Misce, deinde adde:  
 Pulv. acaciæ,  
 Syrupi simplicis.....āā 5·0;  
 Aquæ destillatæ..... 80·0.  
 M. Sig.: Two to four small teaspoonfuls a day.

We can state from our own experience that the remedy is usually very well borne, and, in fact, often shows its beneficial action after a few weeks, the fontanelles growing smaller and the bones becoming firm.

It may be eventually necessary to resort to orthopædic or surgical treatment in order to correct the deformities of the bones.

[The comparative rarity of rickets, especially in its extreme degrees, in this country strikes all observers who have studied in Germany. With a fairly extensive experience among the poorer classes of the city, the writer can recall scarcely half a dozen cases of craniotabes. The colored race furnishes a large contingent of cases of rickets, although, as is shown by Haven, in attention to diet and fresh air its members are superior to the Irish laboring classes, as a rule. The more pure the negro blood, the greater does the liability to rickets seem to be in this latitude—an indication, perhaps, that a northern climate is unsuitable to the African race.]

## CHAPTER V.

### OSTEOMALACIA.

**Ætiology and Pathology.**—As a rule, osteomalacia does not, like rachitis, consist in a disturbance of development. The growing bones are not prevented from ossifying, but, having already undergone normal development and acquired normal firmness, they afterward become soft. It is mainly a disease of adults, say between thirty and forty years\* of age. The female sex is noticeably predisposed to the disease, although occasionally it has been observed in men.

The true cause of osteomalacia has not yet been ascertained. It is a remarkable fact that the disease is much more frequent in certain regions than in others. It

\* Rehn maintains that genuine osteomalacia may occur in children; but his statement has not yet been fully corroborated.

is very common along the Rhine, and in Westphalia, in eastern Flanders, and northern Italy. This suggests that there is some specific cause for the disease, endemic in certain localities. Among exciting causes, child-bearing is certainly the most important, for both the first signs of osteomalacia, and also fresh exacerbations of the disease, usually date from a pregnancy. Another factor said to promote the development of the disease is found in unfavorable hygienic surroundings, such as damp dwellings and the like.

The anatomical process of osteomalacia consists in a disappearance of the earthy salts of the bone, which begins interiorly and spreads outward, and causes a corresponding softening of the bony structure. The marrow is at first extremely hyperæmic; and extravasations of blood are not infrequently found here and there. The bony substance surrounding the myeloid spaces and the Haversian canals becomes transformed into a soft fibrous tissue, while the irregularly arranged bone-corpuscles are either destroyed or lose their characteristic shape. The softening process gradually extends over the spongy substances outward to the cortex. The central cavity grows larger and larger, so that finally the cortical substance is as thin as paper, and the whole bone like an "inflated and dried coil of intestine." At this stage the original hyperæmia of the marrow has vanished. The marrow acquires a yellow color, and may finally be entirely transformed into a yellow, viscid fluid. The affected bones are now flexible and soft, they can be easily cut, and they are of less specific gravity than normal. The periosteum is also at first thickened and hyperæmic, as if inflamed. When it is removed, the surface of the bone beneath it is found to be rough and uneven. The attendant alterations in the shape of the bones will be mentioned below.

Upon chemical examination of the bones in osteomalacia, we naturally find a marked diminution in the proportion of lime-salts. It is also stated that lactic acid has been discovered in the bones. This is an interesting fact, as it may be that the acid plays an important chemical part in the process of decalcification.

**Clinical History.**—Osteomalacia begins very gradually in most cases. Usually the first thing noticed is an ill-defined, deep-seated pain, most often felt in the sacral region, the nape of the neck, and the back and thighs. The affected parts are also sensitive upon pressure.

The pain is persistent. While it still keeps on, motion becomes gradually impaired. The patient experiences more and more difficulty in walking, partly because of the pain and partly because of muscular weakness. The gait is either uncertain and tottering, or characterized by short painful steps, the lower limb and the pelvis being jerked forward as if in one piece. Sooner or later it becomes impossible to walk, and the patient is permanently bedridden. Even now the pains usually persist in great severity. They are not actually spontaneous, but the mere pressure of the mattress and the bedclothes is sufficient to excite them.

In the meanwhile many of the bones will probably have become distorted. Usually the deformity of the spinal column is the first change which attracts attention. This is generally kyphotic; less often the curvature is in the opposite direction. At the same time the head approaches the sternum more and more, and the patient is thus made to appear much shorter than she really is. In most cases, also, the thorax is much distorted. It is compressed laterally, while the sternum becomes very prominent, and is sharply bent. The change in the shape of the pelvis in osteomalacia is less obvious externally, but it can be detected on internal examination. It is, of course, of great importance from an obstetrical point of view. The pelvis, like the chest, is compressed laterally, while the symphysis is made to project forward like a beak. The sacrum and its promontory are also pushed forward, and the superior strait thus acquires somewhat of a heart shape.

The extremities are less often distorted, particularly if the patient becomes bed-ridden at an early period. Manifold changes are, however, possible. Sometimes there is also fracture. In a few reported cases the softness of the bones of the extremities was so extreme that one could bend the limbs at will, like wax, and give them the most extraordinary positions. In cases so far advanced as these, the pain in the bones seems finally to cease.

The bones of the head and face seldom undergo noticeable change, but we often find the teeth carious or lost. In the muscles, several observers have noticed trembling and fibrillary contractions. It is also said that sometimes even a slight irritation of the skin suffices to excite painful contractions of the underlying muscles. These phenomena have not yet been thoroughly investigated.

The general condition of the patient is often unimpaired for a long while, except for the pain and the impairment of motion. The internal organs perform their functions in a normal manner, and the appetite is good. Fever is observed only when the disease is undergoing some temporary exacerbation. With regard to changes in the urine, there have been a good many statements made, but their significance is extremely doubtful. It is said that the amount of phosphoric acid excreted is diminished. With regard to the amount of lime, no definite statement can be made. Lactic acid has been repeatedly detected in the urine, as has also albumen. Concretions of lime have been found in the bladder and the kidneys.

The disease runs a chronic course, occupying seldom less than two or three years, and sometimes even five or ten. Apparent arrest of the disease is not infrequently observed, but this is followed by fresh exacerbations. The most frequent termination is in death. This results either from general debility, or, more often still, from the dyspnoea caused by the compression of the lung, or by some such disease as lobular pneumonia. Recovery is exceptional, although not impossible.

**Diagnosis.**—In well-developed cases it is not difficult to recognize the disease, but at first a correct diagnosis is often impossible, unless the endemic frequency of osteomalacia suggests it. In the onset of the disease we may often be led to the false belief that there is incipient disease of the cord on the vertebræ. An examination of the pelvis is then of distinct diagnostic importance, as its peculiar deformity can be recognized early. The very peculiar hobbling gait of osteomalacia is also unlike anything that is seen in spinal disease. As the disease is almost entirely confined to adults, we are seldom in danger of confounding it with rickets. Besides, osteomalacia does not produce swelling of the epiphyses, nor changes in the bones of the skull. It is said that osteomalacia is occasionally confounded with diffuse carcinosis of the bones, as this may produce similar symptoms and deformities.

**Treatment.**—As has been already implied, therapeutic efforts have thus far proved in severe cases almost unavailing in this disease. In the onset of the disease we can obtain a distinct improvement by the use of hygienic remedies, good air, proper food, etc. Internally we give cod-liver oil and iron. Many patients praise warm baths, with or without salt.—The exhibition of lime seems to be of no special use, but, from our own experience, we must urgently advise trying small doses of phosphorus in the form given above (page 925).

The changes in the bony pelvis produced by osteomalacia may eventually demand obstetrical interference, but we need not discuss such procedures here. We should invariably warn women who suffer from the disease of the dangers of becoming pregnant.

# DISEASES AFFECTING THE BLOOD AND TISSUE-METAMORPHOSIS.

## (*CONSTITUTIONAL DISEASES.*)

---

### CHAPTER I.

#### ANÆMIA AND CHLOROSIS.

**Definition and *Ætiology*.**—The word “anæmia” might properly be taken to signify diminution of the total volume of the blood, such as, for example, is directly brought about by a severe hæmorrhage. Usually, however, the word is employed to signify not so much diminution in quantity as deterioration in quality. The total volume of the blood is not liable to nearly so great variation as is the number of its most important constituents—the red corpuscles—inasmuch as the total volume is dependent merely upon the amount of watery constituents, and even after large hæmorrhages the water is quite rapidly replaced by absorption. This is undoubtedly the case in most instances of sudden loss of blood. Even in chronic anæmia there is usually no reason to assume that the total amount of blood is diminished, although it may be where there is general emaciation, or diminished supply of liquids (persistent vomiting, dysphagia), or large watery discharges (as in cholera). The essential element in anæmia is, therefore, a diminution in the number of the red blood-corpuscles, or so-called oligocythæmia. Changes in the character of the red blood-corpuscles, however important, are not taken into consideration here; nor is there usually any stress laid upon any incidental variations in the proportion of albumen, especially as oligocythæmia is not invariably accompanied by a diminution in the amount of serum albumen (“hypalbuminosis”).

The circumstances under which anæmia is observed are manifold. They admit, however, of our distinguishing the two great classes of anæmia—primary and secondary. Primary anæmia is developed as an apparently primary and idiopathic disease in people previously healthy, while secondary anæmia is merely a symptom of some already existing disease. However simple this theoretical distinction, yet in actual practice it is often quite difficult to determine whether the particular case before us should be regarded as primary or secondary. A secondary anæmia may occur where the true primary cause can not be at all readily determined. There are, nevertheless, quite a large number of cases which would seem to deserve the name of primary or essential, in which we feel compelled to assume that some pathogenetic influence acts directly upon the blood and the hæmatopoietic processes.

In the first place, we would class as primary, cases which may best be described

as "simple constitutional anæmia." These often stand close to the borderland between health and disease. There are not a few individuals who present a striking pallor for a large part, if not all, of their lives. These persons may feel so well and vigorous that we scarcely have a right to regard the existent anæmia as an actual disease. Sometimes, however, such individuals do betray some diminution of energy, are easily fatigued, and are subject to headache. We may then certainly regard the condition as pathological. In many instances the cause of this simple anæmia is found in the general hygienic surroundings of the patient, for such cases are most often met with among the poorer classes. Deficient nutrition, bad air, unhealthy occupation in factories or the like, not only affect the general health, but more especially interfere with the processes of normal blood-making. Other cases of constitutional anæmia, apparently primary, occur in individuals who are entirely beyond the reach of such influences as have just been mentioned, in whom the anæmia has developed and persists despite the best of food and air. Here we are forced to the conclusion that the organs engaged in the manufacture of the blood are in some way prevented from performing their proper functions. The trouble often seems to be congenital, for such individuals may present the symptoms of anæmia in their earliest infancy. There are persons who have always been pale and feeble. Or, again, anæmia does not develop until later on, in which case it not infrequently associates itself with certain phases of physiological development, as when growth is particularly rapid, or when adolescence occurs. Virchow has directed attention to another factor, which he regards as potent in many of these cases of congenital anæmia. He has found that the arteries may be congenitally small, or that the whole arterial system may be imperfectly developed. The condition may be associated with a congenitally weak and small heart. The importance of this factor has not yet been fully determined. Possibly the condition of the circulatory system just mentioned may be the result rather than the cause of the anæmia.

A second division of primary anæmia includes cases which present a far more definite and distinct group of symptoms. They quite often appear in persons previously healthy, last for a certain length of time, and then end in complete recovery. The typical form of this variety is chlorosis (*χλωρός* = greenish yellow), or "green sickness." This well-known disease is especially frequent in young girls fourteen to twenty years of age—that is, at puberty. It often comes on quite rapidly without any ascertainable cause. There are not infrequently predisposing influences in the outward circumstances of the patient. Thus it is promoted by an unhealthy sedentary mode of life, as in seamstresses; bad air, as in factory operatives; mental and physical over-exertion, as in teachers, governesses, and students; and, finally, by mental influences. It is, nevertheless, true that chlorosis also appears in girls who have lived under the most favorable hygienic conditions possible. Sometimes the disease seems to be merely a temporary exacerbation of a simple constitutional anæmia which has existed a long while; but it may also appear in young women who were previously healthy, and even robust.

The true cause of chlorosis is unknown. In all probability it is a disease of the blood itself, or a process interfering with its normal manufacture. Its pathological physiology is, however, as yet entirely beyond our grasp. The old view, that chlorosis was referable mainly to sexual derangement, such as disturbance of menstruation, or defective development of the genital organs, must be regarded as a confusion of cause and effect, although it is true that such disturbances are often seen in the disease. Furthermore, cases of marked temporary anæmia, precisely like ordinary chlorosis in their symptoms and behavior, occur in men and in elderly individuals.

A third variety of primary essential anæmia is the so-called progressive-perni-

ious anæmia. This is likewise an idiopathic disease, distinguished from chlorosis mainly by its continuous progress and fatal termination. We must confess that in our opinion it is not possible, at least from a clinical point of view, to draw a sharp dividing line between "ordinary chlorosis" and "pernicious anæmia." Some future investigator may discover ætiological as well as anatomical differences between the two diseases, which will separate them widely. In the meanwhile we have only the clinical phenomena to guide us, and must acknowledge our inability to make any sharp distinction. There are "severe cases of chlorosis" which resemble "pernicious anæmia" in every respect, except that they finally get well; so that the only point which would enable us to distinguish them from the fatal disease is the mode of termination. To take this for a criterion is evidently unscientific. Cases of "severe essential anæmia" also have many points in common with certain other diseases, such as pseudo-leukæmia and splenic anæmia. These will be discussed later.

The forms of secondary anæmia offer a contrast to the forms of primary or essential anæmia just described in the much greater number of their causes. Under this head come cases of anæmia which do not occur idiopathically, but as a result of other abnormal processes. The simplest variety is anæmia from hæmorrhage. This is produced by profuse loss of blood, whether from the stomach, lungs, uterus, intestines, kidneys, or some wound. Repeated small hæmorrhages finally produce the same result as a single large one. Thus the most profound anæmia may be observed where there is a very frequent epistaxis (hæmorrhagic diathesis), or where cancer of the womb gives rise to a constant oozing of blood.

Other cases of secondary anæmia may be divided into two great groups. In one class the anæmia is a symptom of impaired nutrition. This is seen in almost every severe disease, acute or chronic, and is usually associated with more or less emaciation and loss of strength. The bad appetite, the lack of fresh air and exercise, and perhaps an impairment of digestion, or fever, or some abnormal drain upon the system, as in suppuration—these injure the entire body. It is not surprising that the blood shares in the universal misfortune. This is why most chronic invalids seem pale, particularly if they suffer from disease of the stomach, kidneys, chest, or nervous system. In the second class, the anæmia is secondary to some other disease, but assumes especial prominence as a symptom, independently of any general impairment of nutrition. Of course, it is often associated with emaciation, but nevertheless its extraordinary intensity offers a striking contrast to the condition of the rest of the body. This "specific secondary anæmia" must, like essential anæmia, be due to a special lesion of the blood itself, and is, therefore, to be regarded as in a certain sense a special complication or localization of the primary disease. General malnutrition never directly produces anæmia of this grade. This fact is illustrated in stenosis of the œsophagus. Here the ingestion of food is very greatly, if not completely, impaired, and there is the greatest emaciation, with a subnormal temperature and slow pulse. Of course, such a patient appears pale and wretched, but he does not present that peculiar waxy pallor which is the infallible sign of genuine anæmia.

The exact mode of origin of specific secondary anæmia is often obscure. We have already reported, in a preceding chapter, a very instructive example. In cancer of the stomach we find usually emaciation and pallor. This is natural enough; but sometimes the carcinoma is complicated by an extraordinarily profound anæmia, comparable only to the pernicious variety. In one such case we found, at the autopsy, an extensive secondary carcinosis of the bone-marrow. Here, therefore, the anæmia certainly was not the result of the general impairment of nutrition occasioned by the gastric carcinoma, but of the disease of the

marrow, which tissue undoubtedly plays an important part in the manufacture of the blood.

Some cases of specific secondary anæmia deserve special mention, although it is seldom possible to demonstrate their precise cause. In the first place come such cases as develop after certain acute diseases, usually of an infectious character. For example, there may be great anæmia after typhoid fever, or less often after acute articular rheumatism. A peculiar form of anæmia is often observed during the secondary stage of syphilis, although nutrition seems to be otherwise well maintained. This is known as "syphilitic chlorosis." Tuberculosis, chronic malarial poisoning, and other cases of chronic poisoning (lead), as well as amyloid disease, renal disease, etc., may also be attended by anæmia of such intensity as to justify the conclusion that there is some special disturbance of secondary origin affecting the manufacture of the blood or the blood itself. [Chronic arsenical poisoning from wall papers, dress fabrics, furniture covering, and the like, is a not infrequent cause of anæmia and debility, which resists treatment as long as the exposure to the toxic influence lasts. The classical symptoms of chronic arsenical poisoning are not necessarily present. The number of cases in which prompt recovery has taken place after the removal of the poison which was proved to exist in the surroundings as well as in the urine of the patient is too large and too striking to explain by simple coincidence. Recovery may, however, be slow in those whose toleration of arsenic is slight, or in whom the cause of the symptoms has remained long undetected.]

We shall now proceed to describe the symptoms common to all forms of anæmia. Upon this will follow a sketch of chlorosis. A special chapter is assigned to the grave form of essential anæmia known as progressive pernicious anæmia; and in the same connection will be set forth the little that is known with regard to the relations of anæmia to pathological changes in the hæmatopoietic organs.

**Symptomatology of Anæmia.**—The first symptom which attracts the attention of the physician in any case of anæmia is the altered appearance, the pallor of the skin and visible mucous membranes. This is especially striking in the face, but it is sufficiently evident everywhere. Special value is usually assigned to pallor of the mucous membranes, for example, of the lips and conjunctivæ, inasmuch as their color is not liable to be interfered with by pigmentation or opacity of the epidermis. The degree of pallor, of course, varies greatly. The whole body may present a waxy appearance. Such pallor, of course, indicates a very decided diminution in the number of the red blood-corpuscles, which elements impart to the blood its normal color. More information about this and other changes in the blood will be found below, under chlorosis and pernicious anæmia.

Besides the alteration in complexion, there is always a group of symptoms ultimately referable to an impairment of the normal processes of innervation resulting from a lack of arterial blood. First among these phenomena comes general weakness of the motor system. The voluntary muscles are easily fatigued, and the patient suffers from constant languor. When the anæmia is very great, as after severe hæmorrhage, this weakness may be so pronounced that the patient can neither walk nor stand.

This diminished nervous energy is also shown by the mental condition. There is no intellectual vigor. The patient is incapable of any great mental exertion, and experiences a constant feeling of weariness and sleepiness. Whether the special senses are blunted in anæmia has not yet been determined. It is very probable that a careful investigation would reveal an impairment of the perceptive powers, corresponding to the muscular weakness. If the anæmia reaches a certain degree, the patient becomes unconscious.

explains the frequent

fainting attacks (compare page 708), which are referable to a temporary aggravation of the cerebral anæmia, and are therefore apt to come on after the patient has been standing for some time, or when he rises from a horizontal position. It is an extremely interesting fact that a circumscribed portion of the nervous system may alone suffer; thus we may have an anæmic amaurosis after profuse hæmorrhage. There is no doubt that this blindness is due to anæmia of the optical nervous apparatus. The only question is whether the anæmia affects chiefly the retina or the central portion of the optic tract (cortex of the occipital lobe).

If the anæmia be at all marked, many other organs exhibit functional derangement. In particular, the secretory organs are disturbed. The mouth and tongue are frequently dry. This is in part due to the diminished secretion of mucus and saliva. Of course, where there is a sudden great loss of blood, the condition is also in part a result of the compensatory abstraction of water from the tissues. Other and still more important glands belonging to the digestive system are affected. Our knowledge in this regard is as yet very far from complete; but Manassein has called attention to the interesting fact that the amount of hydrochloric acid in the gastric juice is considerably less than normal, and that the dyspepsia so often seen in anæmic patients must in part be referable to this condition. Analogous disturbances in the functions of other digestive organs are presumably present, but they have not yet been actually proven to exist. We would add only that the constipation to which anæmic persons are very liable is usually due to diminished energy of peristaltic action.

The symptoms thus far described are all referable to diminished functional activity. On the other hand, anæmia gives rise to certain symptoms of irritation in the nervous system. It would, of course, be illogical to say that these symptoms are the direct result of a lack of oxygen-carrying blood. They are, in all probability, expressive of the irritation excited in certain portions of the nervous system by the products of abnormal tissue-metamorphosis. It may be that these products are themselves the result of a deficiency in the supply of oxygen.

The symptoms of cerebral irritation observed in anæmia include vertigo, spots before the eyes, and tinnitus aurium. This last is an almost constant symptom, if the anæmia be at all severe, and it may cause the patient great discomfort. It is usually aggravated if the patient lies upon his side.\* Another irritative symptom is eructations. We also have anæmic vomiting, and no doubt this is usually of central origin. It may be very troublesome. Sometimes violent hicoughs are observed, as well as frequent yawning of a convulsive character. Anæmic headache may be very severe. It is usually referred either to the entire head or the forehead; there is a painful feeling of pressure, which may attain great severity.

Other important evidences of irritation are to be found in the behavior of the pulse and the respiration. The changes here are apparently in part of a compensatory character. The pulse is accelerated in most cases of any severity, reaching 80 to 100 beats per minute, or even more. It is also very excitable, so that comparatively slight external influences suffice to increase its rapidity for the time being. This increase in frequency would not, of course, necessitate an increase of intravascular tension, or of the rapidity of the circulation; but it may exert a favorable influence in this direction, and so be teleologic. Respiration is also usually accelerated in anæmia. In cases of great severity the breathing may be so deep and noisy as to justify the term "anæmic dyspnoea." This is the direct expres-

\* We may also state that the tinnitus of the anæmic is sometimes nothing but the jugular venous hum (*bruit de diable*) heard by the patient.

sion of the body's hunger for oxygen. It is obvious that this increase in the number of respirations favors, to a certain extent, the absorption of that gas.

There are still other symptoms referable to the circulatory system. It has been already stated that the total volume of the blood is not diminished in anæmia unless, of course, there has just been an actual hæmorrhage. This explains why the pulse in anæmia is often comparatively full and strong. Quite frequently there is a peculiar quickness of the pulse. This seems to be due to a vigorous cardiac systole, in conjunction with a low intra-arterial tension. This supposition explains the fact, which we have often observed, that there may be in profound anæmia a loud sound in the femoral artery similar to that heard in aortic regurgitation.

It has long been known that anæmia may produce functional cardiac murmurs, often called "anæmic murmurs." Their mode of origin is not yet fully explained. They are usually heard loudest over the base of the heart, in the neighborhood of the pulmonary valves, although sometimes at the apex of the heart. As a rule, they are purely systolic in time, but we certainly heard in one case of pernicious anæmia a loud diastolic murmur of anæmic origin. The murmurs are of a blowing character. Sometimes they are so rough as to simulate pericardial friction-murmurs; it has therefore been suggested that many anæmic murmurs are actually due to the rubbing upon each other of the abnormally dry folds of the pericardial sac. Another explanation of their occurrence is, that the movements of the cardiac valves are interfered with, as a result perhaps of fatty degeneration of the myocardium (*vide infra*). It is also possible that they are due in some cases to relative insufficiency, resulting, for instance, from dilatation of the heart or imperfect action of the papillary muscles.

Murmurs in the large veins of the neck are very often heard in anæmia, either with or without cardiac murmurs. They are often called *bruit de diable*. No less an authority than A. Weil has maintained that murmurs in the jugular veins are just as frequent in healthy persons as in the anæmic; but our experience obliges us to differ from this view. We believe that the loud venous murmurs are more frequent in the anæmic than in other persons. We can not claim, however, that they are of any great diagnostic value.

The processes of tissue metamorphosis in profound anæmia are of great interest, but, unfortunately, they have not yet been thoroughly investigated. It is extremely probable that the absorption of oxygen in severe anæmia is less than normal, and that the body must, therefore, suffer from a diminished supply of oxygen. It has been demonstrated by the experiments of A. Fränkel that there is an increased destruction of albuminoids within the body and a correspondingly increased excretion of nitrogen through the kidneys. This experimental deduction we were the first to confirm in a case of very severe essential anæmia; and later various observers have in other cases arrived at similar conclusions. Of course, the excretion of nitrogen is influenced by many different factors, so that the truth of the above statement is not easily established. There can be no doubt, however, that in many instances of profound anæmia a larger amount of nitrogen is excreted than is ingested. This fact acquires a special significance when taken in connection with certain anatomical lesions produced by anæmia: there is almost invariably a well-marked fatty degeneration of many organs, particularly of the heart and kidneys. This fatty degeneration is the direct result of the abnormal destruction of albuminoid structures. The fat represents the non-nitrogenous remnants of the decomposed albuminoids. The reason why the fat itself does not undergo oxidation is the same that leads to the destruction of the albuminoids—namely, a lack of oxygen. This explains why the panniculus adiposus is for a long while preserved in many cases of anæmia.

It is evident that the fatty degeneration once produced must, in its turn, lead to unfavorable results. It has already been suggested that the fatty degeneration of the heart may be the cause of certain irregularities in its functional activity; but it should be said that this is not invariably the case, for often the heart exhibits a surprising energy despite marked fatty degeneration of its muscular tissue. The corresponding changes in the walls of the blood-vessels are, however, of great importance, as they frequently occasion disturbance, above all by hæmorrhage. In many instances (for example, in leukaemia, *vide infra*) an actual hæmorrhagic diathesis is developed; but we shall find later (see the chapter on pernicious anæmia) that the condition of hæmoglobinæmia and the chronic fibrine-ferment intoxication caused by it play a part in producing capillary hæmorrhages in severe anæmia. There is also strong evidence in many cases that there is an abnormal permeability of the vascular walls. From this results the mild grade of cedema frequently seen in anæmic patients, although in some few cases this cedema may be ascribed to passive congestion, resulting from the cardiac debility (*vide supra*). The increased permeability of the renal blood-vessels is sometimes shown by polyuria.

The urine is usually rather light-colored, if the anæmia be at all marked. It is evident that there is a diminished production of urinary pigment, the material for which is the coloring matter of the blood. Another reason for the light color of the secretion is the polyuria above mentioned. There may be fifty to seventy ounces (1,500-2,000 c. c.), or more, secreted in twenty-four hours. The specific gravity may nevertheless be comparatively high, and higher than one would expect from the appearance of the urine, not infrequently ranging between 1015 and 1021. This indicates, of course, that the amount of solid constituents is comparatively large; and in fact we find a corresponding amount of urea, say four or five hundred grains (grm. 25-32) in twenty-four hours. This is a large figure when we consider the amount of ingesta. As to the other constituents of the urine, we possess as yet little definite knowledge. The amount of phosphoric acid is sometimes surprisingly small, compared with the amount of nitrogen. Albuminuria is exceptional in cases of simple anæmia.

The bodily temperature is very often affected in anæmia. An "anæmic fever" is very frequently associated with pernicious anæmia, and even with cases of profound secondary anæmia, as after a large hæmorrhage from the stomach. There are irregular elevations of temperature, usually occurring at evening, and attaining 101°-102° (38.5°-39° C.), or even still higher figures. This fever is not due to inflammatory organic changes, but, in all probability, is rather the result of the presence of fibrine ferment in the blood.

**Clinical History of Chlorosis.**—Chlorosis, or "green-sickness," as already explained, is a term applied to the mild forms of essential anæmia, such as are most often seen in females at the time of puberty. The disease sometimes develops in previously healthy girls with considerable rapidity, and may completely vanish again at the end of a few weeks or months. In other cases it runs a more tedious course, without sharp limits, so that the condition resembles that of constitutional anæmia, or it may be described as an habitual chlorosis. In many instances the disease may be said to undergo repeated relapses.

The various symptoms of chlorosis are almost all direct results of the anæmia, so that they have already been described. Their intensity and variety are, however, very different in different cases. There are mild cases where the patient can hardly be called ill. She feels perfectly well, but is "a little pale." From these cases there is a gradual and unbroken transition to the other extreme of severity.

A constant and essential symptom is the greater or less pallor of the face as

well as of the rest of the surface of the body, and of the mucous membranes so far as visible. There is also almost invariably general languor; the patient is easily fatigued, and has neither the desire nor the ability to make any great bodily or mental exertion. There is also a tendency to headache and vertigo. Other nervous or "hysterical" symptoms, if they occur, are not directly ascribable to the disease itself, but are merely complications. Chlorotic patients often complain of dyspepsia. The appetite is usually diminished, and there is often a sense of pressure in the epigastrium after meals. There may also be severe cardialgia. This is usually of a purely nervous origin, but is sometimes produced by a gastric ulcer existing as a complication of the chlorosis. There is not infrequently constipation, as might be expected from the small amount of food taken, and from the diminished activity of intestinal peristalsis. Over the veins in the neck we often hear a loud murmur, above referred to, and called *bruit de diable*. Sometimes the heart is found to be slightly dilated. This is probably a result of the diminished power of resistance of the cardiac tissues. Anæmic cardiac murmurs are not infrequent; the pulse is accelerated and easily excited. Otherwise physical examination does not reveal any abnormal condition of the internal organs. It is a very great exception to find any indications of disturbance in the spleen or lymph-glands, or the bone-marrow. Fever is rare in cases of simple chlorosis, but in severe cases we sometimes see, especially at night, a slight rise of temperature, up to 101° F. (38.5° C.). The urine is usually pale, but seldom differs greatly, either in amount or constituents, from the normal character. It is noteworthy that chlorotic girls are very apt to suffer from disorders of menstruation. The menses may not appear until late, or, if they occur, they are very scanty. It is only in exceptional instances that chlorotic patients have menorrhagia.

Examinations of the blood have been made, in the hope of gaining a clearer insight into the true character of chlorosis. The blood is usually pale. Upon microscopic examination, we notice that the red blood-corpuscles do not tend to form rouleaux so much as normally, and sometimes we can perceive that the globules are comparatively light-colored, and are not all of the same size. There are some of the normal dimensions, others are notably small (microcytes), while there are a few which are unusually large (macrocytes). Here and there we see corpuscles of irregular shape (poikilocytes). Often there is some increase in the number of white blood-corpuscles—that is, there is a slight degree of leucocytosis (*vide infra*). In occasional instances there are considerable numbers of "granular bodies" in the blood. These are usually regarded as products of the disintegration of white blood-corpuscles. Malassez, Hayem, Thoma, and others have endeavored to determine the number of blood-corpuscles in chlorosis and allied diseases by means of special methods of counting. In general, we may say that in most cases of chlorosis the number of red blood-corpuscles is decidedly diminished. In a cubic millimetre of blood we find perhaps only 3,000,000 to 3,500,000 red blood-corpuscles, instead of the normal number of 5,000,000. The diminution may be even greater than this. On the other hand, it should be noted that Duncan, Hayem, and Laache have met with cases where the number of corpuscles was not diminished. Probably here the amount of hæmoglobin in the blood-corpuscles was diminished. An intelligent and satisfactory explanation of all these isolated facts has not yet been given. There are certain hypotheses which have been brought forward, and these we shall discuss in the following chapter, where also a more extensive description will be found of the changes presented by the blood.

We have already intimated that there is great variety in the general course of chlorosis. Many cases which seem severe at first terminate in complete recovery by the end of four to six weeks, or a few months. Other cases are much more

obstinate, resist all modes of treatment, and undergo frequent relapses. The prognosis may therefore be regarded as favorable on the whole, but it should always be given with a certain degree of reserve. It is true that ordinary chlorosis never involves direct danger to life. We shall, however, find that there is no sharp dividing-line between "simple chlorosis" and "pernicious anæmia"; and in any individual case it may not at first be possible to decide which variety of anæmia is before us.

**Diagnosis.**—The diagnosis of chlorosis may be regarded, therefore, either as extremely easy or extremely difficult to make, according to the point of view. It is easy in that we can readily perceive the characteristic symptoms of pallor and the like; but it is difficult in that the term chlorosis should be applied to those cases only where the anæmia is primary and essential. We therefore have no right to declare the diagnosis of chlorosis until we have made a careful and thorough physical examination, and have found that no factors are present which might produce a secondary anæmia. We should, above all, bear in mind the possibility of incipient tuberculosis, and examine the lungs, the expectoration, and the general condition of the patient, and also consider hereditary and other predisposing influences. We should also bear in mind the possibility of some organic disease of the stomach, such as ulcer, catarrh, or dilatation, or chronic renal disease, or possibly constitutional syphilis, giving rise to the syphilitic chlorosis before mentioned. In many cases it is easy to exclude all these secondary forms of anæmia, but occasionally the task is a very difficult one.

**Treatment of Anæmia and Chlorosis.**—The first indication in treating chlorosis as well as every other form of anæmia, is to promote the regeneration of the blood. There are two ways in which we can endeavor to fulfill this indication: first, by general hygienic and dietetic measures, and, secondly, by employing certain internal remedies.

First among general measures comes a care for pure air and proper food. Many a pale city girl regains her ruddy cheeks after a few weeks spent either in the country, or on the mountains, or at the seashore. The choice of a place must, of course, depend mainly upon the circumstances of the patient. In many instances, boarding in any suitable country place answers as well as a long and expensive journey. If the seashore be chosen, some bathing resort on the North Sea will usually be preferable. There are other places where the patient can combine the advantages of pure forest air and ferruginous mineral water; these will be mentioned below.

The diet of anæmic patients should be easily digestible and rich in albumen: carbo-hydrates and fat should be given in but limited amounts to patients in whom the panniculus adiposus is already well developed. Lean patients, on the other hand, require such ingredients in their diet, and should be recommended to take simple puddings, extract of malt, butter, and cod-liver oil. If milk be well borne it is an excellent article of diet for the anæmic; but what is called the "milk cure"—that is, an almost exclusively milk diet—is not advisable, as we have already had occasion to observe (see the chapter on tuberculosis). Some authors ascribe an exaggerated value to alcoholic beverages. They may be allowed in moderate amount if the patient asks for them and finds the appetite improve under their use. The best to choose for an emaciated patient are porter and other varieties of beer rich in extractive principles, but wine is often ill borne by chlorotic girls.

Many physicians also insist upon "abundant exercise in the open air." This can, however, be carried too far. A chlorotic girl is often made to take long walks in spite of her own reluctance to do so, with the result of becoming more languid and exhausted than she was before. We even believe that a case of pro-

found anæmia will be benefited by a certain degree of bodily rest. Thus any needless tax upon the muscles is avoided. The most brilliant results we have ever observed in the treatment of chlorosis have been within the hospital. The patients, who are usually factory operatives and shop-girls, are often kept in bed for the first week. We admit that pure country air may be very beneficial, but we would strongly advise moderation in bodily exercise. If the patient begins to feel more vigorous, she will of herself take more exercise, and may safely indulge in long walks or extended excursions on foot.

Of internal remedies, the preparations of iron have long occupied the first place in the treatment of all varieties of anæmia. The manner in which their good effects are exerted was until recently unknown, for careful investigation had established the fact that the salts of iron are absorbed by the intestines only in an extremely small amount, and that the system needs so little iron that the iron in ordinary food ought to be entirely sufficient. Bunge has recently enabled us to understand why iron possesses therapeutic value, at least in some cases. He has shown that the iron contained in ordinary food does not exist in an inorganic form, but in a very complex organic combination, to which he has given the name of hæmatogen. The inorganic salts of iron given as a medicine protect the hæmatogen from being decomposed, a danger to which it is liable from the sulphides which are generated in the intestinal canal.

Hence it follows that iron can not act in the same way in all cases of anæmia, and, in fact, we often see that iron may be taken by anæmic patients for a long time without any effect; but, on the other hand, the action of iron is often apparently so beneficial that, in spite of our unsatisfactory theoretical knowledge, we still give one of the many iron preparations, together with general dietetic prescriptions, in severe anæmia and especially in chlorosis. It may be regarded as a general rule to give not too small doses, and to give these two or three times a day, directly after meals. Ferrum redactum is perfectly pure iron, in a state of very fine subdivision, and may be given either as a powder or in pills, several times a day, in the dose of one to three grains (grm. 0·05–0·20). A very good preparation for children consists of pastiles made of chocolate containing reduced iron. Two other powders are contained in the list of the German pharmacopœia, ferrum carbonicum saccharatum, and ferrum oxydatum saccharatum, the dose of each being half a teaspoonful to a teaspoonful in water three times a day. The second of these preparations, ferrum oxydatum, has the advantage of not blackening the teeth. An easily digestible preparation is ferri lactas, which may be given either as a powder or in pills, the dose being five to twelve grains (grm. 0·3–0·75). Finally, the sulphate of iron should be mentioned. This is one constituent of the well-known and very valuable Bland's pills (ferri sulphatis exsicc., potassii carbonat.,  $\text{aa}$  grm. 15; pulv. tragacanth, *q. s.* Misce et div. in pil. No. 100. Sig.: Three to five pills three times a day). The German pharmacopœia contains three tinctures of iron—viz., tinctura ferri acetici ætherea, tinctura ferri chlorati ætherea [resembling tinctura ferri chloridi, U. S. P.], and tinctura ferri pomata. We must also praise the liquor ferri albuminati, a teaspoonful three times a day, which often has a good effect on the appetite. Repeated trials have lately been made with successful results, in giving hæmoglobine internally, especially Pfeufer's hæmoglobine pastiles, made of ox blood, giving six of them a day. Often iron is given in combination with other remedies, of which quinine is chief. This is said not only to increase the tonic action, but to lessen the headaches to which anæmic patients are subject. Stomachic tonics, such as gentian, or laxatives, such as aloes, are also combined with iron.

Exceptionally iron is not well borne, and causes digestive disturbances or diarrhœa. We must then try another preparation or diminish the dose. It is com-

mon to forbid the ingestion of sour articles of diet while taking iron, but the injunction is due mainly to prejudice.

The use of mineral waters containing iron is quite common, although the amount of iron thus introduced into the system is so small that it is hard to understand their therapeutic value. Of those artificially produced, that which contains the pyrophosphate of iron is the best, and does not irritate even a delicate stomach. The natural chalybeate waters are also bottled and sent to distant places. They are often more effective if drunk upon the spot, but merely because, in that case, the general hygienic surroundings of the patient are better than they would be at home. The best-known and most popular ferruginous springs in Germany and Switzerland are situated at Cudowa, Rippoldsau, Homburg, Elster, Schwalbach, Pyrmont, Driburg, Liebenstein, St. Moritz, and Tarasp. "Steel baths" are also much employed; but the effect is not due to the iron contained in the water, but to the temperature of the water and the carbonic-acid gas it contains. Baths generally seem to be of distinct service in chlorosis, and hence we often prescribe simple baths or salt baths, giving a bath of fifteen or twenty minutes duration, at a temperature of 90°-95° F., two or three times a week, adding five or six pounds of salt to the bath.

No other remedies for chlorosis approach iron in popularity. Arsenic is the only one which needs to be mentioned. Its effects are often very beneficial, and it deserves a trial, especially in severe cases. It may be given alone or in combination with iron. Hydrochloric acid also deserves special mention, and often does good service in cases with digestive troubles, pressure in the stomach, etc. We give ten or fifteen drops of the dilute acid in a quarter of a tumbler of water, half an hour after meals. Scholz and Strübing recommend the use of sulphur—one part of purified sulphur to two parts of milk sugar—giving as much as will go on the point of a knife, three times a day. We must refer to the following chapter for the experiments with subcutaneous injections of blood.

If there be constipation, it is desirable to remedy it rather by suitable diet than by laxatives. Thus we may prescribe fruit, Graham bread, and other foods which promote peristaltic action by the mechanical irritation which they exert.

## CHAPTER II.

### PROGRESSIVE PERNICIOUS ANÆMIA.

*(Grave Form of Essential Anæmia.)*

WE term pernicious anæmia that variety of essential anæmia which does not, like chlorosis, terminate in recovery, or maintain a low degree of severity, but which goes on uninterruptedly from bad to worse, in many instances leading to a degree of anæmia which of itself proves the immediate cause of death. The word "essential" is here used to signify that the anæmia is a primary one, the result of some pathogenic cause acting upon the blood itself, or the hæmatopoietic system. We must hold fast to this conception of the disease, especially as the attempt has been repeatedly made of late to degrade pernicious anæmia from the rank of an idiopathic disease, and regard it as merely a grave form of secondary anæmia which may result from any one of the most various causes.

Of course, the diagnosis of primary anæmia may be wrongly made in cases where a more careful search will detect some special cause for the condition. Such a mistake may become evident at the autopsy. Thus, in repeated instances,

cases which have been during life regarded as "pernicious anæmia" have been shown to be cancer of the stomach (*vide* page 391). In other cases, however, it is much more difficult to discover the primary cause of the anæmia. Thus the profound anæmia which attacked the men at work upon the St. Gothard Tunnel was at first regarded as idiopathic, but more careful investigation showed that the disease was really due to *anchylostoma* (*vide* page 448), the ravages of which parasite have in other cases also been confounded with the symptoms of pernicious anæmia. Reyher and Runeberg have lately called attention to the fact that the presence of *bothryocephalus latus* in the intestine may produce an affection resembling severe and apparently primary anæmia. Of late there have been a number of cases reported where the post-mortem examination showed that the progressive marasmus and anæmia of the patient had resulted from an extensive atrophy of the coats of the stomach and intestine, associated in some instances with well-marked lesions of the sympathetic plexus. These cases are very interesting, but have nothing whatever to do with pernicious anæmia, except in so far as the changes are of a secondary nature, analogous to the fatty degeneration seen in other organs (*vide infra*). Often the symptoms even during life differ not a little from those of pernicious anæmia, so that we can not think it right to establish what is called a "gastro-intestinal variety of pernicious anæmia." It is proper to group and classify the forms of secondary anæmia according to their various causes, but not the cases of primary idiopathic anæmia, which are all essentially alike.

The credit of having been the first to study pernicious anæmia as a special form of disease belongs to Biermer (1868), although occasional instances of the disease had long before been noticed. Its occurrence during pregnancy was first pointed out by Gusserow.

[The puerperal form of pernicious anæmia was described by Walter Channing in 1842.]

With regard to the special ætiology of progressive pernicious anæmia, it must be confessed that we have as little definite information as about the ætiology of chlorosis. Klebs, and more lately Frankenhäuser, have discovered micro-organisms in the blood, to which they have given the names "*cercomonas globulus*" and "*cercomonas navicula*"; and they ascribe to them a pathogenic influence. These discoveries, however, have not yet been satisfactorily confirmed. It is a noteworthy fact that pernicious anæmia is much more frequent in some countries than in others; thus, it is seen far more frequently in Switzerland than in North Germany. This would be one argument for assuming that the disease is an infectious one. In Leipsic, pernicious anæmia was comparatively frequent several years ago, while of late it seems to have become decidedly less common. There do not usually seem to be any special exciting causes. It has been maintained that unfavorable hygienic surroundings and insufficient nourishment promote the development of the disease; and this would apply perhaps to some cases, but certainly it does not to all. We are inclined to regard it as characteristic of this disease, as well as of chlorosis, that the anæmia may develop despite the most favorable outward circumstances. There is, however, one factor which seems to have a decided influence, and that is the condition associated with pregnancy and childbirth. The first symptoms of pernicious anæmia in women are very apt to date from this period. It is a very interesting but somewhat puzzling fact, that the disease may appear as a sequel to a great loss of blood, whether from one or several hæmorrhages. It seems as if the body were sometimes unable to recover from the effects of large hæmorrhages of this sort, so that the acute merges into a chronic and progressive anæmia, which, despite nursing and treatment, advances to a fatal termination. It is quite doubtful, however, whether such cases should be classed as genuine pernicious anæmia.

Most of the cases occur during middle life, between twenty-five and forty years of age. Both sexes are equally liable to the disease, except for those cases already referred to which seem to be especially connected with the sexual functions.

**Pathology.**—Pernicious anæmia so often terminates fatally that there has been abundant opportunity to make accurate anatomical investigations of the lesions it produces. We shall not here discuss the changes in the blood itself, inasmuch as they will more properly be described among the clinical phenomena. The changes in the internal organs are divisible into two groups: First, such as are secondary and the result of the anæmia; and, secondly, such as may perhaps be primary and pathognomonic. All the internal organs are, of course, anæmic. Another striking change is fatty degeneration. This is usually best marked in the heart, but it also affects the kidneys, liver, and the walls of the stomach and intestines, as well as the intima of the blood-vessels (compare page 934). We have already pointed out that this fatty change is to be regarded as the direct result of the anæmia, or more particularly of the diminished supply of oxygen in the tissues; and we have also explained that the destruction of albuminoids indicated by this fatty degeneration maintains a direct ratio to the increase of nitrogen in the urinary secretion.

The second important lesion found at the autopsies of those who die of pernicious anæmia is the frequent hæmorrhages, usually small, but occasionally large; these are found in all sorts of locations. The most important of these hæmorrhages are into the retina, because they can be demonstrated by means of the ophthalmoscope during life. They are very frequent. We may also find minute hæmorrhages in the serous membranes, such as the pleura or pericardium, in the brain and in the mucous membranes. Cutaneous ecchymoses are also occasionally found. As we shall note later, the hæmorrhages are probably due to little capillary embolisms caused by the formation of fibrine ferment in the blood.

Still another secondary symptom is an abundant deposit of iron in the cells of many organs. This can usually be determined only by the aid of the microscope or micro-chemical tests. It is most abundant in the peripheral zone of the hepatic lobules, but it also occurs in the kidneys, pancreas, and other organs. Quincke has studied this point very carefully, and finds that the total amount of iron contained in the liver in pernicious anæmia is much larger than normal. The most natural and most probable interpretation of this fact is that the iron originates from the destruction of large numbers of red blood-corpuscles.

The changes thus far described are the result of anæmia, and hence are the same in all severe anæmias, whatever their cause. On the other hand, search has been made for specific changes which could be regarded as the primary disease, and thus, of course, our attention has been especially directed to the organs engaged in the formation of the blood. The lymph-glands do not usually present any special changes in pernicious anæmia. If they are much altered, it is probable that the disease is quite a different one, which we shall later have an opportunity to study (*vide pseudo-leukæmia*). The spleen is in many cases normal. In exceptional instances, however, it is decidedly enlarged, although never enormous. Even when the organ is enlarged there are no important histological changes to be detected. Cases of pernicious anæmia with marked splenic tumor are often termed splenic anæmia (*vide infra*), but we do not ourselves see how such cases differ essentially from others in which the spleen is not enlarged. The changes in the bone-marrow are by far the most constant. This structure plays a much more important part in the formation of the blood than does the spleen. C. Wood, and after him Cohnheim, called attention to the fact that the bone-marrow is almost invariably affected in pernicious anæmia. Instead of its normal

yellow color, it has a reddish-purple appearance. This is due mainly to the fact that the numerous fat-cells of the marrow are all, or nearly all, destroyed. This is the more surprising as the fatty tissues in other parts of the body are often very little affected in pernicious anæmia. The specific cellular elements of the marrow also exhibit certain changes. There is a decided hyperplasia, and often, although not always, there are found large numbers of nucleated red blood-corpuscles. Cohnheim is inclined to regard the disease of the bone-marrow as specific and primary, but it must be confessed that there are many reasons which strongly oppose this view, and suggest the possibility of this change in the marrow being merely a secondary phenomenon, a sign of the extremely active formation and regeneration of the red blood-corpuscles. Neumann's investigations would lead to the belief that the nucleated red blood-corpuscles are young blood-cells in the process of development. Furthermore, these vigorous processes of regeneration, and the corresponding changes in the bone-marrow, are often found in cases of profound anæmia which are beyond a doubt of secondary origin.

We can not, therefore, feel certain that the lesion of the bone-marrow is the primary anatomical disturbance, and we are therefore obliged to assume that essential anæmia may be a disease of the blood itself—that is, some process which does direct injury to the red blood-corpuscles, possibly of an infectious character (?).

**Symptoms.**—As already stated, the symptoms of pernicious anæmia usually begin, independently of any demonstrable cause, in individuals previously healthy, and develop so slowly and gradually that it is hardly ever possible to determine the precise date of the commencement of the disease. This is still more likely to be the case if the trouble occurs, as indeed it may, in individuals who were previously feeble and pale without being actually ill. Occasionally a more acute onset is observed in pregnant women.

The first symptoms are almost invariably traceable to the incipient anæmia. They include the subjective disturbances and the objective changes which are seen in ordinary chlorosis. The patient feels languid and is easily fatigued, is liable to headache, vertigo, palpitation, and tinnitus aurium; there are anorexia, frequent nausea, and, above all, a striking pallor of the skin and mucous membranes. While these symptoms, however, usually remain of slight or moderate severity in chlorosis, they attain, in pernicious anæmia, the greatest conceivable intensity. Of course, it would be impossible to describe all the stages through which the patient passes, but we append a sketch of those symptoms which are almost sure to be present, in greater or less completeness, in any well-marked case of pernicious anæmia.

If the anæmia be profound, the patient may be so weak as to be confined to the bed. If he sits up for any length of time, symptoms of increasing cerebral anæmia develop, and he is apt to faint. Usually the patient lies upon his back, with his head rather low, and presents a countenance of waxy pallor. Very frequently a slight but distinct yellowish hue may be detected. Occasionally there are cutaneous ecchymoses, but those are exceptional. The mucous membrane of the lips, the gums, and the conjunctivæ are likewise pale and colorless. The intellect is unimpaired, but all answers to questions are slow, apathetic, and delivered in a low and feeble tone of voice. The patient is usually incapable of any great mental exertion. If the body be moved, and especially if an upright position be substituted for a horizontal one, there is great liability to syncope, as already mentioned. This may result from other slight physical exertions, and is often accompanied by a peculiar spasmodic rigidity of the body. The main subjective symptoms are weakness, and more especially intense headache; this often assumes a

pulsating character, and is located mainly in the temples or forehead. There is also an annoying ringing in the ears, described as a rushing or roaring sound. There are certain other subjective sensations, namely, nausea, a sense of thoracic oppression, and pain in the bones, which will be further considered below.

If we now proceed to a systematic physical examination, we are struck, in the first place, by the condition of the eyes. The pupils are often somewhat enlarged, but react in a normal manner. Vision is often disturbed by spots before the eyes. The anæmic amaurosis seen after a sudden large hæmorrhage has not yet been observed in pernicious anæmia. The ophthalmoscopic examination of the fundus has very great diagnostic importance. We find in a majority of cases, although not in all, retinal hæmorrhage. There may be either one or many hæmorrhages. If they are extensive enough to involve the macula lutea or the disk, they may disturb vision greatly. Retinal hæmorrhages invariably signify that the anæmia is profound, and are, with considerable justice, regarded as distinguishing pernicious anæmia from chlorosis.

*Respiratory Symptoms.*—Breathing is usually accelerated, and, in the most advanced cases, is often remarkably deep and noisy (anæmic dyspnoea, *vide supra*). Sometimes there is a very annoying and almost painful sense of thoracic oppression, which is evidently connected with the dyspnoea. There is a "hunger for air." Physical examination of the lungs gives negative results. Sometimes there is a little cough, and there may be sufficient hæmorrhage into the mucous membrane of the air-passages to give rise to a slight hæmoptysis. Even in this case no anatomical changes can be detected during life. We may also mention in this connection that epistaxis is not very infrequent.

Phenomena referable to the circulatory system are of still greater clinical importance. The area of cardiac dullness is usually normal, although sometimes slightly increased. Upon palpation, we often find that the heart's action is exaggerated, and that its beat is felt over a larger area than normal. The pulse is usually decidedly rapid (100-120), but it is regular, and sometimes, but by no means invariably, small. It is often surprisingly strong. The loud "anæmic murmurs" are very characteristic. They can be appreciated at the apex of the heart, but are usually still better heard at its base. We generally hear a loud *bruit de diable* in the veins of the neck.

*Digestive Organs.*—The tongue is usually pale, smooth, and dry. The appetite is often very poor. The most prominent disturbances, however, are not due directly to the condition of the stomach, but they result from the cerebral anæmia—that is, they are symptoms of the irritation of the nervous centers. We refer to eructations and vomiting, which may be very frequent and distressing. There is usually a tendency to constipation. Occasionally there is diarrhoea.

The liver is usually normal; as is also the spleen in many instances, while in others it is shown by percussion and palpation to be enlarged. It is sometimes possible, as we can ourselves bear witness, to observe an enlargement of the spleen increasing as the anæmia grows more profound, and again decreasing if improvement occurs (*vide infra*). On ordinary examination, the urine does not usually differ essentially from normal. With few exceptions it is free from albumen, and it never contains sugar. As already set forth, however, accurate quantitative analysis often furnishes important evidence of changes in tissue-metamorphosis resultant upon the anæmia (cf. page 934). We will merely mention once more the comparative increase in the amount of urea excreted, and the occasional excess of uric acid. Sometimes the urine gives an unusually vivid reaction for indican.

In regard to what has already been said about the bones, it is an interesting fact that they are very sensitive to pressure in many cases of pernicious anæmia.

The sternum in particular is painful upon light percussion; and sometimes pressure will cause pain in the bones of the extremities. In rare instances swelling of the knee and other joints has been observed.

The blood has been made the subject of numerous and careful investigations; nevertheless, no characteristic change has been discovered. The changes presented in pernicious anæmia likewise occur in cases of profound secondary anæmia. This seems the more readily intelligible to us because of the view which we have already expressed on page 930 with regard to the origin of secondary anæmia. To the naked eye the blood seems extremely pale and watery. The number of red blood-corpuscles is sometimes so diminished that it seems incredible that life should persist. It is not at all unusual, in the last stages of the disease, to find less than 500,000 red blood-corpuscles per cubic millimetre—that is, about one tenth of the normal amount. The red blood-corpuscles are found to present striking varieties in size and form (*vide* Fig. 118). While some corpuscles have a normal appearance, others may be of an unusually large size (macrocytes). These "giant corpuscles" appear normal except in dimensions, and some observers (Laache) have thought that they were even possessed of an unusual amount of hæmoglobin. It is therefore surmised that they represent an effort on the part of nature toward compensation. In contrast with these large cells are found a varying number of minute red cells of a spherical shape; these were first described by Vanlair and Masius, and called microcytes. Their mode of origin and significance are not known. Finally, there are numerous red blood-corpuscles of abnormal shape. These Quincke was the first to notice. They present remarkable forms, being biscuit-shaped, hammer-shaped, or anvil-shaped, and so on, as illustrated in the accompanying cut. These "poikilocytes" are found in perfectly fresh undiluted blood, so that there is no reason to suppose that they are artificial products. Both the microcytes and poikilocytes are at present generally regarded as blood-corpuscles which have undergone imperfect or abnormal development, or suffered changes due to disease. Nucleated red blood-corpuscles have also been seen by Ehrlich a number of times during life. The white blood-corpuscles are not usually increased in number; in occasional instances, however, a temporary leukocytosis has been found. "Granule-masses" are often found in considerable abundance. Chemical examination of the blood has not as yet brought to light any facts of great importance. Of course there is a great diminution in the total amount of hæmoglobin. The amount of albumen in the blood-serum remains nearly normal.

FIG. 118.—Changes in the red blood-corpuscles in pernicious anæmia. (From QUINCKE.) *a*, Normal blood-corpuscles, *b*, Macrocytes, *c*, Microcytes, *d*, Poikilocytes.

We observe in pernicious anæmia the tendency to fever common to all varieties of profound anæmia. In many cases the evening temperature will for weeks reach  $100^{\circ}$ – $101^{\circ}$  ( $38^{\circ}$ – $38.5^{\circ}$  C.), or even higher. Previous to death, however, the temperature may become subnormal, falling to  $86^{\circ}$  ( $30^{\circ}$  C.), or even lower.

As to the origin of all these symptoms we must, as we have said, regard the impairment of the blood, especially its poverty in red blood-corpuscles, as the essential morbid process. How this impairment is produced, whether by injury

to the blood-corpuscles themselves or to the place where they are formed, we do not know. A large part of the other morbid symptoms—the pallor of the skin, the weakness, the “anaemic cerebral symptoms,” tinnitus, vertigo, nausea, faintness, etc., are due directly to the anaemia. In regard to certain other important symptoms, however, another factor is probably of great significance, namely, an auto-intoxication of the body with fibrine ferment.

By the destruction of many red blood-corpuscles, probably a certain amount of hæmoglobin is always set free, and enters the blood plasma. There is then a hæmoglobinaemia. From many experiments, however (Dorpat school of Alexander Schmidt, Ponfick, Silbermann, etc.), we know that hæmoglobin dissolved in the blood destroys the white blood-corpuscles, and in some way produces from them fibrine ferment. Chronic “ferment intoxication” of the body causes certain symptoms, which are almost never absent in pernicious anaemia—capillary hæmorrhages and fever. The hæmorrhages are usually associated with embolism of the smaller vessels, seldom with local thrombi. Many severe nervous symptoms may perhaps also be referred to this intoxication.

**General Course, Duration, and Prognosis.**—As the very name “pernicious” indicates, the disease generally terminates unfavorably. Death usually seems to be the direct result of the extreme anaemia; special complications are exceptional. The disease often maintains a slow but gradual progress to the end. Its duration, reckoning from the appearance of the first symptoms, may not exceed three to six months. It may even run its course in a still shorter time. It seldom lasts more than a year. Sometimes its course is interrupted; there may be an arrest of the process, or improvement, or even apparent recovery. Usually, however, there are fresh relapses. In a certain class of cases the disease lasts two or three years, and is marked by a number of “attacks of anaemia” so intense that the subsequent improvement of the patient seems simply marvelous. It is in cases of this sort that splenic tumor has been made out at the time the anaemia was at its height; yet we do not perceive the necessity of establishing “splenic anaemia” as an affection essentially different from progressive pernicious anaemia. It is merely a clinical variety of the disease under discussion. Apparently, it likewise has an invariably fatal termination.

Permanent recovery may occur in cases of idiopathic anaemia so profound that we are at first inclined to regard them as pernicious. These cases are unfortunately very rare, and even where there is a marked improvement the danger of a relapse is to be borne in mind. The prognosis is therefore always very grave, if not absolutely unfavorable. Of course, general hygienic surroundings and good care may exert some influence upon the course of the disease. It is noteworthy that if pregnancy be complicated by profound anaemia there is a great liability to premature delivery, after which there is often a rapid change for the worse. There are exceptions to this rule.

**Diagnosis.**—It is seldom difficult to make out the existence of a profound anaemia, or to determine the degree of danger which the consequent symptoms indicate. We have, however, the same difficulty here as in chlorosis in proving that the anaemia is primary and idiopathic. The factors essential to this diagnosis have been already indicated. We should bear in mind the possibility of incipient tuberculosis, organic diseases of the stomach, or such parasites as the *anchylostoma* and tapeworm.

**Treatment.**—For treating progressive pernicious anaemia we have only the same remedies as for the benign variety of anaemia. Abundant and suitable nourishment is requisite, and all hygienic influences should be carefully regulated. Internally, our main reliance is to be put upon the preparations of iron. With us, a favorite remedy in pernicious anaemia is the *tinctura ferri chlorati*

*ætherea* (analogous to *tinctura ferri chloridi*, U. S. P.), of which ten drops in sweetened water may be given several times a day. It would also be extremely advisable to try the effect of arsenic. This remedy sometimes accomplishes striking results in the whole group of blood diseases, including leukæmia and pseudo-leukæmia as well as anæmia. It is much better administered in pill form than in Fowler's solution. Iron may be given at the same time with arsenic. Some authorities recommend phosphorus.

If the case be not too far advanced, baths may prove useful adjuvants to the internal treatment. Salt baths or artificial carbonic-acid baths may be employed. Symptomatic treatment is often indicated: the dyspepsia may call for dilute hydrochloric acid, or the troublesome vomiting may require bits of ice, bromide of potassium, or opium.

The transfusion of blood has been employed in pernicious anæmia. Sometimes the effect seems to be favorable. Experience thus far, however, would not lead one to expect very great benefit from it. Von Ziemssen has lately recommended in all severe forms of anæmia the subcutaneous injection of blood. It is done by injecting under the skin, by thoroughly disinfected instruments, fifty cubic centimetres of defibrinated human blood, divided into two parts, twenty-five cubic centimetres being injected into each thigh. The point of injection is vigorously rubbed, and thus the injected blood is forced into the lymph-channels. In severe cases this procedure should be frequently repeated. Experiments on this method are thus far very favorable. Not only the subjective symptoms, but the objective condition of the blood, the number of red blood-corpuscles, sometimes show a striking improvement after the injection.

[In the experience of American and English clinicians, arsenic, long continued and in as large doses as are tolerated, is of far greater value than iron.

The inhalation of oxygen is expensive, but seems to be of distinct service in some cases of grave anæmia of all forms.]

### CHAPTER III.

#### LEUKÆMIA.

(*Leucocythæmia*.)

**Definition and Ætiology.**—Virchow, in 1845, was the first to obtain an insight into the disease leukæmia ("white blood"). He detected the great increase of white corpuscles occasioned by it, and from this time these constituents of the blood were subjected to observation in all sorts of diseases. It was soon found that there may be a temporary increase of the white corpuscles in various primary diseases, and that in certain instances this increase may actually constitute the essential symptom. In this latter case the increase is due to a depraved condition of certain internal organs. In the temporary cases, where the increase of white blood-corpuscles is usually not very great, we find one white corpuscle to one hundred red, or even one to fifty—the normal ratio being one to six hundred or more. This is usually termed leukocytosis, in distinction from leukæmia proper. Leukocytosis is most frequent in acute infectious diseases, such as typhoid fever, recurrent fever, intermittent fever, and pyæmia, and is also often seen in anæmia.

Genuine leukæmia is a rather rare disease. Its characteristics are well marked in most cases, but of its true nature we remain entirely ignorant. In a majority of the cases the change in the blood is associated with a disease of the spleen and the bone-marrow, and often also with changes in the internal organs.

just enumerated being concerned in the manufacture of the blood, it is very reasonable to suppose that leukaemia is a disease which primarily affects these organs, and that the increase in white corpuscles results from the disturbance thus occasioned. The cause of the disease in the organs mentioned is as yet unknown. Various authors have suggested that there may be some specific infection, but they have not been able thus far to produce any evidence of the truth of their surmise. In few cases can we discover even any exciting cause. The illness seems to develop spontaneously in perfectly healthy persons. In some cases, on the other hand, leukaemia does seem to be a sequel of some other disease. Thus it is occasionally preceded by a tedious attack of intermittent fever. It has also been asserted that syphilis and other infectious diseases, such as typhoid, may give rise to leukaemia, but this is not very probable. Finally, trauma of the spleen or bones has in repeated instances been regarded as the occasion of the disease.

The hygienic surroundings of the patient have also been regarded as causes of leukaemia. The disease is more frequent among the poorer classes than among the wealthy; but there are numerous exceptions to this rule. Aetiological importance has also been ascribed to anxiety, trouble, and mental depression in general, but with how much justice is doubtful.

Leukaemia is most common in middle life, between thirty and forty-five years of age, but well-marked cases have been observed repeatedly even in childhood, as also, though less frequently, in old age. Men are somewhat more liable to the disease than women. It has been repeatedly stated that in female patients the disease is sometimes referable to sexual derangement, but this has not been proven.

**Pathological Anatomy.**—The pathognomonic change in leukaemia is an increase in the number of white blood-corpuscles; this may be so considerable that there may be one white to three red, or even one white to two red corpuscles. The characteristics of the blood can be studied during the life of the patient, and upon them the diagnosis is mainly based. They will therefore be discussed under symptomatology, while we shall here confine ourselves to the lesions presented by the spleen, bone-marrow, and lymph-glands.

Of the organs just enumerated, the spleen is the one most frequently affected (splenic leukaemia). It is often greatly increased in size, not seldom attaining a weight of six to thirteen pounds (3-6 kilogrammes) and a length of a foot (30 cm.). There is a true hyperplasia of the whole organ: all the histological constituents are increased. The cut surface is usually a rather vivid red in early cases, but later on it often has a lighter, yellowish color. The consistence is usually diminished, but in the later stages it may be greater than normal. Upon microscopic examination, we find enlargement of the blood-vessels and a great increase in the cells of the pulp and of the follicles. Sometimes the hyperplasia of the follicles predominates, giving the spleen a spotted appearance, like marble. In such cases the pulp usually presents retrograde metamorphosis, with atrophy and fatty degeneration of its cells and deposits of pigment. In advanced cases a considerable amount of firm connective tissue may be present. There are often hæmorrhagic infarctions, presenting the appearance of circumscribed spots, dark red, or in the later stages brownish yellow, in color.

Lesions of the bone-marrow are next in frequency to those of the spleen (medullary and myelogenous variety of leukaemia). Neumann and a few other authorities regard changes in the bone-marrow as an essential lesion, and hold that they can be demonstrated in every case of leukaemia. There would certainly seem to be exceptions to this last rule, but nevertheless in a majority of cases the marrow does present a peculiar yellowish or almost puriform appearance. By means of the microscope we can detect a great increase in the lymphoid cells of

the marrow and the presence of a considerable number of nucleated red blood-corpuscles.

In many cases the lymph-glands remain perfectly normal; but in others they become considerably enlarged, and form actual tumors in various parts of the body, such as the axilla, neck, and groin, and sometimes the internal lymph-glands. Such cases are examples of lymphatic leukæmia. Histologically, the change here is simple hyperplasia of the glandular tissue.

These three forms of leukæmia—splenic, myelogenous, and lymphatic—can not be regarded as distinct diseases, inasmuch as cases occur which present all sorts of combinations of these different lesions. Purely myelogenous cases are very rare, if they occur at all; and we rarely meet with cases which are purely splenic or purely lymphatic. Most cases present lesions of the spleen and marrow conjointly. In less frequent instances splenic disease is associated with that of the lymphatic glands. The fact that these combinations exist indicates that there is one common cause for the disease, which assails sometimes one, sometimes two, or sometimes all three of the organs named.

Just what the connection is between the changes in the blood and the lesions of these various organs is an unanswered question. A view which seems to us very plausible regards the disturbance in the spleen, or marrow, or lymph-glands, as the case may be, as the primary one, and the alteration in the blood as a result of this primary disturbance; there is an increase in the number of colorless corpuscles formed, and a consequent increase in the number of them introduced into the circulatory fluid. Some authorities have taken for granted that the colorless blood-corpuscles normally undergo transformation into red blood-corpuscles, and believe that in leukæmia this metamorphosis is hindered; but the assumption lacks support. It is true, however, that the number of red blood-corpuscles is diminished in leukæmia. This diminution in number might be ascribed either to scantiness of supply or to increase in the processes of destruction, but which factor is in reality the important one must remain undetermined.

*Changes in Other Organs.*—Leukæmia sometimes causes new growths of a lymphatic character in certain organs other than those already mentioned. The growths may either be diffuse or circumscribed and nodular. They are observed in the tonsils, Peyer's patches, and the intestinal follicles. They are also very frequent in the liver, kidneys, and retina, and more rarely in the lungs and the pleura. These various lesions may be regarded as in a certain sense analogous to the metastatic tumors of cancer or sarcoma, and suggest the possibility of the diffusion of the pathogenic poison throughout the whole body. In one or two cases a well-marked leukæmia has been found independent of any demonstrable organic lesions. It is impossible, at present, to explain such occurrences. Leube and Fleischer have reported a case of this sort, and are inclined to believe that the blood itself was diseased. There is little known as yet as to changes in the chemical characters of the blood and viscera in leukæmia. Xanthine and hypoxanthine have been found in the blood, as have also lactic acid and formic acid. It is also noteworthy that octahedral crystals are often found after death in the blood, spleen, and marrow, and in other parts. These are known as Charcot's crystals, and have already been described as occurring in the sputum in certain pulmonary diseases (compare page 169).

*Symptoms.*—The clinical phenomena of leukæmia are in many respects similar to those of progressive pernicious anemia, and need not be enumerated again here. In leukæmia, however, we have, in addition to the symptoms referable to the spleen or lymph-glands or bone-marrow (as in anemia), and also the characteristic alterations in the blood. The latter are so pathognomonic, demand a full description.

The pallor and watery character of the blood in leukaemia are noticeable even to the naked eye in advanced stages of the disease. They can not, however, be distinguished without the aid of the microscope from the changes present in grave anaemia (*vide* Fig. 119). Looking through that instrument, we frequently per-

FIG. 119. — Anaemic blood. (From FUNKE.) *a*. White blood-corpuscles. *b*. Red blood-corpuscles.

ceive at once an enormous increase in the number of the white blood-corpuscles. As already stated, there may be almost as many white as red corpuscles. The size of the white corpuscles varies in different cases, and also in the same case. Virchow has called attention to the fact that the smaller cells originate mainly in the lymph-glands, and are therefore especially numerous where the leukaemia is of a lymphatic type. The larger cells are referred mainly to the spleen and the marrow. The marrow is also said to contribute certain extremely large nucleated cells, the dimensions of which considerably exceed those of the normal white blood-corpuscles. It is not always possible to determine the origin of the white cells from their size. Ehrlich has suc-

ceeded in making out various forms of white corpuscles by staining. What are called "eosinophilous cells" are especially increased in the blood of leukaemia. These are colorless cells, the granules of which take a deep stain with acid pigments, but not with basic. Coincident with this increase in the white cells in leukaemia there is almost invariably a considerable diminution in the number of red blood-corpuscles. We also find an occasional nucleated red blood-corpuscle in leukaemic blood, and sometimes also microcytes, poikilocytes, and almost always a large number of "granule-masses" interspersed between the blood-corpuscles.

Splenic tumor is the most frequent and important of the organic lesions produced by leukaemia. It is rarely possible to observe its development. In most instances the spleen is already large when the patient first comes under observation. It projects from under the ribs as a firm, hard mass, the lower and anterior extremity of which often extends to the median line of the body. The inner edge of the tumor is somewhat characteristic; it is rather sharp, and presents one or two notches. At first there is little subjective disturbance or pain referred to the spleen. Where the enlargement is very great, there is often an annoying or even distressing feeling of distention and fullness in the abdomen. Respiration may also be interfered with by the crowding up of the diaphragm.

The lesion of the bone-marrow can never be determined absolutely during life. The only symptom which renders its existence probable is pain in the bones, but even this is not an infallible symptom. There is seldom pain except upon pressure. It is usually brought out by percussion of the sternum, but there may be well-marked disease of the marrow without this "sternal pain."

As already stated, the lymph-glands often remain perfectly normal. If they are affected, the disturbance is betrayed by their increase in size. Not only may the glands in the neck, axilla, and groin be enlarged, but occasionally also those of the mesentery and retroperitoneum, as can be demonstrated upon palpation of the abdomen. The enlarged lymph-glands rarely cause severe pain, if any at all.

We have already referred to leukaemic new growths in other internal organs. These possess, for the most part, merely a scientific interest, as they cause no spe-

cial symptoms. Sometimes hepatic enlargement occurs, as the result of a diffuse leukæmic infiltration. The changes in the retina associated with leukæmia are of importance, as they can be detected by means of the ophthalmoscope. The retina presents white spots or stripes running parallel with the blood-vessels. They are due to collections of lymphoid cells, or to actual lymphoid growths. These lesions have been inappropriately called leukæmic retinitis. Retinal hæmorrhages occur also in leukæmia, as in grave cases of idiopathic anæmia.

All the other clinical phenomena of leukæmia result from the abnormal condition of the blood, meaning thereby the anæmia. The ability of the blood to perform its normal functions is impaired mainly through the loss of red blood-corpuscles; the resulting symptoms are therefore precisely the same as in essential anæmia, and we do not need to describe them again. They usually are the most prominent symptoms of the disease, and include noticeable pallor of the skin, equal to that sometimes seen in anæmia; anæmic murmurs over the heart and the veins of the neck; general debility; anorexia, and digestive disturbances; palpitation and dyspnoea; and, finally, the whole group of the "cerebral symptoms of anæmia," that is, headache, vertigo, syncope, and tinnitus aurium. Sometimes there is a troublesome pruritus. We would also call attention once more to the frequent hæmorrhages. These must be due to impaired nutrition of the vascular walls, and sometimes justify our speaking of a "hæmorrhagic diathesis." Obstinate epistaxis is particularly frequent. Less often we have hæmorrhage from the intestine, stomach, kidneys, or into the skin or muscles, etc. We may have cerebral hæmorrhage, with hemiplegia, or sometimes immediate death, consequent upon it. Severe cases may present a slight œdema of the skin and serous effusions into the various cavities of the body.

The urine in leukæmia is essentially like that excreted in pernicious anæmia. Fleischer and Penzoldt have shown that in leukæmia as well as in pernicious anæmia there is increased destruction of albuminoids, and a consequent increase in the excretion of nitrogen. There is often also a considerable increase of uric acid.

The temperature is apt to undergo slight elevations, as in severe cases of anæmia. In advanced stages there may be quite high fever of an intermittent character, reaching  $103^{\circ}$ – $104^{\circ}$  ( $39.5^{\circ}$ – $40^{\circ}$  C.). The fever is sometimes accompanied by chills, and when the temperature falls there is often a profuse and debilitating perspiration.

Complications are, on the whole, rare. Sometimes we observe pulmonary tuberculosis, or some acute intercurrent disease such as pneumonia. We saw one case end in death from hæmorrhagic angina and œdema of the glottis.

In regard to the pathogenesis of the different symptoms the conditions are manifestly very like those of simple severe anæmia. Poverty of the blood in red blood-corpuscles and chronic ferment intoxication are the most important factors. We may therefore refer to what was said on page 944.

**Clinical History.**—Leukæmia is almost always chronic in its course. The disease begins insidiously and progresses gradually; the patient grows pale, feels languid, and has slight and apparently insignificant symptoms, which gradually give place to alarming phenomena. The patient may himself notice the organic lesions incident to the disease. If the leukæmia be of the lymphatic type, he is apt to be struck by the swelling of the lymph-glands, while in splenic leukæmia his attention is attracted by the feeling of tension and pressure in the abdomen, the increasing prominence of the left side, and the unusual sense of resistance present in that part of the abdomen. Sometimes it is obstinate epistaxis, or hæmorrhage from some other source, which first attracts attention and leads to a careful examination of the blood and spleen.

The disease usually lasts several years. Many cases are rather mild and gradual in their progress; there is a rapid development of all the symp-

toms. Some cases go on so rapidly, occupying but a few months, that they might almost be termed "acute leukæmia." Instances of this form are most frequently seen in children. Apparent arrest of the disease is frequent, as is also temporary improvement, followed by fresh exacerbations. The final termination is almost invariably unfavorable. Death is usually preceded by symptoms of the most profound anæmia, and is caused directly by the general debility. It is sometimes hastened by the occurrence of hæmorrhages, for instance, obstinate epistaxis or cerebral hæmorrhage.

Recovery is not absolutely impossible, but still it is very rare, and it is out of the question after the disease has passed its first stages. In an advanced case, therefore, the prognosis must be regarded as hopeless.

**Diagnosis.**—Leukæmia can be easily and unmistakably recognized by a microscopic examination of the blood. In a very early stage of the disease the increase of white blood-corpuscles may be so slight that a definite decision can not be made; but the later developments will afford absolute certainty in any typical case.

We can not fail to recognize a case of leukæmia if the blood be examined. Such an examination is therefore demanded in every case of obstinate anæmia, and, above all, in such patients as have a chronic enlargement of the spleen, or swelling of the lymph-glands in various parts of the body. The enlarged lymph-glands are readily recognizable. The splenic tumor can usually be diagnosed from its characteristic position and shape, and especially from its internal edge, with the notches already spoken of. It may be simulated by hydronephrosis and other diseases causing enlargement of the kidneys, and in women by ovarian tumors. In cases of doubt the blood should be examined, and if the result be a positive one, we may feel certain of our diagnosis. If there is a chronic enlargement of the spleen without a leukæmic change in the blood, we must consider all the possible causes of such an enlargement; thus there may be a passive congestion of the spleen, with enlargement, as the result of hepatic disease, portal thrombosis, or disease of the heart, or a splenic tumor from malarial poisoning. Again, there are cases where we have the signs of a gradually progressive anæmia, apparently idiopathic, and a chronic enlargement of the spleen, or still more frequently enlargement of the lymph-glands in various parts of the body, without increase in the number of white blood-corpuscles. Such cases are termed pseudo-leukæmia, and are described in the next chapter.

**Treatment.**—Nearly the same remedies are employed in leukæmia as in idiopathic anæmia. Of course the greatest attention should be paid to general nutrition. Of internal remedies, the preparations of iron have been mainly employed. They seldom produce any brilliant or permanent effects. We have much more confidence in the administration of arsenic, and this remedy should certainly be tried in large doses. It may be given either in the shape of pills, or, possibly with still more advantage, subcutaneously. Of course no permanent benefit is to be hoped for even from this, except in the early stages of the disease.

What are called "splenic remedies" have been often employed, but do not seem very effectual in leukæmia. Mosler obtained good results from the long-continued use of quinine (5-8 grains = 0.30-0.50 gm., or more, in twenty-four hours). He also recommends a trial of piperin and oil of eucalyptus:

R Olei eucalypti..... gtt. 100;  
 Piperini,  
 Cere albæ ..... āā 3 j (grm. 4.0);  
 Pulv. altheæ..... 3 ij (grm. 7.5).  
 M. et fiant pilulæ no. c.  
 S. Three to five pills three times a day.

Local treatment of the spleen has also been attempted. If an ice-bag be constantly kept on the splenic region, it will sometimes diminish the size of the tumor, and may also relieve pain. Botkin has recommended faradization of the spleen, but we can scarcely expect any great benefit from such a procedure. Injections of quinine, arsenic, and other remedies, have been made into the substance of the spleen. We do not believe that this is advisable. The splenic tumor of leukæmia has actually been extirpated surgically; but the proceeding is so ineffectual and so fatal that it is now universally abandoned. The transfusion of healthy human blood has also been tried, but without satisfactory results. Subcutaneous injections of blood (*vide supra*) have been tried in only a few cases, but they may, perhaps, have good results. In some recent cases inhalations of oxygen have acted favorably.

Many other particulars of treatment have been mentioned under anæmia.

#### CHAPTER IV.

##### PSEUDO-LEUKÆMIA.

(*Hodgkin's Disease. Adenia. Malignant Lympho-sarcoma. Pseudo-leucoerythæmia.*)

It was mentioned in the preceding chapter that there are cases in which the organic lesions are apparently the same as in genuine leukæmia, and yet there is little if any increase in the number of white corpuscles in the blood. There is generally, however, a diminution in the number of red corpuscles. These cases usually receive the name which Cohnheim gave them of pseudo-leukæmia. It is nevertheless doubtful whether they are to be regarded as a special form of disease, and there are various facts which indicate that they are at least very closely allied to genuine leukæmia. There is a great similarity in most of the symptoms of the two diseases and in their general course, as well as in the organic changes they produce. Furthermore, a case of pseudo-leukæmia may finally assume the character of genuine leukæmia, with its characteristic blood changes.

The purely splenic type of pseudo-leukæmia is the least frequent one. As yet very few such cases have been reported. There is a gradually increasing anæmia with the usual symptoms, and associated with these increasing enlargement of the spleen. It is impossible to draw any sharp dividing line between such cases and cases of pernicious anæmia attended with moderate enlargement of the same organ (splenic anæmia). It may be said to be a matter of taste which name the physician shall give to a case of this sort. The bone-marrow seems to present the same characteristics in splenic pseudo-leukæmia as in pernicious anæmia.

**Pseudo-leukæmia Lymphatica.**—Pseudo-leukæmia of a lymphatic type is a much more frequent and well-defined disease. It was first described in 1832 by the Englishman Hodgkin, and is sometimes called Hodgkin's disease. Wunderlich was the first in Germany to study the disease thoroughly; he described it in 1858 under the name of "progressive multiple hypertrophy of the lymph-glands"; and later Billroth termed it "multiple malignant lymphoma." Trousseau gave it the name of "adenia."

Little is known about the ætiology of lymphatic pseudo-leukæmia. It is said to be connected with malarial poisoning, syphilis, and some other diseases; but such statements are without a satisfactory basis. The tendency of late is to assign adenia to the group of infectious tumors, although the reasons for this belief are as yet purely theoretical. Pseudo-leukæmia is most common in young and

middle-aged people, and is apparently rather more frequent in men than in women.

*Pathological Anatomy.*—The hyperplasia of the lymph-glands may be very great, producing large tumors of varying consistency. These have been called lymphoma, lymphadenoma, and lymphosarcoma. On section, the tumors display a white or grayish-red surface, and are seen to be made up of a number of swollen glands fused into nodular masses. Upon microscopic examination, we find a very abundant proliferation of lymph-cells, sufficient to obscure the reticulum of the gland completely. The new growth may even escape beyond the capsule of the gland and invade surrounding structures. Inflammatory adhesions often take place between the tumor and the overlying skin. There does not seem to be any essential difference between the harder and the softer varieties of these tumors.

These changes in the lymph-glands are often, though not invariably, associated with a swelling of the spleen. Its increase in size is usually slight. Lymphomata may also develop in the tonsils, the intestinal lymphatics, liver, kidneys, and other organs. Whether there are changes in the bone-marrow has not yet been determined.

The symptoms are very gradually developed. It is almost invariably the swelling of the lymph-glands which first attracts the attention of the patient or his physician. The glands upon one or both sides of the neck are usually the first to be enlarged, and they may finally grow to tumors the size of the fist, or even larger, producing great disfigurement. To the changes in the neck succeed swelling of the axillary, inguinal, and perhaps also the internal lymph-glands. The changes are gradual, and vary in their rapidity and extent.

At first the general health is hardly at all affected, but as the disease progresses its constitutional effects become more and more marked. The patient grows pale and languid, and finally presents all the symptoms of profound anæmia. We may also have certain symptoms due to mechanical compression occasioned by the growth of the lymphomata. The tumors in the neck may cause dysphagia, from compression of the pharynx and œsophagus; dyspnoea, from compression of the larynx and trachea; and perhaps alarming cardiac disturbance, from interference with the vagus. Hypertrophy of the bronchial glands sometimes occasions great difficulty in respiration; enlargement of the abdominal glands may produce ascites or jaundice; and enlargement of the glands in the groin may give rise to œdema in the lower extremities. In advanced stages we may have "cerebral symptoms of anæmia" precisely similar to those seen in genuine leukaemia or in pernicious anæmia. There may be a tendency to hæmorrhage and pruritus, and the urinary secretion and temperature may be abnormal. For particulars the reader is referred to the preceding chapters.

Upon examination of the blood, there are usually found the changes characteristic of ordinary anæmia, without increase in the number of white blood-corpuscles. Sometimes, however, there may be a slight leukocytosis; and sometimes, as already said, lymphatic pseudo-leukaemia may merge into genuine leukaemia. The examination of the blood must therefore be repeated from time to time. The spleen should also be examined. It is usually somewhat enlarged, and in some cases the enlargement may be considerable. Such cases might be properly denominated splenic-lymphatic pseudo-leukaemia. We may also discover a tenderness of the sternum or other bones.

The disease often lasts but a few months; it may, in rare instances, extend over two or three years or more. Recovery is not absolutely impossible in the early stages of the disease (*vide infra*), but at a later period the prognosis is absolutely unfavorable. The fatal termination results either from increasing debility and

anæmia, or from the effects of mechanical compression, or from hæmorrhage, or from some intercurrent disease.

The diagnosis of pseudo-leukæmia is usually easy. It is to be based upon the objective signs and the condition of the blood. The disease is most apt to be confounded with swelling of the lymph-glands occasioned by tubercular infection; but in this latter case the changes are seldom seen in so many parts of the body, and the patient usually presents other indubitable evidences of tuberculosis.

*Treatment.*—We possess only one remedy capable of promoting absorption of the lymphomata, namely, arsenic. We have ourselves, in common with a great number of observers, had the most convincing evidence of the favorable influence of arsenic. It must, however, be given in sufficient doses: for example, a pill containing one fifteenth of a grain (0·004 grm.), or even a larger amount of arsenious acid, three times a day; and its use must be persisted in for a long time. It might also be tried subcutaneously. We have also seen apparent benefit from associating with the arsenic inunctions of iodoform (iodoform one part, vaseline fifteen parts) over the tumors.

In early stages decided benefit may be expected from this mode of treatment. At a later period we may obtain a decrease in the size of the tumors, but we can hardly hope for any permanent improvement. Operative interference is out of the question, except at the very beginning of the disease. Later on, it would be perfectly useless, and could seldom be carried out.

Other suggestions with regard to treatment may be obtained from the chapters on anæmia and leukæmia.

## CHAPTER V.

### HÆMOGLOBINÆMIA AND HÆMOGLOBINURIA.

**Definition and General Ætiological Considerations.**—If any cause produces a solution of the red blood-corpuscles in the blood-serum, hæmoglobin is excreted through the kidneys. The hæmoglobinæmia—the presence of free hæmoglobin in solution in the blood—excites hæmoglobinuria, i. e., the excretion of hæmoglobin in the urine. The causes of hæmoglobinæmia and its correlative hæmoglobinuria are manifold. In the first place, there are a whole series of poisons which, if introduced into the blood in sufficient amount, exercise a directly destructive influence upon the red blood-corpuscles, and thus excite hæmoglobinuria. To this list belong chlorate of potash (Marchand), pyrogallie acid and naphthol (Neisser), glycerine, toluyleudiamine, and many other substances. Distilled water is also in this sense a poison. Boström has discovered a fact of practical importance which deserves mention in this connection. It is, that a certain kind of mushroom (*Helvella esculenta*), when fresh, contains a poison which is capable of producing intense hæmoglobinuria, and such grave symptoms as jaundice, delirium, drowsiness, and tetanic convulsions, with perhaps a fatal termination. This poison is, however, so evanescent and so readily soluble in hot water that the mushroom becomes perfectly harmless if thoroughly soaked and then boiled, or if it has been dried.

Secondly, hæmoglobinuria may be developed in connection with infectious diseases. In this case, also, it may be referable to the action of poisons created within the system. Thus hæmoglobinuria has been observed in the course of a severe attack of scarlet fever or typhoid fever. Possibly malarial poisoning and

syphilis may give rise to paroxysmal hæmoglobinuria. This question will be discussed later on.

There is a third mode of origin which also possesses practical importance. If blood from one animal be injected into another of a different species, hæmoglobinuria is almost sure to result. Not only do the injected blood-corpuscles undergo solution, but also the injected serum acts as a poison upon the original blood-corpuscles, destroying and dissolving them. This transfusion-hæmoglobinuria has been described by Prévost, Dumas, Ponfick, and Landois. It can be produced in human beings, as there was only too good opportunity to observe during the brief period when the transfusion of lamb's blood was in vogue. The practical deduction is evident, that we should not use for injection into the circulatory system of a patient anything but an unirritating salt solution, or human blood.

A fourth and very important ætiological factor is exposure to extremes of temperature. Hæmoglobinuria is a very frequent result of severe burns. The blood-corpuscles in that region of the periphery exposed to the heat are destroyed. Cold is capable of producing precisely analogous results. This is particularly evident in the cases of so-called paroxysmal hæmoglobinuria described by Wickham Legg, Lichtheim, and Küssner. [Raynaud's disease (see page 588) and hæmoglobinuria are associated in a sufficiently large proportion of cases to show some relationship between the two.]

**Pathology and Symptoms of Hæmoglobinæmia, particularly the Paroxysmal Variety.**—In most of the cases above enumerated, hæmoglobinuria is the result of an obvious or easily demonstrable cause. There is, however, another variety which appears paroxysmally in individuals who are otherwise perfectly well. Its symptoms are extremely characteristic. Although not a very frequent disease, there has been abundant opportunity to study it.

As just intimated, the disease is paroxysmal. Very often an attack is ushered in by frequent and persistent yawning. To this symptom are soon added pain in the limbs, headache, nausea, vomiting, and coolness of the periphery. The temperature speedily rises to  $102^{\circ}$  ( $39^{\circ}$  C.) or more. With this is often associated a decided chill. Sometimes there is a violent, cramp-like pain in the hepatic region. Then the temperature falls again, perspiration appears, and the patient, although languid and depressed, soon recovers. A slight icteric hue can almost invariably be detected toward the end of the attack, the ordinary duration of which is from two to twelve hours. An eruption of urticaria is noticeably frequent in connection with the attacks.

The most interesting phenomenon of all remains to be described. We refer to the condition of the urine during and directly after the paroxysm. This secretion presents a dark brownish-red color resembling blood; it may even appear almost black. Its reaction is almost invariably acid; its specific gravity is usually rather low, say 1008–1012. On boiling the urine, the hæmoglobin is decomposed and a brown coagulum of albumen formed. If the excretion be examined through a spectroscope, we find the stripes characteristic of hæmoglobin, and sometimes also the narrow stripes indicative of methæmoglobin. It is therefore impossible to doubt the existence of hæmoglobin in the urine; and yet, upon microscopic examination, we find no red blood-corpuscles in the urine, or, in other words, no "hæmaturia." Frequently there are great numbers of opaque red granules in the urine, the shape of which is extremely irregular. These are, doubtless, granules of hæmoglobin. Some of them are free in the urine, some are attached to casts. Of the latter, we find hyaline and a few epithelial casts present. Sometimes masses of hæmoglobin assume the appearance of casts. The sediment may also contain a few cells of renal epithelium. The presence of this

and of hyaline casts indicates that the kidneys have been slightly irritated by the excretion of hæmoglobin.

If now we examine the blood during a paroxysm, we shall find that hæmoglobinæmia is associated with hæmoglobinuria of the paroxysmal type, as well as with that occasioned by the action of various poisons. Küssner obtained blood from a patient during a paroxysm, and found that its serum had a ruby-red color, and contained hæmoglobin in solution. This proves that the destruction of blood-corpuscles takes place within the circulatory system. Indubitable tokens of this destructive process are to be seen upon microscopic examination of the blood during a paroxysm, especially when the paroxysm has been produced artificially in the manner described below. The red blood-corpuscles have little tendency to form rouleaux. They are pale, and many of them are irregular in shape (poikilocytes). Irregularly shaped flakes of hæmoglobin are also present, and often large numbers of decolorized red blood-corpuscles are to be seen. To these latter Ponfick has given the name of "shadows." Hæmoglobinæmia is also of the greatest clinical importance, because it probably must lead to a ferment intoxication of the body (*vide supra*, p. 944), to which a great part of the symptoms of the hæmoglobinuric attack, such as chill, fever, and nervous disturbances, must be referred. The origin of jaundice will be considered below.

In many cases the exciting cause of each separate paroxysm is perfectly evident. There is a cooling off of peripheral portions of the body—that is, the temperature of the blood in those parts is lowered (or the cold acts on the walls of the vessels?) and this leads to a destruction of red corpuscles. Patients are free from attacks unless they have been out in cold or stormy weather, or have been wet through in a cold rain. As we might expect, the paroxysms are extremely rare in summer; they may, however, as Rosenbach showed by experiment, be artificially produced at any time, by exposing the surface of the body to severe cold, as by giving the patient foot-baths of ice-cold water. Ehrlich and Boas have both performed experiments which show that the action of cold is a purely local one. They have separated a finger of the patient from the general circulation by means of an elastic ligature, and then immersed it for a quarter of an hour in iced water. Blood taken from this finger invariably exhibited the above-mentioned changes, while the condition of the rest of the blood in the patient's body remained almost perfectly normal.

There can, therefore, be no doubt that in certain cases cold affects any portion of the peripheral circulation exposed to it in such a way as to excite a paroxysm of hæmoglobinuria. The paroxysms cause headache, fever, nausea, and other symptoms, the immediate origin of which is not perfectly understood. Several authorities believe that these phenomena are uræmic; and it has indeed been proven, both from the post-mortem appearances in such patients as have from some coincidence come to autopsy, and from experiments upon animals, that the kidneys may be plugged up with granules of hæmoglobin in sufficient amount to give them a dark-brown hue. The granules collect chiefly in the straight tubules, and also in the convoluted tubes and the glomeruli. Such a condition may present a considerable obstacle to the excretion of the urine, and more especially to the elimination of its solid constituents. In point of fact, the urine is usually of low specific gravity. This retention of urinary constituents in the blood certainly might produce some of the symptoms observed; but it is not certain whether we must not consider other influences.

No explanation has yet been offered for the liability of certain unfortunate individuals to paroxysms of this sort, from which most men are exempt. It may be mentioned that most patients have had a syphilitic history; so that a connection between these two affections is in many cases very probable (Murri). Par-

oxysmal hæmoglobinuria has also been observed in hereditary syphilis. It is doubtful whether hæmoglobinuria can have, as is claimed, any relation to malaria. We must note, however, that the individual attacks may be due not only to cold but sometimes to other influences, especially great physical exertion, long walks, etc. In conclusion, certain pathological facts should be mentioned. The kidneys are not the only receptacles of the *débris* resulting from the destruction and solution of the blood-corpuscles. Ponfick has been led by the result of certain experiments to believe that the spleen and liver are also affected. The spleen appropriates the undissolved remnants of the corpuscles, and, as a consequence, may undergo considerable enlargement. The liver absorbs a large part of that portion of the hæmoglobin which has undergone solution, and converts it into bile. As a result there seems to be an increased secretion of bile. Jaundice is probably due to local biliary stasis and biliary absorption in the liver itself ("hæmo-hepatogenous jaundice" of Afanassiew). It is not yet established whether a part of the hæmoglobin dissolved in the blood can be changed into bile pigment (true "hamatogenous jaundice").

**Prognosis.**—When hæmoglobinuria is merely a symptom of other abnormal processes caused by poisoning or by some specific infection, the future of the patient depends entirely upon the severity of the primary disease. An attack of paroxysmal hæmoglobinuria would not seem to involve any direct danger to life. Recurrence of the paroxysms is always to be feared if the patient be exposed to those influences which produce it. There are no certain means of decreasing the patient's liability to attacks. In a few cases, however, where there had been syphilis, the paroxysms are said to have been permanently banished by mercurial inunctions. Likewise, if we suspect malarial influences, quinine should be tried.

No special treatment is required during the paroxysm itself. The patient must escape as soon as possible from the exciting cause; it is then advisable for him to lie quietly in bed, and to drink a large amount of fluid, so as to wash out the masses of hæmoglobin from the kidneys.

## CHAPTER VI.

### SCURVY.

(*Scorbutus*.)

**Prefatory Remarks.**—Scurvy is one of a group of diseases which may be termed "hæmorrhagic." They all have one predominant symptom, namely, a decided hæmorrhagic diathesis, respectively associated in the different diseases with various other more or less pronounced disturbances. This tendency to spontaneous hæmorrhage is in many cases, particularly the milder ones, more or less exclusively confined to the skin, but in numerous other instances hæmorrhage also takes place into the underlying tissues, such as the muscles or joints, as well as into the mucous membranes.

The distinctions between these various diseases are founded upon the manner in which the hæmorrhages occur and the symptoms which attend them. We may mention scorbutus, purpura simplex, purpura hæmorrhagica, and peliosis. It should, however, be stated that, although it is possible to distinguish several varieties of disease, each one of which presents a tolerably characteristic picture, there are innumerable transitional forms. It may, indeed, be almost a matter of taste in any particular case what name shall be applied to it. The existence of so many intermediate forms renders it evident that the various members of this

group of diseases are at least closely related if not actually identical. We shall even find, upon careful consideration, that certain other diseases not usually regarded as hæmorrhagic are nearly akin to the group now under consideration. We refer to certain skin diseases, which are characterized mainly by inflammatory and exudative lesions of the skin. Chief among these should be mentioned erythema exudativum multiforme, which not very infrequently exhibits some tendency to hæmorrhages, and thus presents external appearances closely simulating the forms of purpura.

In order to understand the underlying connection between these various disorders, a precise knowledge of their ætiology is requisite. Already considerable evidence has been gathered pointing to the importance of infectious influences in their production (*vide infra*), but no absolute proof has yet been obtained. In the meanwhile, we must be guided mainly by the purely clinical phenomena. These, again, indicate that sharp distinctions between the various hæmorrhagic diseases would be purely artificial. In this and the following chapters we shall discuss the two main types of hæmorrhagic disease.

**Ætiology of Scurvy.**—Scurvy is sometimes sporadic, and sometimes epidemic and endemic in its occurrence. There were formerly very extensive and fatal epidemics of the disease, at a time when the laws of health with regard to large aggregations of human beings were little regarded. The disease was prone to attack armies, or the inhabitants of besieged cities, or, especially, seamen. It was, and to a certain extent is still, one of the diseases most dreaded by the mariner. It has often swept away an entire ship's crew. To-day endemics of scurvy are by no means infrequent, although not so extensive as formerly. They are most apt to occur in prisons and similar institutions, and in barracks.

These facts, under the light of our present views in regard to such matters, would almost force us to seek some organic infectious poison as the origin of the disease. Formerly men were inclined to direct their sole attention to such circumstances as the character of the food, the dwelling, the climate, and similar conditions; nor can it indeed be denied that these hygienic factors do exert a decided influence upon the spread of the disease. It is, however, evident that they can not be its proper cause, for, beyond a doubt, scurvy may occur independently of any of the factors usually regarded as essential to its development. These causes must therefore be regarded as simply predisposing influences.

Great ætiological importance has long been ascribed to certain errors in diet. These include the use of bad or insufficient food, the undue predominance of certain kinds of food, and in particular of the salt meats so much employed on shipboard; or, again, the deficiency of certain varieties of food, in particular the lack of vegetable food, and still more of fresh vegetables. Much industry and acuteness have been expended in defending the theory that the lack of vegetable food is injurious because of the deficient supply of potassium salts under such circumstances (Garrod). Nevertheless, this view does not reach the heart of the matter, for in numerous epidemics of scurvy there has been no such lack of vegetable nourishment; and in some instances the diet employed has contained an unusual abundance of potassium compounds.

A like predisposing but not specific influence is exerted by the other factors to which ætiological importance has been assigned. They are indeed often present in epidemic as well as in sporadic cases, but, as previously stated, they may not exist at all. To this class belong damp and unfavorable quarters, cold, moisture, persistent heat, and excessive muscular exertion.

Age and sex exert no great influence upon the disease. Weakly persons seem to be somewhat more liable to be attacked than are the vigorous. The possibility of contagion has been maintained repeatedly, but contagion has not been

proven to exist, and unprejudiced observation would incline one to doubt its existence.

[It seems probable that the dietetic causes of scurvy lie rather in a want of variety in the food than in the absence of any one class or order of foods. Wales says (Pepper, "System of Medicine"): "No single natural order contains plants that supply all the elements essential to the nutrition of the body and the right composition of the blood. The graminaceous and leguminous articles of food, for instance, are numerous but not various; they all afford the same or analogous albuminous elements, which have about the same nutrient value as the corresponding substances in animal food, and hence health and vigor can not be sustained on a diet of flesh combined with wheat, rice, and oatmeal, or with beans and peas, or with all of them together. Outbreaks of scurvy have occurred on shipboard where the ration is made up principally of these articles—as in Anson's ship when supplied with an abundance of fresh animal, farinaceous, and leguminous foods. It is clear, therefore, that, in order to obtain a variety of materials required in nutrition, we must resort to several of the natural groups, those particularly which comprise the succulent vegetables and fruits."

It is certain that scurvy is a disease which we can produce artificially, and that it is preventable in the vast majority of cases. It is now as rare among seamen as it was formerly common—a change which is the result chiefly of care to vary the diet, especially on long voyages. The United States law requires that lime- or lemon-juice, sugar, and vinegar shall be carried by all sailing vessels bound on ocean voyages or engaged in the fisheries, specifies the circumstances and minimum doses under which the antiscorbutics are to be given, and provides penalties for violation or neglect.]

**Clinical History.**—The disease does not usually begin suddenly. There is a gradual onset, marked by certain constitutional symptoms. The chief of these are languor and debility, a sense of thoracic oppression, palpitation, and usually a "rheumatic, dragging pain" in the loins and extremities, especially in the lower extremities. The patient is obliged to take to his bed if the case be at all severe; he is very sensitive to cold, and often is drowsy and apathetic. These somewhat indefinite premonitory symptoms last for a few days or a week, when other and more characteristic phenomena appear.

Among these new appearances are spontaneous hæmorrhages, occurring chiefly in the lower extremities. There are cutaneous hæmorrhages, producing dark-red macules of varying size, most of them with a hair-follicle in their center, and there are almost invariably hæmorrhages into the deeper tissues also. The subcutaneous connective tissue and muscles, and sometimes the periosteum, are affected. These deeper extravasations are a peculiarity of scurvy. They can sometimes be felt as hard, painful swellings in the parts affected, and are sometimes discernible from the discoloration of the skin, which soon results from the solution and diffusion of the blood-pigment. The patches present a diffuse bluish color, merging into greenish or yellowish at the periphery, and they are often quite large. They have a precisely similar appearance to "black-and-blue" spots resulting from injury. Of course, the more abundant and the more superficial the extravasation, the more extensive and darker is the macule. Similar appearances may sometimes be observed in the upper extremities and trunk, mainly in severe cases. The face and scalp rarely present ecchymoses.

Sometimes a hæmorrhage results in the necrosis and sloughing away of a portion of the skin. The necrosis is succeeded by ulceration ("scurbetic ulcers"). Under unfavorable hygienic influences this process may assume a grave significance. It should also be stated that we may observe other cutaneous disturbances, such as erythema, wheals, vesicles (the contents of which may be tinged with

blood—"scorbutic pemphigus"), papules, and pustules. These eruptions are more frequent in some epidemics than in others; they may either be associated with or replace the cutaneous ecchymoses.

In the ordinary sporadic cases of scurvy which occur among us, hæmorrhages into the mucous membrane, except of the gums, are very rarely seen. The same is true of hæmorrhages from the stomach and other internal organs. In severe cases, during epidemics and under bad hygienic surroundings, it is otherwise; hæmorrhage may take place from the nose, stomach, intestines, bronchi, and kidneys, and blood may be effused into the serous membranes.

Next in importance to hæmorrhage is another peculiar symptom, presented by the mucous membrane of the mouth, and particularly that of the gums. In order to establish a diagnosis of scurvy in sporadic cases, we must demonstrate the existence of these two main symptoms—namely, the hæmorrhage into the skin or muscles, and the changes in the gums now to be described.

The scorbutic changes in the gums usually appear quite early in the course of the disease, being in many cases simultaneous with the hæmorrhages, although they may either precede or follow the latter. The gums assume a bluish hue, become swollen and spongy, are painful, and have a tendency to bleed. The changes are usually most pronounced in the salient parts of the gums between the teeth. It is a remarkable fact that they are hardly visible at all at places where there are no teeth; and the gums of very young children and of aged patients remain almost intact. In severe cases the gums are not only swollen but necrosed; the change is at first a superficial one, but it may extend inward and produce dirty-looking ulcers. Other parts of the mouth are liable to become involved in the ulceration, producing a diffuse ulcerative stomatitis, and giving the breath a most offensive odor.

Certain other local and constitutional phenomena are not infrequent, though less characteristic than the hæmorrhages and the alterations in the gums. Chief among the general disturbances is scorbutic anæmia. This is often in part referable to the unfavorable hygienic influences surrounding the patient, but the disease seems itself to impair the general nutrition. The patient looks pale, has a dry skin, and loses flesh rapidly. The temperature is often normal. Sometimes there may be an occasional rise of temperature, either in the beginning or in the further course of the disease. If complications occur, they are not infrequently accompanied by considerable fever.

Among more localized symptoms should be mentioned the premonitory sore throat which sometimes occurs. It is usually of the ordinary catarrhal variety, but it may assume a hæmorrhagic character. Bronchitis may also occur. Lobular pneumonia and genuine lobar pneumonia have been repeatedly seen in severe cases. Pleurisy, pericarditis, and inflammations of other serous membranes occasionally complicate the disease. They may likewise display a hæmorrhagic tendency in the exudations to which they give rise. Disturbances in the joints are sometimes seen, and are characterized by an effusion of liquid into the articular cavities, which effusion may be either serous or hæmorrhagic. This is a favorable opportunity to call attention to a peculiarity common to all the hæmorrhagic diseases and allied affections (*vide supra*)—they are apt to be associated with articular swelling.

The pulse may be somewhat accelerated, or may be slower than normal. It is usually small and compressible. Endocarditis may occur, but it is very exceptional. The blood does not present any constant and characteristic alterations in scurvy. The spleen may be decidedly enlarged, particularly in severe cases. Albuminuria has been repeatedly observed, but it is almost wholly confined to severe cases, in which, indeed, a typical acute nephritis may be developed.

**Varieties of Scurvy. Prognosis.**—The sporadic cases usually met with in this region almost invariably pursue a favorable course. The symptoms are mainly confined to constitutional disturbance, ecchymoses in the lower extremities, and the affection of the gums, the grave complications above mentioned being rarely met with. The average duration of the disease is, nevertheless, some weeks. Recovery is deferred in proportion as the hygienic surroundings are unfavorable, but even then the termination is almost sure to be favorable.

The prognosis in grave cases, occurring under unfavorable hygienic influences, and aggravated by the lack of proper food and attention, is far otherwise. Here death is not infrequent, sometimes as a result of progressive cachexia, sometimes because of pneumonia, pericarditis, cerebral hæmorrhage, or a similar intercurrent disease.

Anomalous or rudimentary cases of scorbutus may occur. They are most apt to be seen when the disease is epidemic or endemic. As a rule, the symptoms are mild. We find, for example, a scorbutic gingivitis and stomatitis without hæmorrhage, or, on the other hand, hæmorrhage into the skin and mucous membranes unattended by alteration in the gums. There have even been cases reported of simple scorbutic anæmia without any local symptoms.

[The experience of army surgeons during our late civil war deserves mention in this connection. Hammond, Woodward, and others state that many cases classed in the sick reports as "general debility" were cases of incipient or imperfectly developed scurvy, hæmorrhage from mucous membranes or into the skin being absent.]

**Diagnosis.**—The diagnosis of scorbutus is almost self-evident when the two chief symptoms of hæmorrhage and alteration in the gums are both present. If, however, one or the other of these symptoms is suppressed or imperfectly developed, it may be difficult to determine what disease we have before us, or to exclude ordinary stomatitis, rheumatic peliosis, and similar diseases. If we remember the statements made at the beginning of this chapter, and bear in mind that these various diseases are probably ætiologically related to one another, we shall be less disturbed by these uncertainties. It may be mentioned, in conclusion, that various septic disorders, and also acute ulcerative endocarditis, may occasion the appearance of numerous hæmorrhages, and thus simulate scurvy.

**Treatment.**—The essential requisites in the treatment of scurvy are proper hygiene and diet. Fresh air, suitable nourishment, and good nursing, if promptly supplied, are usually of themselves sufficient to induce recovery, while the physician possesses no remedies which compensate for their absence.

The belief that a main cause of scurvy lies in a deficiency of fresh vegetables has given rise to a practice, still in vogue, of prescribing a great abundance of fresh vegetables, such as lettuce, spinach, and sorrel, fruit, lemonade, and other drinks prepared from fruit syrups. There is no reason to deviate from a course to which experience has given its sanction, although we have repeatedly had opportunity to see that the administration of fresh vegetables is by no means essential to rapid recovery. Patients supplied with any other proper nourishment thrive equally well. Certain varieties of plants have attained a special reputation as "antiscorbutics," such as the spoonwort (*Cochlearia officinalis*), so frequently mentioned in accounts of early polar expeditions. None of these plants, however, possess the specific properties assigned to them. The administration of vegetable acids and the salts of potassium (bitartrate and nitrate of potassium), in a chemically pure form, has also been repeatedly tried, but it has not gained popularity.

The drugs most employed are the bitters and tonics. They have no specific value, but are perhaps as good remedies to prescribe as any. We may give a

decoction of cinchona, to which may be added a small amount of dilute sulphuric acid and sirup, or some preparation of gentian or a similar bitter. It was once believed that the internal administration of the mineral acids exerted a specially favorable influence upon the hæmorrhagic diathesis; but this is very doubtful.

Certain symptoms may demand attention; in particular, the affection of the mouth and gums. It is of great importance to cleanse the mouth frequently with disinfectants and mild astringents, such as chlorate of potassium or sage tea. It is also advisable to paint the inflamed and spongy gums at short intervals with tincture of myrrh or tincture of rhatany. The absorption of the ecchymoses in the lower extremities will be promoted by cautious massage. Inunctions of linimentum chloroformi and the like give great relief from the pain caused by the extravasations into the deeper tissues. In severe cases stimulants are often demanded, such as camphor, ether, and alcohol. Such complications as appear may also demand special treatment.

Convalescence is promoted by continued attention to diet, bathing, and the administration of iron and quinine.

## CHAPTER VII.

### PURPURA. MORBUS MACULOSUS WERLHOFII. PELIOSIS.

As already stated in the preceding chapter, the various "hæmorrhagic diseases" are so intimately related to one another that it is quite impossible to make a rigid categorical division of them. The numerous names which have been introduced into the literature of this subject certainly contribute more to obscure than to elucidate the attendant phenomena.

From a clinical standpoint this fact is the all-important one—namely, that there are cases in which the foremost symptom is the spontaneous occurrence of hæmorrhage. There are cutaneous ecchymoses, and there may be at the same time hæmorrhages in the internal organs and into the mucous membranes. In the milder cases of this sort these hæmorrhages constitute almost the only symptom of disease; but they may be associated with considerable general disturbance, indicated by fever and weakness, or with certain local complications. The true cause of these diseases has not yet been discovered. There is seldom any evidence of an exciting cause, and the disorder may attack either the well-nourished or the poorly nourished, the old or the young, men or women. There is, however, an indisputable relationship between these diseases and certain others—namely, scurvy, erythema exsudativum, and perhaps acute rheumatism and endocarditis. This similarity indicates that the process is of an infectious, or toxic, character. Such an assumption promotes greatly a proper understanding of the phenomena under consideration. It is also said that subcutaneous injections of blood from patients with morbus maculosus may cause a like affection in rabbits (Petrone and others). In some few cases the weight of evidence would seem, however, to point to an antecedent impairment of nutrition in the walls of the blood-vessels. A good example of this is seen where cutaneous ecchymoses occur in old and marantic individuals (*peliosis senilis*). There is some doubt whether these exceptional cases belong with the others.

The mildest forms of the diseases under discussion are termed **purpura**. The hæmorrhages are seen mainly in the skin of the lower extremities, and are apt to take place into the follicles. There may also be ecchymoses upon the trunk and

upper extremities, but the mucous membranes and the deeper tissues remain intact. A means of distinguishing purpura from scorbutus lies in the fact that in purpura there are no hæmorrhages into the muscles and no lesions of the gums, although it should be confessed that transitional forms between the two occur. The disorder is called *purpura simplex* if the cutaneous ecchymoses constitute the only symptom, or, at any rate, the only important one. These cases almost invariably terminate in recovery, and are over at the end of ten days or three weeks. Sometimes elevations of the skin are formed resembling wheals, and hæmorrhages take place here and there into them. This subvariety has been called by some *purpura urticans*. It forms a connecting link between purpura simplex and those cases of erythema exudativum which are associated with hæmorrhage. Further particulars may be found in special works upon dermatology.

Quite often the hæmorrhages are attended by "dragging rheumatic pains": such cases are termed *purpura rheumatica* or *rheumatic peliosis* (Schönleini). There may also be constitutional disturbance, slight fever, anorexia, and indisposition to either bodily or mental exertion. There may sometimes be actual arthritis, with an inflammatory effusion into the joints. The knee and other joints of the lower extremities are most apt to suffer in this way. The gums are usually normal; nor is there, as a rule, hæmorrhage into the mucous membranes or the viscera. These cases may last but two or three weeks. Often, however, they are more tedious, being marked by the recurrence of the ecchymoses and articular pain. Most of them get well at last.

No sharp dividing line can be drawn between the forms of purpura thus far described and certain graver cases. These latter are most of them grouped under the name of *purpura hæmorrhagica*, or its preferable because more distinctive synonym—every purpura being hæmorrhagic—*morbus maculosus Werlhofii*. The cutaneous ecchymoses in this class of cases are usually extensive; and, furthermore, we have hæmorrhages into the mucous membranes of the nose, mouth, soft palate, stomach, and intestinal canal, as well into internal organs (the brain and kidneys), and also into the serous membranes. The constitutional disturbance is apt to be severe. The condition may be distinctly "typhoidal." Fever may be entirely absent, even in grave cases, although sometimes there is a considerable rise in temperature.

There are usually no local symptoms beyond those already mentioned. In typical cases the gums remain intact. Swelling of one or more joints has been repeatedly observed, as have also endocarditis and acute hæmorrhagic nephritis. If marked cerebral symptoms are developed, suggesting an apoplectic shock, we may surmise that a cerebral hæmorrhage has taken place. It should also be stated that marked gastro-intestinal disturbance may occur. Cases of this sort have been observed by Henoch in children. They may also occur in adults. In rare instances there may be intestinal ulceration, with perforation and consequent peritonitis. The spleen may undergo acute enlargement.

The prognosis in purpura hæmorrhagica should always be a guarded one; the patient is in danger both from the general depression and anæmia, and from certain special lesions. Even a severe case may, however, recover. The disease sometimes proves very tedious; it may occupy several months.

**Treatment.**—The general regimen to be prescribed is similar to that directed in scurvy. The physician must strive to support his patient's strength by means of proper nourishment. A great many internal remedies have been recommended, most of them on purely theoretic grounds. It is difficult to say whether they actually exert a favorable influence upon the course of the disease. The following drugs are chiefly employed: Ergotine, perchloride of iron, dilute sulphuric acid, and cinchona. If there be swelling of the joints or endocarditis, we should ad-

vise a trial of salicylic acid or antipyrine. Such special symptoms as demand attention should be treated according to general principles.

## CHAPTER VIII.

### HÆMOPHILIA.

**Definition and Ætiology.**—Hæmophilia is the term used to denote a peculiar constitutional anomaly, exhibited in a remarkable tendency to spontaneous and traumatic hæmorrhage. The condition is probably in every instance congenital, and is usually hereditary; the existence of families of "bleeders" has long been known. Generation after generation displays frequent cases of hæmophilia, both among the direct descendants and the lateral branches. Bleeders are very apt to have a numerous progeny. Not all of the children, however, fall victims to the disease. Grandidier has pointed out two facts which are of interest in this connection, as they might aid in deciding as to the marriageability of certain persons.

If a man belonging to a family of bleeders marries a healthy woman, neither a bleeder herself nor inheriting a predisposition to hæmophilia, his children are almost certain to be healthy, even though the father himself be a bleeder. On the other hand, a woman belonging to a family of bleeders, even though she herself be healthy, will almost always have some children who are subject to hæmophilia. In other words, hereditary predisposition is transmitted much oftener through the female than through the male members of the family. Hæmophilia itself, is, on the contrary, much more frequent in the male sex than in the female; at least this is true of the pronounced cases. Hössli, who has lately published a very careful family tree of bleeders of Tenna (Canton Graubünden), comes to the following conclusions: "The inheritance of hæmophilia is often from the father, through the daughter, to the grandson, also from the mother, through the daughter, to the grandson, and most rarely directly from the father to the son." It is doubtful whether race and place of residence are of ætiological importance. So far as is known, hæmophilia appears to occur in all countries, although it is fortunately rare anywhere.

[A similar transmission through the females, who themselves usually escape, is seen in color-blindness and in pseudo-hypertrophic paralysis.]

The real causes of hæmophilia are entirely unknown to us. We can make one or two steps toward finding the source of the hæmorrhage, but we are unable to proceed further. It would seem that the bleeding must depend, in the first place, upon an abnormal delicacy of the walls of the vessels predisposing them to rupture, and, secondly, upon deficient coagulability of the blood. This latter abnormality is evident from the fact that in hæmophilia it is difficult to check even the most insignificant hæmorrhage. Thus far all attempts to discover any anatomical or chemical explanation of this imperfect coagulability have been vain. It has not been possible to detect any variation in the saline constituents of the blood, or in the amount of albuminoids, such as fibrinogen, that it contains, or in its morphological elements. And likewise no anatomical change in the vascular walls or the heart has yet been reported which throws light upon the character of the disease. Various authorities have laid stress upon the small diameter of the arteries and the thinness of the intima, but these conditions may occur independently of hæmophilia. Fatty degeneration of the intima is, to be sure, often found in connection with this disease, but it is doubtless rather a result of the coincident anæmia than the cause of the hæmophilia. The observations with regard to the heart are

very contradictory; sometimes it is found to be very small, sometimes of normal size, and again actually hypertrophied.

The subjects of hæmophilia do not present any distinctive constitutional peculiarities. It has been stated that they are very apt to be blondes with a delicate white skin, and superficial and abnormally distended cutaneous veins; but the exceptions to this rule are not a few.

**Clinical History.**—Hæmophilia does not display equal malignity in all cases. If we have opportunity to obtain thorough information with regard to families of bleeders, we shall find that quite often rudimentary varieties occur side by side with typical and severe cases. There is, to be sure, a striking tendency to hæmorrhage even in them; but the hæmorrhage never assumes threatening proportions. By perseverance and industry it is possible to collect an almost unbroken series of cases, varying in degree from extreme mildness to extreme severity. The following sketch applies mainly to typical and severe cases.

That hæmophilia is a hereditary constitutional disease is shown by the fact that it sometimes appears in earliest infancy. Many cases of umbilical hæmorrhage in the newborn are referable to hæmophilia. Of course this does not apply to all cases. In Jewish children the disease may betray itself for the first time when the rite of circumcision is performed. In many cases the disease does not betray itself at so early a period; but this is no proof that the disease is not already developed, inasmuch as the young child is not much exposed to traumatism and other causes which naturally occasion hæmorrhage.

The most striking symptom in a fully developed case of hæmophilia is the occurrence of severe hæmorrhage as a result of the most insignificant causes. A slight blow produces a "black-and-blue spot" such as is ordinarily seen only after a very violent injury. The prick of a pin, a slight cut on the finger, or the extraction of a tooth, may give rise in hæmophilia to an obstinate and alarming hæmorrhage. Epistaxis may be caused by blowing the nose, and hæmorrhage from the gums by brushing the teeth, and so on. Whether there is ever a perfectly spontaneous hæmorrhage is uncertain. It is true that in severe cases hæmorrhages take place independently of any visible cause. This may be seen in the skin and mucous membranes (nose and gums); and in rare instances we may even have free hæmorrhage from the stomach, intestines, or urinary passages. Yet it may be doubted whether these occurrences are not the result of comparatively insignificant mechanical injuries which escape our notice. At any rate, we scarcely ever find hæmorrhage taking place into the parenchyma of the viscera, in places where injury from external sources is entirely out of the question. This fact constitutes an important point of distinction between hæmophilia and the acquired hæmorrhagic diathesis.

The second important symptom of hæmophilia has been already referred to: it is extremely difficult, and may even be impossible, to check by artificial means any free hæmorrhage which may occur. It is this which makes the disease so dangerous, and prevents most patients from reaching old age. It has frequently happened that an apparently trifling wound of the skin, or some insignificant operation, or a leech-bite, or in women childbirth, has started up a hæmorrhage, which eventually became fatal. In other cases the hæmorrhage is finally checked, but not until it has caused profound anæmia. Bleeders are apt to recover with remarkable rapidity from the effects of excessive hæmorrhage; yet continually repeated hæmorrhages may lead to a persistent and profound anæmia, attended by all the symptoms described in preceding chapters.

We see, therefore, that the general condition in hæmophilia varies with the severity of the individual case, and with the more or less fortuitous circumstances which develop its dormant characteristics. If no special accident occurs, the

patient may maintain the appearance of perfect health for years. In the worst cases, however, such a state is very temporary, if it exists at all, because the hæmorrhages can be so easily excited. As a consequence, the skin almost always presents a greater or less number of ecchymoses, while hæmorrhages from the internal organs contribute from time to time to the general debility and anæmia. Certain complications may occur in hæmophilia, but they are little characteristic. There is a noticeable tendency to "rheumatic" inflammation of the muscles and swelling of the joints, wherein is seen a striking analogy to the "hæmorrhagic diseases." Often there is an actual effusion of blood into the joints. This may cause considerable functional disturbance of the joints, and eventuate in ankylosis. Various writers have also called attention to the comparative frequency of neuralgia, especially in the trigeminus.

**Prognosis.**—In only too many instances the victims of hæmophilia die in childhood; in other cases the patient attains an advanced age. A fact of great practical importance is that often, although not invariably, hæmophilia grows gradually milder with advancing years. If, therefore, the patient have survived the period of adolescence, we may believe that his prospects are gradually improving. The prognosis of hæmophilia is obvious. The amount of danger at any given time depends upon the severity of the hæmorrhage and the consequent anæmia. The comparative severity of the case must be judged from its previous history; as has just been said, the prognosis grows more favorable as the patient grows older.

**Treatment.**—Prophylaxis assumes a very important place in the treatment of hæmophilia. First, children who inherit a tendency to the disease, or who have given evidence of its existence, should be treated with a view to improve their general constitutional condition, so as to check the development of the disease as far as possible. The means to this end need not be described at length. They comprise good nourishment, fresh air, cautious endeavors to harden the system, baths, and tonics. Secondly, when hæmophilia already exists, the patient should be guarded as much as possible from any mechanical injury, such as might excite hæmorrhage. Thus caution is demanded in performing vaccination and other apparently trifling operations.

As regards direct treatment of the disease, no effectual remedy is known. The general tonic treatment already referred to should not be neglected; but the administration of ergotine, acetate of lead, and similar drugs is indicated, if at all, only when hæmorrhage is actually taking place, and even then it is very apt to fail. The only way to stop the hæmorrhage is by surgical methods, and these need not be described here. They do not differ essentially from those employed when hæmorrhage occurs independently of hæmophilia. If mechanical efforts to check the bleeding fail, we can expect nothing from the remedies above mentioned, nor from sulphate of sodium and the other laxatives which have been recommended. For the symptomatic treatment of the anæmia and of its results, we may refer to the first chapter of this section.

## CHAPTER IX.

### DIABETES MELLITUS.

**Definition and Ætiology.**—Under normal circumstances the blood always contains a slight amount of sugar; but this ingredient does not usually pass over in appreciable quantities into the urinary excretion. If, however, the amount of

sugar in the blood exceeds certain limits—that is, if there exists an abnormal “glykæmia”—then sugar is excreted in the urine, and we have glycosuria. This is seen as a more or less temporary phenomenon under the most varied conditions. The amount of sugar in the urine is usually comparatively slight, and it soon disappears again. Its presence does not imply any persistent abnormal condition. This phenomenon has been termed glycosuria or melituria, in contrast with the peculiar disease which has for its chief symptom a persistence of sugar in the urine, and has therefore received the name of diabetes mellitus.

The causes of glycosuria need not be discussed here at any length. We will briefly state that sugar may appear temporarily in the urine as a result of poisoning from various substances, chief among which are carbonic-acid gas, morphine, hydrocyanic acid, mercury, nitrite of amyl, and curare. Von Mehring has lately discovered in phloridzine, a glucoside in the bark of the roots of apple and cherry trees a substance which causes a very large amount of sugar in the urine if given to dogs, rabbits, etc. A marked glycosuria may also be produced in man by giving phloroglucine, or by other disturbances of the general condition. Temporary glycosuria has also been seen in connection with the acute infectious diseases—for example, malignant pustule, cholera, typhus or typhoid fever, scarlet fever, diphtheria, and malarial poisoning. A far more frequent cause is disturbance of the nervous system. Thus, glycosuria may result from severe concussion of the brain, fracture of the skull, cerebral hæmorrhage, cerebro-spinal meningitis, and after epileptic fits. It is especially apt to occur when there is disease of the medulla; and we need hardly point out how close is the connection between this clinical fact and the famous discovery of Claude Bernard, who found by experiment that, when certain injuries are inflicted upon the floor of the fourth ventricle, glycosuria inevitably follows. It has been thought that diseases of the stomach and liver may occasion glycosuria; but this is doubtful. With regard to the theory of diabetes (*vide infra*), it is an interesting fact that extensive disease of the liver—as seen in phosphorus poisoning or cirrhosis—occasions no glycosuria, even when the patient's diet contains large amounts of sugar (Frerichs); but atrophy of the pancreas seems to have a definite relation to diabetes (*vide infra*). As Minkowski and Von Mehring have found, we can produce a severe diabetes in dogs by extirpation of the pancreas. Ligature of the duct of the gland does not produce this condition. There must therefore be some special function of the pancreas not yet known, and after this function ceases to be performed the consumption of sugar in the animal economy ceases to be complete.

Diabetes mellitus is a disease in which a considerable amount of sugar is constantly present in the blood, and consequently in the urine. The immediate cause and the true nature of this strange disease are entirely unknown. It is therefore difficult to determine whether all cases of “diabetes mellitus” are essentially identical. In most of the typical cases this question may, indeed, be answered affirmatively with little hesitation; but other cases, particularly many of what are called the “milder varieties” of diabetes, afford more room for doubt. We must not forget that diabetes mellitus is at present known to us only through its symptoms, and that the individual cases do not exhibit any uniformity either as to causation or as to anatomical changes.

As has been said, we know practically nothing of the true causes of diabetes. All that the physician can do in any particular case is to search for certain exciting or predisposing causes, the significance of which has been learned from clinical experience. It must, however, be borne in mind that in many cases of diabetes, and some of them most severe, no cause whatever can be made out; the disease seems to have developed of itself in persons who were previously perfectly well. We append a list of such exciting influences as seem to be most frequent and

important. First, heredity: diabetes has been repeatedly observed to occur in several generations of the same family, or in several brothers and sisters. It is noteworthy that the disease may also occur in families where there is a hereditary predisposition to nervous diseases. Second, improper mode of life: by this is meant chiefly unsuitable diet, especially the persistent overindulgence in starchy foods and sugar; sedentary habits are also considered harmful, especially if associated with overeating. This is said to be the reason why diabetes is more frequent among the wealthy classes, and why it is quite common in corpulent persons. Third, taking cold and getting wet seem, in occasional rare instances, to determine the appearance of diabetes. Fourth, emotional disturbances, excessive mental exertion, anxiety, and passion, are sometimes thought to occasion the disease. Fifth, it is very remarkable that sometimes the same factors which we have already seen to be possible causes of temporary melituria, may also occasion a chronic diabetes mellitus; thus, cases of diabetes have been known to follow injuries to the head, and such acute infectious diseases as typhus, typhoid, or scarlet fever, cholera, and malarial poisoning. Sixth, certain chronic constitutional and infectious diseases, particularly gout and syphilis, may perhaps promote the development of diabetes. The disease also appears in connection with certain organic diseases; this list includes cerebral diseases, such as hæmorrhage, tumor, or sclerosis, particularly when in the region of the fourth ventricle; other nervous disorders, such as organic disease of the peripheral nerves, and functional diseases; and, in rare instances, disease of the pancreas, such as suppuration and cancer. It is obvious that such cases of diabetes should be regarded as "accidental," in distinction from the true idiopathic disease.

Diabetes occurs everywhere, but certain countries and districts seem to be particularly liable to it—for example, India, Ceylon, and Italy. In Germany, Würtemberg and Thüringen are said to present the largest relative number of cases. Jews are very liable to the disease. Most cases occur in patients between thirty-five and fifty years of age. Next in liability to the disease come younger individuals, under thirty-five and over twenty years old. After the fiftieth year diabetes is not very exceptional; but, in the other direction, children under ten are very seldom attacked by it, although they are not absolutely exempt. With regard to sex, males are much more often attacked than females.

**Clinical History.**—With few exceptions, the symptoms of diabetes mellitus come on slowly and gradually. Sometimes the symptoms are merely general and indefinite, such as languor, emaciation, weakness, and deficient endurance. Sometimes we have mild nervous disturbances, including headache, mental depression, wakefulness, and neuralgia, and in still other cases gastro-intestinal symptoms, including nausea, eructations, and irregularity of the bowels. At last the patient's attention is called to the altered character of the urine, and particularly to its increased amount. He also notices that he is very thirsty, and that, in spite of his enormous appetite, he is constantly growing weaker. Sometimes quite different symptoms first arouse suspicion of the existence of diabetes; these will be mentioned later. In order to make a diagnosis of diabetes mellitus, a knowledge of the abnormal character of the urine is indispensable. We shall therefore proceed to describe the changes produced in the urinary excretion as a result of diabetes mellitus.

1. **CHARACTER OF THE URINE. DEMONSTRATION OF SUGAR.**—Usually the first point that attracts attention is the increased amount of urine. There are often a hundred to a hundred and fifty ounces (three to five quarts, 3,000–5,000 c. c.) excreted in twenty-four hours, and sometimes there may even be as much as ten or twelve quarts (8,000–12,000 c. c.). Under suitable treatment and with proper diet the amount may, of course, be much smaller. In some cases the polyuria will

almost cease from time to time ("*diabetes decipiens*"). Often the amount of urine undergoes diminution, when some intercurrent disease appears, or when death is imminent.

In color the urine is light yellow, corresponding to its amount. It often has something of a greenish hue, but a small quantity of it may seem almost as colorless as water. Ordinarily the urine is clear and without sediment; but after it has stood for some time it may become cloudy, usually as a result of the abundant development of fermentation spores.

The odor may be somewhat aromatic, suggesting acetone (*vide infra*). Its taste, as determined by earlier observers, may be distinctly sweetish. The reaction is acid, and the acidity of the urine may increase on standing, because of the alcoholic and lactic-acid fermentation processes which the sugar undergoes.

The specific gravity is almost invariably greatly increased, as a result of the large amount of sugar. If a pale urine is found to have a specific gravity of more than 1025, we may feel almost certain that it contains sugar. Specimens often have a specific gravity of 1030-1045, and even higher. In exceptional instances the specific gravity may fall below 1020; this may occur, for instance, where the patient is very much debilitated.

The diagnosis requires that sugar be detected in the urine. The sugar found in both the blood and the urine of diabetic patients is grape-sugar (glucose, dextrose). The amount of sugar secreted in twenty-four hours often reaches half a pound to a pound (grm. 200-500). Of course the amount varies greatly according to the diet, mode of life, and treatment of the patient. The greatest amount ever known to be produced in twenty-four hours was more than two and one fifth pounds (grm. 1,000). The percentage of sugar in the urine varies between 0.5-1 per cent. at the lowest extreme, and 8-10 per cent. as the maximum; usually it is about 2-4 per cent. It is noteworthy that in the last weeks, or just before death, the sugar in the urine may become greatly diminished in amount, or may absolutely disappear.

The most important tests for sugar in the urine are, first, Trommer's test: To urine in a test-tube sufficient potassic or sodic hydrate is added to make the reaction strongly alkaline; then a solution of sulphate of copper (about one part of the salt to ten of water) is added, drop by drop. If the urine contain sugar, the hydrated cupric oxide, which is at first formed in large amounts, is dissolved, and usually the fluid assumes a beautiful deep-blue color. We ought, properly, to go on adding the sulphate of copper until the hydrated cupric oxide ceases to be dissolved. The urine is then heated, whereupon the cupric oxide is reduced and a yellow, or reddish-yellow, precipitate of cuprous oxide, or hydrated cuprous oxide, is formed. The application of heat should not be continued long after the precipitation begins to take place, lest the test be obscured; the reduction will go on even without heat. If the urine contains more than 0.5-1 per cent., this test is perfectly reliable. If the reaction be a doubtful one—that is, if there be no precipitate of cuprous oxide, although the urine becomes yellow—we should be cautious in making a diagnosis, as the urine may contain substances other than sugar capable of reducing the copper, such as uric acid, kreatinine, mucine, etc. Second, the bismuth test (Böttger's): Sodic hydrate or sodic carbonate is added to the urine, and then a small pinch of subnitrate of bismuth. Upon boiling, the urine, if it contains sugar, quickly assumes a perfectly black color, the oxide being reduced to the metallic state. Third, the potassium test (Moore's): Potassic hydrate is added to the urine in the test-tube and the uppermost layer cautiously heated; if it contains sugar, the urine quickly assumes a deep-brown color, as a result of the action of the potassium on the sugar; and this upper dark-colored layer contrasts strongly with the clear urine below.

[Fehling's test is justly a favorite in this country, and has the advantage of

being applicable to the quantitative as well as to the qualitative analysis. The difficulty of its not keeping well can be met by having separate bottles for the copper and tartrate solutions, and making the mixture at the time of using the test. The Fehling's-test pellets put up by chemists are convenient for the qualitative analysis, but, on the whole, they are inferior to the solution.]

If the above-described tests leave us still in doubt, there can be only a small amount of sugar, if any, present. We may, however, attain certainty by employing the fermentation test (which causes a decomposition of the sugar into alcohol and carbonic dioxide), or circumpolarization (deflection of the plane of polarization to the right by the grape-sugar). Further particulars in regard to these and other tests, and also in regard to the quantitative estimation of sugar, may be found in works on medical chemistry.

Diabetic urine sometimes contains other varieties of sugar in small amounts—namely, levulose, which deflects the plane of polarization toward the left, and inosite; these are, however, of no practical importance.

The amount of urea is usually somewhat increased (*vide infra*). Uric acid, on the contrary, is excreted in small amounts. The amount of kreatine is normal or even increased (Senator). The amount of phosphoric acid and sulphuric acid usually corresponds to the amount of urea, or, in other words, to the decomposition of albuminoids. Occasionally, according to Teissier, the amount of phosphates is surprisingly great, and may either correspond with the amount of sugar simultaneously excreted, or replace the sugar in the urine. This subject has not yet been fully investigated. The amount of sodic chloride excreted depends, as in health, merely upon the amount ingested.

Hallervorden has discovered an important fact in regard to the excretion of ammonia. In many cases of diabetes, although not in all, it is much increased; forty-five to ninety grains (grm. 3-6), or even more, may be excreted in twenty-four hours. Despite this, diabetic urine has an acid reaction; and, as Stadelmann has shown, the basic elements are considerably out of proportion to the acids known to us. It is, therefore, evident that diabetic urine, since it contains a large amount of ammonium and yet has an acid reaction, must have among its constituents some unusual acid. Stadelmann was at first inclined to believe that this was crotonic acid. Minkowsky and Külz have, however, shown, by their more recent investigations, that the acid in question is really oxybutyric acid, or, more accurately, beta-oxybutyric acid. This acid is readily decomposed into crotonic acid, which explains Stadelmann's error. Another interesting fact is that, upon oxidation oxybutyric acid changes to acet-acetic acid, a substance easily decomposed into carbonic-dioxide gas and acetone. This suggests the possibility that oxybutyric acid may give rise within the system to acetone, a substance which has occupied an important place in the literature of diabetes.

Acetone was first discovered by Petters in diabetic urine. This was regarded as an important discovery, because it was believed that the accumulation of this substance in the blood produced those grave nervous disturbances (*vide infra*, diabetic coma) sometimes observed in diabetes. More recent developments have rendered this view extremely improbable, but it is an established fact that acetone is quite often present in the urine of diabetic patients.\* Whether it is a primary or secondary product remains uncertain. It was formerly believed that acetone was formed from ethyldiacetic acid (acet-acetic ether), but of late the tendency is rather to regard acet-acetic acid as the source of acetone (Deichmüller and Tollens, Jaksch). Acetone is probably the cause of the reaction to which Gerhardt

\* It should be added that acetone has been found by Kaulich and Jaksch to occur frequently in the urine during many other diseases, both febrile and nonfebrile, and even in normal urine.

has called attention—namely, the development of a Burgundy-red color in the urine upon the addition of ferric chloride. This is quite often to be observed in the urine of diabetic patients. In speaking of diabetic coma we shall have occasion to revert to this ferric-chloride reaction.

Albumen may be found in diabetic urine, as will be seen below under renal complications; small amounts, to be detected only after careful examination, are common.

2. TISSUE METAMORPHOSIS IN DIABETES. SOURCES OF THE SUGAR AND VARIATIONS IN ITS AMOUNT OCCASIONED BY EXTERNAL INFLUENCES.—Inasmuch as the presence of sugar in the urine is the most prominent symptom in diabetes, the question of its origin is all-important. One fact is indubitable—namely, that the secretion of sugar depends in large part upon the amount of potential sugar ingested—that is, upon the proportion of starches in the food. The amount of sugar excreted with the urine increases and diminishes with the amount of starchy food eaten. If a diabetic patient abstains totally for any length of time from such articles of food as contain starch, sugar will, in many instances, entirely disappear from the urine. In other words, the system of a diabetic patient is almost, if not quite, incapable of oxidizing sugar into carbonic-dioxide gas and water. Voit and Pettenkofer have made an experiment the result of which confirms this statement. By means of the great Munich respiration apparatus, they have demonstrated that in diabetes the amount of oxygen absorbed from the air, and of carbonic-dioxide gas and water given off from the body, is less than in health, the diet being precisely the same in both cases. Previously to this many investigators had shown that there was a diminution in the amount of the "insensible excreta."

The oxidation of sugar is not absolutely *nil* in diabetes. Külz has proved by numerous experiments that not all the starch is excreted in the form of sugar, and he has also found that many varieties of sugar, such as mannite, fruit sugar, and inosite, are decomposed even in diabetes, so that their ingestion does not lead to an increase of sugar in the urine.

The disturbances in metamorphosis affect other substances than the carbohydrates. While they escape oxidation, on the other hand, the destruction of albuminoids is increased. We have already stated that diabetic urine contains a large amount of urea. Gäthgens and others have shown, by means of carefully conducted investigations, that this increase in the amount of urea is not merely relative, but absolute. The system of the patient destroys a larger amount of albumen than does the system of a healthy man, the ingesta in both cases being alike. Whether this is true in all cases of diabetes is quite doubtful, but the fact is established with regard to severe cases. It is also certain that in severe cases a part of the albumen is transformed into sugar, escapes oxidation, and is excreted in the urine. The proof of this is that in some cases of diabetes sugar continues to be present in the urine, although the diet is exclusively nitrogenous. Seegen accordingly divides all cases of diabetes into two varieties: a milder form, where sugar ceases to be excreted if starchy food be excluded from the diet, and a severer form, where sugar persists upon an exclusively meat diet.

Muscular exertion is one of the external influences which modify the excretion of sugar in diabetes. According to our present views, muscular activity wastes mainly non-nitrogenous substances, and, accordingly, we find in diabetes that an increase of muscular exertion, other things being equal, diminishes the amount of sugar excreted.

Emotional excitement is said to increase the amount of sugar excreted.

Intercurrent acute febrile diseases may cause a great diminution in the amount of sugar, but sometimes there is no essential change. Probably the altered diet of the patient plays an important part in this connection, although doubtless the

special modifications of tissue-metamorphosis occasioned by the high temperature or by the disease itself also exert some influence.

3. CONSTITUTIONAL SYMPTOMS IN DIABETES MELLITUS.—In many of the milder cases there is for a long time little apparent disturbance of the general health. The patient is well nourished, and suffers little discomfort, except the inconvenience occasioned by the polyuria and the polydipsia. In severer cases the system is deeply affected by the drain upon it. The patient becomes emaciated, weak, and easily exhausted, and at length there may be profound marasmus. Mentally, the patient is apt to be depressed and irritable. The intellectual powers are not impaired, but there is indisposition to mental effort. The temperature is normal or subnormal. Fever invariably indicates some complication.

4. SYMPTOMS REFERABLE TO THE DIGESTIVE ORGANS.—We have already mentioned the excessive thirst experienced in diabetes. This may be a source of great discomfort, obliging the patient to drink at short intervals, even through the night. The interdependence of polyuria and polydipsia is not yet fully understood. The most natural view seems to be that the increased excretion of water by the kidneys is the primary factor, and the increased thirst secondary thereto. One cause of the polyuria is the excretion of sugar, in order to dissolve which a large amount of water is necessary, but certain nervous factors would also seem to be implicated. That they exert some influence is rendered probable by the fact that the amount of urine does not always correspond to the amount of sugar excreted. A very large amount of urine may be excreted containing little or no sugar; and, on the other hand, there are genuine cases of diabetes mellitus where the amount of urine is normal, and the patient feels no unusual thirst (*diabetes decipiens*). It has also been suggested that the sugar may irritate the nerves of the mouth and throat, and thus cause thirst. According to this idea, the polyuria would be merely the result of the excessive ingestion of liquids. The abnormally great appetite in diabetes seems in most cases to be due to defective assimilation of the food. Many patients are never able to eat enough. They have a longing, in many cases, for carbohydrates. Occasionally the hunger becomes ravenous, and is associated with headache and a general sense of weakness, all these symptoms being alleviated when food is taken. This rule has rare exceptions in which the appetite is not unusually great, even though the case be severe.

The tongue is frequently dry; it is broad and thick, with an irregular and fissured surface, sometimes coated and sometimes red. The gums may be spongy, and may exhibit a tendency to bleed. The teeth frequently decay rapidly. The saliva is invariably found to give an acid reaction. This is true of the isolated secretion of the parotid gland also, and is said to be due to the presence of lactic acid. It is only in exceptional instances that sugar can be demonstrated in the saliva. Thrush quite often appears on the soft palate.

There are no marked gastric symptoms. There is usually constipation, but sometimes there is a severe, though temporary, diarrhoea. The liver and spleen are seldom much affected; the liver rarely is somewhat enlarged. Jaundice is frequently observed, but it is always referable to some complication. As a rule, the secretion of the bile goes on as in health.

5. SYMPTOMS REFERABLE TO THE RESPIRATORY ORGANS.—In many cases the organs of respiration are unimpaired for a long while. It may be mentioned that often patients have a decidedly fruity odor to the breath (acetone odor). In the later stages of the disease pulmonary complications are very frequent. Almost one half of all diabetic patients perish from secondary disease of the lungs. Most frequently there is pulmonary tuberculosis; its course, symptoms, the presence of tubercle bacilli, and all other details are the same as in ordinary cases of tuberculosis. Next in point of frequency is pulmonary gangrene. Sometimes there is

a diffuse gangrenous process, and sometimes there are isolated foci of necrosis, which become liquid, and have an acid reaction, but they often have comparatively little odor. The expectoration in these cases may be odorless. Croupous pneumonia may also occur. It often terminates unfavorably, and may, as we have ourselves observed, result in gangrene.

6. SYMPTOMS REFERABLE TO THE CIRCULATORY SYSTEM.—In many instances the circulatory apparatus presents no special lesions. The pulse is either of a normal rate or a trifle slow. It is usually soft, although exceptionally it may exhibit increased tension. There is often distinct evidence of cardiac weakness (Schmitz); the pulse is small, intermittent, sometimes very slow (50 or even 40 beats per minute), and sometimes accelerated (100 to 120 beats per minute). There are shortness of breath, faintness, nausea, and the like. Sometimes sudden and profound cardiac disturbance occurs, and may occasion speedy death (*vide infra*, coma). Not very rarely diabetes is combined with general arterio-sclerosis. This is particularly apt to be the case in patients who have been subject to gout.

7. GENITO-URINARY SYMPTOMS.—Despite the great demands made upon them, the kidneys usually maintain a normal condition. As we shall see when we come to the pathological anatomy of diabetes, the kidneys are often very large. Sometimes a chronic nephritis is developed as a complication, usually in the later stages of the disease. The urine contains albumen, and there are oedema and other symptoms of renal disorder. It was formerly a common opinion that the nephritis results from the irritation of the sugar excreted by the kidneys, but in such cases other irritants are probably to be considered, especially as in most cases of nephritis complicating diabetes there are usually present at the same time other disorders to which the nephritis may be referable, such as pulmonary consumption or cardiac disease. We have seen well-marked suppurative pyelo-nephritis as a complication of diabetes. If the amount of albumen in the urine becomes considerable, the excretion of sugar usually undergoes marked diminution. Many physicians therefore consider the transition of diabetes into chronic renal disease (contracted kidney) as a comparatively favorable symptom.

Saccharine urine is apt, as it decomposes, to cause irritation of the skin. This is the explanation of the troublesome pruritus pudendi, which is especially marked in women. It may, indeed, be this symptom which first directs attention to the disease. Sometimes the external genitals are attacked by eczema or furunculosis. Men often suffer from balanitis, with inflammatory phimosis, or paraphimosis. A frequent and important symptom in men is impotence. This sometimes occurs very early in the disease, but it may afterward undergo improvement. The origin of it is not determined. Some authorities state that diabetes is apt to occasion atrophy of the testicles.

8. DISTURBANCES OF THE ORGANS OF SPECIAL SENSE.—An important and not infrequent result of diabetes is cataract. This may occasion almost total blindness. The cause of cataract in diabetes is not known. It was formerly supposed that the sugar in the blood absorbed water from the crystalline lens, and thus occasioned its opacity; but this has not been confirmed. Diabetic patients are also subject to disturbances of accommodation. Retinitis, atrophy of the optic nerve, and purulent choroiditis may also occur, but they are very rare, and perhaps are merely chance complications.

None of the other special senses are peculiarly affected in diabetes.

9. CUTANEOUS AFFECTIONS.—In most cases the skin is remarkably dry and rough. There may, however, be abundant perspiration. Several authorities claim to have found sugar in the perspiration, but this statement has not been confirmed by later investigators. Sometimes there is a troublesome pruritus. We often see a rapid loss of hair and a shedding of the nails. In many cases there is a great

tendency to furunculosis. This may be the first symptom to suggest the existence of diabetes. In the later stages there are sometimes extensive carbuncles, and multiple phlegmonous abscesses in the subcutaneous cellular tissue, which may prove fatal. Once we saw an eruption resembling pemphigus appear a short time previously to death. Gangrenous processes have been repeatedly observed, and in particular necrosis of one or more toes, which may take the form of perforating ulcer (*mal perforant*), or rarely of an entire extremity. This gangrene often seems to be due to arterial sclerosis; in other cases its cause is obscure.

Œdema of the subcutaneous cellular tissue may occur independently of nephritis. It is then probably occasioned by the cardiac weakness.

[Another skin affection which deserves mention is eczema. In the neighborhood of the genitals it is more common in women than in men, and is attributable to the irritating properties of sugar contained in the urine acting on a skin the nutrition of which is impaired owing to the morbid condition of the blood. Sometimes the eczema involves other portions of the integument, is generally acute, and has an angry appearance.]

10. SYMPTOMS REFERABLE TO THE NERVOUS SYSTEM.—It has already been mentioned that there is frequently in diabetes a moderate disturbance of the whole nervous system, as indicated by headache, physical and mental hebetude, and depression of spirits. Still more characteristic is neuralgia. This is most often located in the sciatic nerve, and an obstinate bilateral sciatica may be one of the first symptoms of diabetes. Occipital or trigeminal neuralgia or hemicrania, and, on the other hand, anæsthesia, have also been repeatedly observed. We once saw peripheral paralysis of the peroneus come on without any discoverable cause. Bouchard has called attention to the frequent absence of the patellar tendon reflex in diabetes. To what this is due, or what relation it bears to the primary disease, is not known. Possibly it is caused by degeneration of the peripheral nerves from toxic (?) influences.

The most important nervous symptom of all is a peculiar disturbance which occurs in a considerable proportion of all cases with more or less suddenness, and usually terminates in a surprisingly speedy death. This strange phenomenon was first thoroughly investigated by Kussmaul, although known long before. It is termed diabetic coma. The condition sometimes develops without any evident cause. In other instances it is apparently brought on by violent muscular exertion, mental excitement, or some trifling illness, such as gastric catarrh, bronchitis, or sore throat.

Frequently certain mild prodromata herald its onset. There may be nausea, headache, a sense of thoracic oppression, and general uneasiness. Soon the condition becomes aggravated. The patient is seized with a feeling of great anxiety, and becomes delirious, sometimes jumping out of bed and growing uncontrollable. Gradually, however, the excitement gives place to an ever-increasing drowsiness, usually terminating in the most profound coma. One of the most frequent and striking symptoms attending this condition is the peculiar alteration in respiration. The breathing becomes remarkably deep and noisy. Its rate may remain nearly normal; or it may be considerably increased, so as to justify the term "diabetic dyspnoea." The patient is sometimes cyanotic. The pulse is usually very rapid and small. The temperature gradually sinks, and has in repeated instances fallen to 86° (30° C.), or even lower. In most instances, also, the breath has a very noticeable odor, resembling fruit or chloroform, which may be perceived on entering the room. Even the urine may have this same odor; and it almost invariably becomes dark red on the addition of ferric chloride (*vide supra*).

Diabetic coma does not pursue the same course in all cases; sometimes the

patient lingers on for several days before death, while in other instances the change is extremely rapid and death speedy. The early stage of excitement may be wanting. The patient becomes somnolent and then comatose, and never regains consciousness. Temporary improvement, and even complete cessation of the threatening symptoms, are not impossible, but they are very exceptional.

We have no definite information as to the cause of diabetic coma. Of course the cases where an autopsy discloses some marked organic lesion, such as cerebral hæmorrhage, capable of producing the nervous symptoms, are not true diabetic coma. Nor do the cases of sudden death reported by Frerichs deserve to be classed as diabetic coma, where death occurred with the symptoms of acute cardiac failure—namely, collapse, coolness of the extremities, small and rapid pulse, and unconsciousness. Besides, these patients never have the acetone odor, the exaggerated respiration, nor the ferric-chloride reaction, and usually the myocardium is found to be in an advanced state of degeneration.

In genuine diabetic coma, on the other hand, everything seems to indicate that the system has been poisoned by some noxious product of the abnormal processes of metamorphosis. Great effort has been made to discover what this product is, but in vain. Kussmaul regarded acetone as the injurious substance, and therefore called diabetic coma "acetoniemia." Other investigators believe that acet-acetic acid (Jaksch) is the cause of the phenomenon in question, or at least regard the coma as a result of poisoning from some of the unusual acids present in diabetes (Stadelmann, *vide supra*). No one view has obtained general acceptance, nor has it been possible to produce diabetic coma in animals by the employment of acetone, acet-acetic acid, crotonic acid, or similar substances (Brieger and others). It is, nevertheless, extremely probable that these substances do have some close connection with "diabetic intoxication" (Frerichs).

**Pathological Anatomy and Histochemistry of Diabetes Mellitus.**—The mysterious phenomena of diabetes mellitus present a problem, the solution of which has been most industriously sought post mortem; but no satisfactory result has been reached, even in this way.

If we exclude the organic diseases, such as pulmonary tuberculosis and nephritis, which are merely complications, the pathological changes in diabetes are trifling. Bernard's discovery, that an injury inflicted in a certain spot on the floor of the fourth ventricle produces glycosuria in animals, has directed the attention of investigators to the condition of the nervous system in this disease. In some instances, tumors, sclerosis, or similar troubles have been found in the medulla and cerebellum; but in these cases the diabetes was evidently not idiopathic (*vide supra*). In idiopathic cases the central nervous system presents no striking macroscopic changes. By means of the microscope, Frerichs has found lesions of the medulla oblongata in frequent instances. The minute blood-vessels are widely dilated; there are small capillary hæmorrhages, some of a more recent and others of a more remote date; and occasionally there are microscopic foci of myelitis. The nervous elements proper, the nerve-fibers and ganglion-cells, betray no alteration. The significance of these changes must be determined by further investigation.

The stomach and intestines present no constant alterations of importance.

The liver has naturally been the object of repeated and careful examinations, because of its well-known part in the manufacture of glycogen. Yet this organ seldom presents any special abnormality. It is usually of the natural size, and may contain either considerable or very little blood. The amount of glycogen in the hepatic cells can be demonstrated with iodine by a micro-chemical reaction. It appears that, other things being equal, there is less glycogen present than normal. It is usually found only in the cells situated upon the periphery of the

lobules, and in small quantities. In an extremely advanced case of diabetes Ehrlich obtained, by means of a hollow needle, small amounts of the hepatic parenchyma for examination during life, and found that glycogen was almost completely absent. In other cases the liver has been examined as early as possible after death, and presented no trace of glycogen, but it sometimes has been found.

The spleen is usually of normal size. Occasionally it is atrophied, or, on the other hand, slightly enlarged. No other changes in it have been observed.

Many cases have presented a striking atrophy of the pancreas (Bouchardat), a fact which has acquired great significance from Minkowsky's discovery, already mentioned, that glycosuria may come on after extirpation of the pancreas. It is uncertain whether the celiac plexus may also sometimes take part in the atrophy of the pancreas. We must also state, however, that atrophy of the pancreas is not a constant lesion in diabetes, so that it is not proper to regard the disease of the pancreas as the special cause of diabetes in all cases.

The kidneys are often enlarged, from functional hypertrophy. Ehrlich discovered in them a glycogenic degeneration\* of the loops of Henle. This change is a constant one. The epithelial cells in the loops are enlarged, and the protoplasm in these cells, although apparently homogeneous, is found, by the addition of a solution of iodine in mucilage, to contain glycogen, in flakes and clumps of varying size. How important this glycogenic degeneration of the kidneys may be has not yet been determined. Perhaps the glycogen represents sugar which has been absorbed by the cells. That chronic nephritis may complicate diabetes has already been mentioned.

No thorough investigation of the chemical composition of the blood in diabetes has yet been made. One important and constant characteristic is the gradually increased proportion of sugar in the blood. There is usually somewhere between 0.2 and 0.45 per cent. of sugar, while in health the blood rarely contains over 0.1 per cent. The lymph, and such serous effusions as are found, contain sugar, but the saliva, perspiration, bile, gastric juice, and other secretions rarely furnish evidence of its existence.

**Varieties, Course, and Prognosis of the Disease.**—The study of a large number of cases of diabetes will show great variations in the course and duration of the disease. As already stated, we may in practice distinguish between mild and severe forms of diabetes. In the mild cases, sugar ceases to be excreted if the patient be put upon a diet containing no carbohydrates. Sometimes it is even possible for the patient to eat a small amount of starchy food without occasioning glycosuria, particularly if he take enough exercise (*vide supra*). In the severe form, sugar persists in the urine even upon a purely meat diet; and upon the ingestion of carbohydrates there will be, at the end of half an hour or so, a large increase of sugar. Most of the other symptoms are alike in both forms of the disease, varying only in degree. The moderate form may finally assume a severe character; and sometimes, although the secretion of sugar remains permanently small, fatal complications, such as tuberculosis of the lungs, finally develop.

The general course of diabetes varies in different cases, exclusive of the differences already referred to. In a few instances the disease occupies only a few weeks, and may almost be termed "acute diabetes." Other cases last one or two years, and still others ten or twenty years. The patient's condition may vary from time to time. We have repeatedly seen the sugar disappear temporarily from the urine, and the patient apparently completely recover; but sooner or later the disease breaks out again. These cases, which are commoner in old people,

\* Ehrstein and Armanni noticed and described this modification; but they regarded it as a necrosis of the epithelium.

have been called "intermittent diabetes." The relapse is often brought about by emotional excitement or some grave error in diet. Again, the disease may undergo apparent arrest and the patient enjoy comparative comfort for years. As a general rule, it may be said that older patients are more apt to have the mild form of diabetes, while in young adults and children the disease is wont to pursue a more rapid and unfavorable course.

Different cases also differ in the relative severity of particular symptoms. Thus, the clinical picture presented by diabetes may be modified by the general constitution of the patient—for instance, his corpulence or emaciation; by such complications as diseases of the lungs, kidneys, or brain, or syphilis and gout; and by many other conditions. In practice, especially in practice among the better classes, it is very important to have a knowledge of the milder forms of diabetes, in which sugar is present in the urine only at times, and not in very large amount. The more we are accustomed to examine every urine for sugar the oftener we find such cases, as to the pathological significance of which our knowledge is still very slight. The glycosuria of the corpulent (Seeger) is worthy of special consideration. It is not uncommon in patients who have formerly suffered from true gout. The tendency to the formation of furuncles and cataract is noteworthy. We must also mention the cases of diabetes in neurasthenics—that is, cases where there is sugar in the urine, and where the chief complaint is of general nervous symptoms, pressure in the head, anxiety, a dull feeling, incapacity for mental work, neuralgic pains, etc. In all such cases glycosuria has not the serious significance that it has in genuine and severe diabetes.

We would again call attention to the fact that diabetes may exist without polyuria or abnormal thirst, and so be overlooked. It is a very interesting fact that diabetes mellitus occasionally undergoes gradual transformation into diabetes insipidus (see Chapter X). Frerichs has given some striking examples of this.

The usual termination of diabetes is death. We have already seen how great a difference there may be in the length of time preceding the fatal termination, and in what various ways it may be brought about. The most frequent immediate causes of death are marasmus, diabetic coma, pulmonary consumption, nephritis, furunculosis, or the development of carbuncles.

There is no doubt that complete recovery may occur; but this is rare, and is possible only in the milder cases. It should also be borne in mind that apparent recovery does not exclude the possibility of a fresh outbreak of the disease.

[It should be clearly understood that the presence of sugar in the urine does not in itself indicate diabetes; and that diabetes is not now considered nearly as hopeless a disease as it was. The diagnosis was formerly seldom made unless one or all of the cardinal symptoms—increased thirst and appetite, with progressive emaciation and polyuria—were markedly present, a condition of things which may be roughly compared to phthisis in the stage of cavity. The prognosis is more grave in the young than in those past middle life, in thin than in stout people, and in those from whose urine the sugar does not disappear under dietetic treatment alone. If the bodily weight and the strength be well maintained, sugar may be excreted for long periods without any obvious ill effects.]

**Theoretical Discussion of the Nature of Diabetes.**—We have endeavored to give an approximately complete summary of the facts pertaining to diabetes. We trust we shall be excused from detailing all the theories and hypotheses which have been devised to explain the peculiar phenomena of the disease, particularly the glycosuria. It is a better way simply to confess that the true nature of diabetes mellitus as yet remains very obscure. We shall confine ourselves to a few remarks upon the present state of the question.

The essential fact which demands explanation is the excess of sugar in the

blood. The source of this sugar is probably the same as of the sugar normally contained in the blood. The largest part of the sugar probably comes from the carbohydrates contained in the food. These are, for the most part, converted into sugar in the *primæ viæ*, which sugar thereupon enters the portal system. It may also be assumed that glycogen, so widely diffused throughout the system, is another source of sugar. The liver is the main seat of the manufacture of glycogen; but it is produced in other parts as well, and in particular in the muscles. The question next arises, From what is the glycogen formed? A part of it is probably manufactured from the carbohydrates contained in the food, but another part is certainly due to the ingested albuminoids. Accordingly, Von Mehring found that in fasting animals, who have no more glycogen stored up in the body, diabetes may be produced by giving phloridzine (*vide supra*). The sugar excreted can therefore come only from the destruction of albumen in the body. Again, the transformation of glycogen into sugar is not confined to the liver, but may take place wherever glycogen is produced. How it takes place is unknown. It is usually assumed that there is some "saccharific ferment."

It would seem, therefore, that the sources of sugar are the same in diabetes as in health. We have next to seek for the reason of its excessive accumulation in the blood. Under normal circumstances, the sugar present in that fluid rapidly undergoes decomposition into other substances. In health there is no great excess of sugar in the blood, even upon a diet extremely rich in starch; and it is possible to eat large amounts of sugar without any glycosuria. We see, therefore, that diabetes can not be explained by assuming that there is an increased production of sugar except in so far as corresponds to the increased amount of ingesta. On the other hand, everything points toward the conclusion that in diabetes the ordinary processes effecting the decomposition and destruction of sugar are suspended. The sugar is excreted by the kidneys unaltered, for the reason that it is not destroyed. It is difficult to conjecture what the circumstances may be which thus interfere with the decomposition of the sugar. Perhaps it is some special nervous influence, or perhaps some ferment may be wanting in diabetes which in health promotes the metamorphosis of the sugar (compare the experiments of Minkowsky, above mentioned, in producing diabetes by extirpation of the pancreas). Another point that is difficult to understand is, that in the milder cases of diabetes only such sugar as originates from the starch contained in the food is excreted, while the sugar manufactured from albumen seems to be completely decomposed. The cause of the excretion of sugar can not lie in the disturbed condition of the kidney, for in diabetes insipidus, as Frerichs shows, no glycosuria is produced, even when a very large amount of sugar is ingested.

**Diagnosis.**—For the diagnosis of diabetes mellitus it is indispensable that sugar should be demonstrated in the urine. We have also to decide whether the condition be a temporary or a permanent one, or, in other words, whether we have to deal with mere glycosuria or genuine diabetes mellitus. This point is to be determined by means of the symptoms and general course of the disease.

Diabetes often exists for some time unsuspected even by the physician. It may therefore be well to name over the symptoms which may be the first to attract the patient's attention, and which should therefore always suggest to a physician the possibility of the existence of diabetes. They are: 1, languor and debility; 2, furunculosis; 3, pruritus pudendi in women, balanitis in men; 4, cataract; 5, sciatica, especially if bilateral; 6, impotence. We should also be in the habit of examining the urine for sugar in all cases where complaint is made of indefinite symptoms, which can not be explained without further evidence, especially in cases where the patient is fat or nervous.

If symptoms similar to those just enumerated lead to an examination of the

urine, and the result of this is ambiguous, it is advisable to have the patient partake of a meal rich in starchy elements, and to examine the urine thereafter. If even then no sugar is found, diabetes does not exist.

[The urine passed three or four hours after a full meal often contains sugar, when that passed on rising is quite free from it.]

**Treatment.**—Medical science does not possess the power to cure the disease, but it can greatly benefit the patient, both by alleviating his symptoms and by shielding him, at least for the time, from many of the secondary effects.

The first requisite is to institute a proper regimen. All the hygienic circumstances of the patient should be regulated. This is more important than any sort of medicinal treatment. We have seen that a large part of the food taken by a diabetic patient escapes from the body unutilized, and that, as a result of this, certain disturbances are produced in the tissues; thus there is a tendency to furunculosis and gangrene and cataract. Furthermore, the sugar contained in the urine gives rise to certain secondary symptoms, such as balanitis, and perhaps its presence in other secretions has analogous bad effects. We must therefore endeavor, first, to promote the conversion of the non-nitrogenous elements of the food; and, secondly, to furnish the system with a substitute for that portion of the food which it can not assimilate, and to obviate the excessive ingestion and production of sugar. It would be erroneous to conclude that this last point is the only essential one, and that we accomplish our whole duty by reducing the amount of sugar contained in the urine to a minimum. The general condition of the patient should invariably be considered. There can be no doubt that a diabetic patient whose strength is well maintained is better off than one whose urine contains only one per cent. of sugar but who yet is daily growing weaker.

Mental excitement has been suggested as a possible cause of the disease; and there can be still less doubt that it usually has a bad effect upon its course. The physician should therefore endeavor, so far as he is able, to guard the patient from excitement, whether incidental to his occupation or to his social position.

A proper diet is of the greatest importance. It has already been stated that in many instances the excretion of sugar may be entirely stopped by excluding starch from the ingesta; but such exclusion does not always result in permanent benefit to the patient. Cantani, however, believes otherwise, and has laid down a very strict dietetic regimen. He states that in not a few cases an almost exclusive meat diet may be persisted in for years, and the patient may at length experience complete recovery, or even acquire the ability to partake once more of starchy food with impunity. That such favorable results may occur we have no doubt; but we must call attention to the fact that it is frequently impossible to enforce the strict regimen of Cantani, and that many patients, while following it, feel worse than when they indulge in a moderate amount of carbohydrates. The "cure" affords them no relief, but merely distress. At present, authorities are generally inclined to recommend a diet mainly of flesh or albuminoids, but not absolutely devoid of carbohydrates. The amount of starch which can be safely ingested varies with the individual. Of course, the best way is to judge of the system's power to tolerate starch by means of daily quantitative estimations of the amount of sugar excreted. We repeat that, within certain limits, the percentage of sugar should not be the only criterion of the suitability of the diet, but that the general condition should also be taken into consideration.

If we consider the most common articles of diet with regard to the proportion of carbohydrates they contain, we shall find that they may be classified somewhat as follows: First, these articles may be allowed *ad libitum*: All sorts of fresh meat, ham, smoked meat, tongue, fish, crabs, eggs, caviare, sour milk, cheese, butter, bacon; also green vegetables, lettuce, spinach, and cucumbers. Secondly,

the following may be used moderately: Bread, milk, fruit, rice, turnips, beets, asparagus, radishes, cauliflower; also light beer, claret, and other dry wines. Thirdly, if possible, the following should be entirely abandoned: Sweet dishes, cake, honey, potatoes, grits, sago, peas, beans, lentils, sweet fruit, sweet wine, and liqueurs.

The greatest trial for most patients is to give up bread. Every physician has had experience of the cunning which patients exercise in order to satisfy their invincible craving for it. Faults of this kind are not so apt to be committed if the patient is allowed a limited amount of bread, say two or three ounces a day in divided portions. There have also been many attempts to make a bread out of such carbohydrates as have been found by experience not to increase the excretion of sugar, and thus to furnish a substitute for ordinary bread; but these succedanea have not become popular, mainly because of their bad taste. They may, however, be tried. We have not space to describe in detail the various kinds of "diabetic bread" which have been recommended. The best known are bread made from bran flour (Prout), from almonds (Pavy), from inulin and lichenin (Külz). Most of these substances contain a considerable amount of starch.

Since we can not supply the system of a diabetic patient with carbohydrates in sufficient amount, it suggests itself that we should endeavor to supply the lack by other non-nitrogenous substances, and that the patient should be allowed a large proportion of fat in his diet. With regard to this, experience and theory coincide. Fatty substances are well borne in most cases, and we should not only allow, but urge patients who are at all emaciated to use butter, cream, and similar articles of diet. Cod-liver oil is also frequently employed, and is even regarded by many physicians as having a specific effect. It may be stated in this connection that for a time it was believed that glycerine might serve as a substitute for sugar (Schultzen); two to three ounces may be given in a day; but, with some apparent exceptions, its administration has not proved especially satisfactory.

Dühring claims that by long-continued boiling the carbohydrates may be so modified as to cease to affect the excretion of sugar in diabetes. Dühring gives his patients mainly rice and fruit, these substances having previously been soaked in water and boiled for several hours. His method also includes certain other dietetic and hygienic measures, but it has not yet been satisfactorily tested.

To quench thirst, we may allow the patient simple water or Seltzer water, and acidulated drinks. If the thirst be very troublesome, the patient may let little pieces of ice melt in the mouth. Tea and coffee may be taken with cream, but without sugar. In place of sugar, we may make trial of glycerine or mannite. Milk does not need to be absolutely banished, but few patients care for it. Alcoholic beverages may be allowed in moderation, particularly red wine, such as Bordeaux, and light beer. Thirst may also be moderated by weak brandy and water.

[The dietetic treatment of diabetes is so important that it is desirable to go more into detail.

There is some discrepancy between the authorities on this point, a more strict diet being laid down by some than by others. Ralfe's list is as rigid as any, and is as follows:

To avoid milk (except very small quantities for cooking purposes). The liver of all animals (as the liver of oysters and all mollusca is large, and abounds in glycogen, these animals must be forbidden), so also the interior of crabs, lobsters, etc. Bread, biscuits, rusks, toast, farinaceous vegetables, such as potatoes, Jerusalem artichokes, rice, oatmeal, corn-flour, sago, tapioca, arrowroot, etc. Saccharine vegetables, turnips, carrots, parsnips, green peas, French beans, beet-root, asparagus, tomatoes. Blanched vegetables of every sort, as celery, sea-kale, endive, radishes; also the stalks and white parts of such vegetables as cabbage, lettuce,

broccoli, etc. Fruits of all kinds. Jams, sirups, sugars. Certain condiments, such as chutnee and sweet pickles, cocoa, chocolate, liqueurs, sweet wines.

May take meat, fish, poultry, game, bacon, ham, eggs. Bread and biscuits made with prepared gluten, bran, or almond-flour. Green vegetables, summer cabbage, turnip-tops, spinach, broccoli-tops, water-cresses, mustard and cress, laver, sauerkraut, the green parts of lettuce, sorrel, mushrooms. Nuts of various kinds (except chestnuts). Cheese.

Flint's list is more lenient, allowing oysters and a much larger choice of vegetables, such as asparagus, string beans, artichokes, cauliflower, tomatoes, etc. ("Journal of the American Medical Association," July 12, 1884; also "Pepper's System of Medicine," vol. ii, page 221).

Donkin's treatment by skim milk exclusively is highly approved by Tyson.

Rhenish and similar wines, moderate quantities of spirits, or a malt liquor in which the sugar has been entirely converted into carbonic acid and alcohol (Bass's ale, for instance), are permitted.

In the opinion of the writer, it is always well to begin treatment with a very stringent dietary, which may be relaxed gradually as circumstances dictate. The severity of the case is to be regarded rather than the name of the disease. The gluten and other diabetic flours are unreliable; and I agree with Flint that, if bread be allowed, it is better to give the crust of a French roll the ingredients of which are known. Saccharine may be used to sweeten tea and coffee, jellies, ice cream, and the like.]

Certain other general directions are important. The patient should take sufficient exercise. Külz has determined by means of accurate experiments that, other things being equal, the assimilation of sugar is increased upon increase of muscular activity, with a consequent diminution in the excretion of sugar. Practical experience also shows that regular exercise is extremely beneficial. A proper discretion should be employed, however; nothing would be more injudicious than to force a feeble patient to exhaustive efforts. But if the patient be vigorous and well nourished, he should be strongly urged to take a walking-trip in the mountains, or to try horseback riding and the like. Methodical massage of the muscles sometimes has a good effect.

Proper care of the skin is indispensable. Baths, cold sponging, and douching may be employed. Strict attention should also be given to the teeth, lest they become carious. Thorough ventilation should be maintained, both day and night.

Of internal remedies, opium should be named first. One good effect of this drug is that it lessens the annoying thirst. It sometimes also causes decided diminution in the amount of urine and sugar excreted. It is further indicated when there is general restlessness or sleeplessness. It is often well borne by diabetic patients, even in large doses. A patient sometimes can take four to eight grains (grm. 0.25-0.5), or even more, of opium in twenty-four hours without any bad effects. It is noteworthy that the alkaloids of opium, such as morphine and codeia, possess much less value than opium itself.

[If sugar does not disappear from the urine under diet alone, or if a strict diet be not tolerated for any reason, opium is indicated. The drug is usually well tolerated, and can be given in divided doses or in one dose at bedtime. If the latter course be adopted, one grain can be given and increased until the sugar either disappears or ceases to diminish in amount; this dose varies with different individuals, but when reached it can be maintained without increase for a long time.

The inhalation of oxygen is worthy of mention as a remedial measure.

Purdy seems to show that diabetes attains its highest mortality in those States which combine relatively high altitude with low temperature. A residence in the Gulf States or Southern California may therefore be curative or prolong life.]

Belladonna, cannabis indica, chloral, and bromide of potassium are also given, but they are less efficient than opium. Bromide of potassium would probably be the best of these, particularly if there were a condition of nervous excitement.

The alkalies, and still more the alkaline mineral waters, enjoy a reputation second only to that of opium. Hundreds of patients visit Carlsbad, Neuenahr, and Vichy every year to return much benefited. Of course it must not be forgotten that it is not merely the waters which produce these beneficial changes. Other factors are also important, in particular the strict diet, fresh air, and freedom from the cares of the household and business. Why the alkalies should act favorably we do not know. Griesinger, and later Külz, as well as others, have made careful comparisons of the amounts of sugar excreted under like circumstances, with and without the ingestion of bicarbonate of soda or of Carlsbad water and similar substances, and for the most part have not been able to perceive any benefit from these remedies. Practical experience, however, shows the value of these alkaline springs; and their use is to be recommended, although the expectations of the patient should not be wrought to too high a pitch.

From a theoretical point of view, there is interest in the fact that certain remedies which are antagonistic to fermentation have been shown by Ebstein and Müller to diminish the excretion of sugar in many cases of diabetes. Chief among these are carbolic acid and salicylate of sodium. The carbolic acid is given in the amount of ten to twenty grains (grm. 0.5-1.5) per diem. The amount of salicylate of sodium is one to two and a half drachms (grm. 5-10) daily. There is no doubt that these drugs possess the property ascribed to them; but they are not advantageous to the patient, inasmuch as the general condition is seldom improved by their use. On the contrary, very unpleasant effects are sometimes observed.

We need not enumerate all the remedies which have been recommended in diabetes. We have already mentioned those that possess any extended reputation. We may therefore merely refer to certain drugs which have been lately introduced.

Cantani has suggested the employment of lactic acid in the amount of one to two and a half drachms (grm. 5-10) per diem, dissolved in half a pint of water. This drug may perhaps serve as a physiological substitute for sugar, as glycerine is supposed to do (*vide supra*), but it has no specific virtues.

Certain salts of ammonia, such as the carbonate and acetate, are said to diminish the excretion of sugar, and have therefore long been employed in diabetes, but without special benefit.

Iodoform has been recommended by Moleschott to the amount of three to six grains (grm. 0.2-0.4) per diem. It is said not only to diminish the amount of sugar in the urine, but also to alleviate other symptoms. Arsenic, tincture of iodine, and quinine have also been employed; and we may mention that even electricity has been tried—we need hardly say, in vain.

It is evident, in brief, that the best mode of treating diabetes, at least according to our present knowledge, is by regulating the diet, and that it is well, in addition, to recommend the employment for a time of the above-mentioned mineral waters, with opium and other internal remedies to combat special symptoms. The treatment of such complications as phthisis or cutaneous eruptions need not be described here.

In diabetic coma, camphor or ether, subcutaneously, should be employed, together with lukewarm baths and douching. As it is possible that the coma may be due to poisoning from the acids in the blood (*vide supra*), we should also try bicarbonate of sodium in large doses, and in some cases use intravenous injections of a three to five per cent solution, or give it subcutaneously; but the efficiency of such treatment remains to be decided. Experience thus far is not very encouraging for further trials.

## CHAPTER X.

## DIABETES INSIPIDUS.

**Definition and Ætiology.**—In the preceding chapter a distinction was drawn between diabetes mellitus and the symptomatic condition termed glycosuria. There is a similar distinction to be made between diabetes insipidus and polyuria. Polyuria is an increase in the volume of urine, and mainly in the amount of water excreted by the kidneys. It is a symptom which may be produced in many different ways. In the first place, it is a natural consequence of the ingestion of large amounts of water, or of the absorption of serous effusions; it also occurs in certain diseases of the nervous system, especially of the medulla and cerebellum; it is also occasionally seen, as we have had opportunity to observe, in chronic hydrocephalus, and is a not very infrequent phenomenon in hysteria. Large amounts of urine are also secreted in certain renal diseases (interstitial nephritis and amyloid degeneration), and often during convalescence from acute diseases, such as typhoid fever, or after the ingestion of certain drugs, called diuretics.

Diabetes insipidus, on the other hand, is a disease which may develop idiosyncratically in people otherwise perfectly healthy. Its ætiology is unknown. It occasionally seems to be excited by emotional disturbance, concussion or other injury of the brain, or some previous acute disease, such as typhoid or typhus fever, malarial poisoning, and cerebro-spinal meningitis. The disease sometimes appears in the syphilitic, and may, therefore, in many instances, be due to syphilis. Patients frequently state that their symptoms began immediately after drinking a very large amount of some fluid, as on a very hot day or after a long march. In such cases the assumption is a probable one that the primary symptom is not polyuria, but an abnormally great thirst (polydipsia), the increase in urinary secretion being a result of the large amount of water ingested. Finally, the disease may be hereditary (*vide infra*). The true nature of diabetes insipidus is entirely unknown to us.

The view which seems most probable of any is, that some nervous disturbance is its direct cause. In support of this, we have the appearance of a "symptomatic diabetes insipidus" in connection with organic disease of the brain (*vide supra*), and the fact that polyuria may be artificially excited by injury to a definite spot in the floor of the fourth ventricle or by section of the vagus nerve. Diabetes insipidus presents a most striking analogy with diabetes mellitus. This is shown both by the similarity in ætiology and symptomatology, and still more by the fact that occasionally one disease merges into the other.

Diabetes insipidus is a disease of very infrequent occurrence, and, at least in Germany, is decidedly less often seen than diabetes mellitus. Most patients are in young adult or middle life. Males are somewhat more liable to the disease than females.

**Clinical History.**—Diabetes insipidus may be developed gradually or with considerable abruptness; the latter case is especially frequent when there is some definite cause, such as the ingestion of a large amount of liquid, or traumatism.

The essential and characteristic symptom is an increase in the volume of urine. This is usually very considerable. Often eight or ten quarts (8000 to 10,000 c. c.) are excreted in twenty-four hours, and cases have even been reported where the amount reached the almost incredible volume of thirty to forty quarts (litres). If a healthy person and a sufferer from diabetes insipidus are each given the same

amount of water in food and drink, the sick man will excrete more urine than the healthy. In color the urine is very pale, and sometimes almost like water. The specific gravity is very low, being usually 1004 to 1002, or even 1001. The reaction is slightly acid, sometimes almost neutral.

The percentage of solid constituents in the urine is, of course, trifling. The total amount of solids, however, corresponds perfectly with the ingesta, or indeed is even somewhat above normal. The amount of urea in particular seems to be increased, but it has also been stated that other constituents of the urine have been excreted in abnormally large amounts—namely, phosphoric acid, sulphuric acid, lime, and kreatinine. Inosite has been found in the urine by Strauss and other observers, so that it has even been proposed to give diabetes insipidus the name of “diabetes inositus,” in distinction from diabetes mellitus. Inosite is not invariably present, however, in the urine of diabetes insipidus. In cases of true diabetes insipidus, albuminuria is extremely exceptional.

Another important symptom is the excessive thirst. To make up for the great loss of water by way of the kidneys the patient is obliged to drink great quantities of liquid, and, indeed, it is always found that the amount of water ingested, in the way of drink and solid food, somewhat exceeds the total volume of urine excreted. Despite this, the tongue is usually dry, as is also the skin, the insensible perspiration being considerably below the normal amount. The furunculosis seen in diabetes mellitus is exceptional in diabetes insipidus. The same is true of pruritus and balanitis. Occasionally profuse salivation has been associated with the disease.

Symptoms referable to the various internal organs are few. Cataract has been occasionally observed, but it is much less frequent than in diabetes mellitus. The same may be said of pulmonary tuberculosis. In most cases the appetite is not excessive. The bowels are regular or slightly constipated. There is seldom much gastro-intestinal disturbance, unless from some chance complication. The sexual functions are usually unimpaired.

The general health is considerably affected in cases of any severity. The patient becomes emaciated, languid, and feeble, and has no inclination to mental or physical exertion. Sleep is often disturbed, the mind depressed. The temperature is normal, or even a trifle below normal, probably as a result of the large amount of cold water drunk.

Diabetes insipidus is a very chronic disease. If there is no serious complication it may last for decades, yet there are cases that run a more rapid and unfavorable course. Sometimes there are considerable vicissitudes in the condition of the patient, in part dependent upon external circumstances and in part apparently spontaneous. In case some intercurrent acute disease develops there may be, during its continuance, a considerable diminution in the amount of urine excreted.

The termination is usually unfavorable. Recovery is extremely rare. In the more fortunate cases the condition finally becomes stationary, and the patient attains to advanced years. Sometimes, however, death occurs more prematurely, being usually hastened by phthisis or some similar complication.

Weil has lately contributed to our knowledge of this disease the results of an accurate study of its hereditary and apparently congenital variety. Weil narrates the history of a family in which marked polyuria and corresponding polydipsia appeared in numerous members for several generations. These persons all enjoyed excellent health, with this exception; and most of them attained old age. We hardly need to emphasize the fact that this form of the disease is radically different from the ordinary acquired variety. Perhaps its true cause is an abnormal congenital permeability of the glomeruli, but we have no certain information in regard to it.

**Post-mortem Appearancea.**—Such lesions as have been found in diabetes insipi-

thus are usually the result of fortuitous complications, such as tuberculosis, carcinoma, and pneumonia. There are but very few changes referable directly to the disease itself; among these are enlargement of the kidneys and dilatation of the ureters. In rare instances a possible cause for the symptoms has been found in some lesion of the central nervous system, but these were properly cases of symptomatic polyuria and not of genuine diabetes insipidus. Instances of this sort are seen in connection with tumors or inflammatory changes in the medulla or cerebellum, and exostoses at the base of the skull.

**Diagnosis.**—The characteristic urinary phenomena usually render the diagnosis of diabetes insipidus an easy matter. It is of course necessary to exclude such diseases as might occasion symptomatic polyuria (*vide supra*); but this is seldom difficult if we make a careful physical examination and carefully consider all the attendant symptoms. The differential diagnosis between diabetes insipidus and diabetes mellitus can almost invariably be made by means of the urinometer. If the specific gravity is below normal, it is scarcely necessary to test for sugar.

**Treatment.**—No special injunctions with regard to diet are required. It would of course be a mistake to forbid the patient to assuage his excessive thirst; but we may possibly lessen the amount of water drunk by prescribing bits of ice, or lemonade and other acid drinks. Opium sometimes lessens both the thirst and the amount of urine excreted. It is also important that the skin should be well cared for by means of baths and friction, and every effort should be made to promote the general vigor of the patient. He should have nourishing food and good air.

Numerous internal remedies have been recommended as specific, but few of these have won any great reputation. Valerian appears, on the whole, to be the most efficient drug, and may be given in powder or infusion to the amount of one to two and a half drachms (grm. 5-10) per diem. Ergotine may also be tried. Carbolic acid, salicylate of sodium, and nitric acid have been said to prove beneficial. It is also said that galvanization of the medulla and upper part of the spinal cord sometimes accomplishes good results.

Occasionally we may find an apparent cause for the disease and endeavor to remove it. If there is a suspicion of syphilis, mercurial inunctions should be tried. Sometimes, as we can confirm by our own experience, they have an excellent effect. Of course, where there is symptomatic polyuria, the primary disease, such as hysteria, demands treatment.

[Da Costa and others report very good results as following the administration of ergot.]

## CHAPTER XI.

### GOUT.

(*Podagra.*)

**Ætiology.**—Thomas Sydenham was the first to write a careful clinical description of gout. He himself suffered from the disease for about forty years, and has given a detailed description of his own case in the treatise which he published in 1683, under the title "*Tractatus de podagra et hydrope.*" It was, however, Wollaston who, in 1797, threw the first light upon the peculiar anomaly of tissue-metamorphosis which exists in this disease. He demonstrated that the gouty deposits found in the joints and other parts of the body are mainly uric acid. From his time an all-important point with regard to the nature of the disease has been the relation between the symptoms of gout and disturbances in the manufacture and excretion of uric acid. In 1848 Garrod showed that in gout the blood contains an excess of uric acid, and that the excretion of uric acid by the kidneys is dimin-

ished. He was thus in a position to frame a theory consistent with all the clinical facts. Numerous investigations have been undertaken since his day; but we still remain with regard to gout in a position analogous to that which we hold toward diabetes. We are, it is true, in the possession of a considerable number of well-established facts relating to it, but we do not know why the normal chemical processes are disturbed, and are unable to explain the connection between the various phenomena observed.

Clinical experience has taught us certain remote causes of gout, first of which comes heredity. About fifty per cent. of all cases occur in patients whose families have already suffered from the disease, and it is sometimes possible to trace this transmitted taint through many generations. It is decidedly more apt to pass down through the male members of the family than through the female.

Next in importance to hereditary influences is the mode of life. From time immemorial this has been regarded as an exciting cause of the disease. It has been a matter of universal belief that over-feeding, and especially the ingestion of too large a quantity of albuminoids, is strongly provocative of the disease. The same opinion has been held with regard to persistent over-indulgence in alcoholic beverages. Seneca relates that at the time of the decay of the Roman Empire women practiced such excesses that they were as subject to gout as the men, and an old verse runs: "Wine is the father of gout, feasting is its mother, and Venus is the midwife." This view is, however, an exaggerated one. It can not be denied that there is some truth in it, but, on the other hand, gout is not exclusively an "arthritis of the rich." It occurs also among the poor, who have had only too little acquaintance with the pleasures of the table; and many a *bon vivant* has reached old age without ever experiencing pain in his great toe.

[Gout is a disease so much more common in England than in Germany or this country that English opinions in regard to it are deserving of especial weight. The most commonly accepted, though by no means the only, view as to its nature is that it depends on defective oxidation, which may be brought about in two ways: either by the ingestion of more food than can be properly oxidized, or by the presence of such conditions that even a moderate supply of food can not be worked up and undergo its proper transformations. This theory will account for gout in the poor as well as in the rich.]

There can be no question that the use of malt liquors, especially in the stronger forms, consumed so enormously in England, is much more favorable to the development of gout than is the use of distilled spirits; so also the stronger wines—such as port, sherry, Madeira, and the heavy Burgundies—are more dangerous than are the lighter and more acid wines of France and Germany. In this country gout is becoming more common, a fact which may be fairly explained by the accumulation of wealth and the consequent growth of luxury.]

There is a noteworthy, although mysterious, connection between gout and chronic lead-poisoning. The fact is well established that persons who have to do with lead, such as type-setters and house-painters, are subject to genuine gout with deposits of uric acid in the joints.

With regard to still other alleged aetiological factors, confirmatory evidence is lacking. Possibly, however, when the foundation for the disease is already laid, an attack may be excited by certain determining causes—namely, trauma, taking cold, errors in diet, and mental emotion.

The geographical distribution of gout is remarkably unequal. The disease is much more frequent in England than in Germany, although in the latter country certain regions appear to be more affected by it than others. In Leipsic, in Saxony generally, and in Bavaria, gout is decidedly rare.

Gout is rarely seen in young persons. It is a disease of advanced life, rarely

appearing previously to the fortieth year. Men are much more often attacked than are women.

**Clinical History.**—Gout may produce symptoms in many different organs; but its effect upon the joints is so characteristic that the arthritic disturbance has long been termed "normal or regular gout," in contradistinction from "atypical, internal gout." This distinction is of course an artificial one, for the various phenomena of gout present the most manifold gradations and transitions. It will, however, be advantageous, in attempting to gain a practical insight into the various symptoms of the disease, if we first discuss the so-called "typical attack of gout," subsequently appending a description of the other manifestations of the disease. Furthermore, the regular attack of gout is, in at least a majority of cases (*vide infra*), the first and earliest symptom of the disease.

1. The typical attack of gout is seldom abrupt. It is usually preceded for a longer or shorter period by certain premonitory symptoms, the meaning of which, though not evident to one who is about to suffer from his first attack, is sufficiently clear to more experienced patients, particularly as each individual case is apt to present a marked similarity in the prodromata of the separate paroxysms. These premonitory symptoms vary in different individuals. Sometimes they consist in dyspeptic disturbances; sometimes in a feeling of languor and mental depression; very often in dragging, muscular pains or cramps in the calves of the legs; or again in slight feverishness, with chilliness, sense of heat, and perspiration. On the other hand, it must be confessed that a patient may feel unusually well just before an attack.

The attack is noticeably apt to begin in the night-time, or very early in the morning. The patient is awakened by a sudden and very violent pain in the metatarso-phalangeal joint of one of the great toes ("podagra"). The joint becomes swollen, the skin over it red, hot, and tense, the veins in the neighborhood distended. At the same time there is chilliness and moderate fever. This condition persists till morning. Then the pain is almost sure to abate, the fever to remit at the same time that sweating begins, and the patient to feel tolerably well during the day. The joint, however, remains swollen, with inflammation and oedema. The next night the pain begins again, and there is a fresh fever; and these alternations are repeated, as a rule, for three to ten days. Even where the attack is more persistent than this, the pain is usually much less severe after the first two or three nights. After that time it gradually abates; and it is commonly said that an attack is brief in proportion to the violence of its first symptoms. When the pain ceases, swelling soon disappears, the skin undergoes a slight desquamation and resumes its normal appearance, the general health of the patient rapidly improves, and he is often found to be much better after an attack than he was before.

For theoretical purposes (*vide infra*) it would be very advantageous to possess a more accurate knowledge of the condition of the urine, and in particular of the excretion of uric acid during the attack. As yet, however, there have been few careful investigations made. Garrod has made a very important observation, which has been confirmed by Cantani: it is, that the amount of uric acid excreted diminishes several days before the commencement of an attack, and remains diminished during the attack. Subsequently to the attack the excretion of uric acid is said to be above normal, while the amount of uric acid in the blood varies in precisely the opposite way—that is, during the attack it is increased, and after, it is diminished. It has not yet been determined how far this variation in the excretion of uric acid may be referable to the altered diet of the patient, and how far to a diminished formation of uric acid or a deposition of that substance in the diseased joints (*vide infra*).

If there has been one attack of gout, there are almost sure to be others. They come sooner or later, at regular or irregular intervals, and separated by weeks, months, or even years. The attacks recur at long intervals in mild cases, more frequently and at gradually diminishing intervals in the severe. Spring and autumn are regarded as the time when attacks of gout are most apt to occur. In these subsequent attacks the great toe still remains the part most constantly and severely affected; but other joints may also suffer—for example, the wrist, the knee, or the shoulder. Sometimes traumatism or some previous affection of the joints—such as rheumatism—apparently determines the localization of the gouty disturbance. In each attack, the trouble is usually confined to a single joint. It is only in exceptional or advanced cases that several joints are simultaneously invaded.

The longer the disease has lasted, the less typical are the separate attacks. There may now be less suffering at the time of an attack; but the articular changes are more persistent. There are symptoms referable to other parts of the body; and the gout gradually passes into its second chronic or "atonic" stage. Occasionally the disease is irregular and atypical from its incipency; and the first manifestations may not be arthritic, but referable to the kidneys (*vide infra*) or other organs.

2. *Atypical Gout. Gouty Disturbance of other Parts than the Joints.*—Gout may affect the mucous membranes. A gouty dyspepsia is very frequent. Its symptoms are more or less severe. The gouty are also subject to intestinal catarrh of varying severity, and to bronchitis and conjunctivitis, as well as to catarrh of the urinary organs. Ebstein regards "gouty gonorrhœa" as essentially a catarrh of the excretory ducts of the prostate gland. It is not an easy matter to explain why these various forms of catarrh should occur in gout. They may be, some of them, complications. In other cases they are doubtless the result of passive congestion, due to cardiac failure (*vide infra*); but in still other instances it must be confessed that they are apparently due to the toxic influence of the accumulated uric acid.

[My experience, though far more limited than that of Draper, nevertheless leads me to believe, as he does, that the irregular forms of gout are by no means uncommon in women as an inheritance from a previous generation. The manifestations in some of these cases are so ill-defined that a diagnosis may be difficult without a knowledge of the family history; in other cases, more or less deformity of the smaller joints, or slight recurrent swellings of those parts, throw much light on the condition underlying the symptoms.]

Inflammation of serous membranes—for example, of the pleura—also occurs; and there may be pneumonia. The skin not infrequently suffers from acute or chronic eczema, which sometimes appears to be referable directly to the gout. Keratitis, iritis, and other inflammatory disturbances of the eye are also said to be caused directly by gout. Cirrhosis of the liver has been repeatedly found, and is perhaps referable to the action of the uric acid upon the hepatic parenchyma. By far the most important of all these gouty manifestations are referable to the kidneys and to the circulatory system. The disorder of the latter is sometimes symptomatic of the renal trouble, but in other instances it occurs independently of it. There may be severe gouty arthritis for years without any lesion of the kidneys; but this is exceptional. In severe cases of gout it is the rule that, sooner or later, symptoms of renal disorder present themselves. The so-called "gouty kidney" is a form of chronic interstitial nephritis. However important this complication, its symptoms do not need to be discussed here, as they are precisely similar to those seen in ordinary cases of contracted kidney (*vide* page 856, *et seq.*). The distinctive symptom of this disturbance is albuminuria; and the

gradually developing secondary hypertrophy of the left ventricle is the pivot on which turns the whole future course of the disease. So long as the heart remains capable of performing its functions, the condition of the patient will probably remain endurable if not actually comfortable. Finally, however, compensation is sure to become impaired; and then appear œdema, dyspnœa, debility, and emaciation—in short, all the familiar symptoms of cardiac failure. A speedy end may be brought about by uræmia, or cerebral embolism, or hæmorrhage; but in other cases the patient suffers for years, both from the heart disease and from fresh arthritic attacks.

The cardiac hypertrophy just mentioned is the result of the contracted kidney. Other disturbances of the circulatory system appear to be referable directly to the gout itself. Among these are chronic endocarditis or myocarditis, and perhaps certain "functional" symptoms, such as palpitation and angina. An important symptom is chronic endarteritis or arterio-sclerosis. This is often seen in gouty subjects, and in many instances seems to be immediately connected with the gout. Sometimes, also, there are gouty lesions of the veins, such as varicosities or thrombosis. Of course, these changes in the blood vessels may, in their turn, give rise to various disorders.

In a few very rare instances gout seems to attack the brain and spinal cord. Usually, however, the nervous disturbances seen in gout are, as already stated, symptoms of uræmia, or of circulatory disturbance, and the like. The patient may also have certain functional nervous troubles, like neuralgia or migraine. The direct cause of these is seldom evident.

The joints, despite frequent attacks, may yet maintain an almost normal appearance, inasmuch as the acute inflammatory changes completely vanish after each separate attack. They may, however, undergo permanent enlargement and deformity from gouty concretions (*tophi arthritici*). In many instances similar masses can be felt here and there in the muscles and tendons, the skin (for instance, of the eyelids), and quite often in the external ear. They consist essentially of accumulations of urates (*vide infra*). Occasionally these concretions break externally, discharging a thick pus mingled with urates, and forming indolent ulcers, slow to heal. Sometimes atmospheric germs thus find ingress into the system, and give rise to phlegmon.

It should be stated, in conclusion, that gout may be complicated with other diseases. Thus, it may be associated with renal calculi, and sometimes with diabetes mellitus (*vide supra*).

**Anatomical and Chemical Changes in Gout. Theory of its Nature.**—The essential anatomical lesion in gout consists of an abundant deposit of crystalline urates in the tissues. This is most evident in the affected joints, the cartilaginous surfaces of which are often completely covered with white, chalk-like material. In severe cases the same appearance may also be presented by the articular ligaments, tendons, and bursæ, while there are at the same time numerous concretions of urates here and there beneath the skin. These deposits are mainly composed of acid sodic urate, with traces of calcic urate, calcic phosphate, and sodic chloride. Ebstein has lately explained how these collections are formed. He found that the deposition of uric acid is invariably preceded by a necrosis of the tissues. The uric acid while still in solution acts as a chemical irritant upon the cartilage here and there, and thus produces necrosis, whereupon the urates are crystallized out and deposited. Then a secondary inflammation develops around these foci of necrosis. By ligaturing the ureters in fowls, Ebstein succeeded in artificially producing similar changes.

The nephritis of gout corresponds in its pathological appearances to that of the true contracted kidney, with one exception; the organs usually present deposits of

uric acid or urates, in stripes, both in the lumen of the urinary tubules and also in the epithelial cells and the interstitial tissue. In the connective tissue it is probable that a necrosis precedes the deposit.

The lesions presented by the heart, blood-vessels, and remaining parts of the body are not especially characteristic of the disease. The blood of gouty subjects, as Garrod demonstrated, contains an excess of uric acid.

There are many theoretical questions which remain unanswered: Whether in this disease there is an over-production, or merely a defective excretion of uric acid? What the true cause of this strange anomaly in metamorphosis may be? What conditions are essential to the crystallizing out of uric acid in the tissues? Why certain parts, particularly the joints, and still more particularly the first joint of the great toe, are especially liable to suffer? And, finally, What circumstances decide the course of the disease, and determine its separate attacks? Not one of these questions has been satisfactorily answered. The fact that gout is prone to attack individuals who have led a luxurious life has led to the belief that in every case of gout the ingesta are not completely oxidized, and an excess of uric acid is consequently accumulated in the system. We have already pointed out that this assumption is too sweeping. And, indeed, our present knowledge with regard to the manufacture of uric acid out of the albuminoids, and its further transformations, is not at all adequate for the establishment of any hypothesis of this sort. We must simply confess that the true cause of the accumulation of uric acid in the tissues is unknown. It may be conjectured, however, that the deposit of crystals of uric acid is either occasioned or promoted by an excessively acid reaction of the blood or lymph in which that acid is dissolved. It is not known what acids give rise to this reaction, nor how they are formed. It has been seen that the articular cartilages are especially apt to present a gouty deposit. Perhaps this is occasioned by the sluggishness of the circulation in these parts. It is doubtful whether the uric acid is produced in the cartilage itself. Ebstein believes that it originates mainly in the muscles and bone-marrow, and is thence conveyed to the cartilage. Others, and among them Cantani, believe that the uric acid is formed in the cartilage and the connective tissue.

**Diagnosis.**—It is usually easy to recognize an acute attack of gout. The sudden onset of the pain at night and its localization in one of the great toes are very characteristic symptoms, and render it easy to distinguish between it and other acute affections of the joints. The diagnosis is more difficult in the advanced stages, where symptoms are more confused. Here the history of the case will often include the description of typical attacks and also ætiological factors, such as heredity and mode of life, which may assist in diagnosis. It must be said that many gouty subjects are reticent as to their past experiences, and sometimes even deny previous attacks of gout. If there is a chronic gouty arthritis, it may be necessary to make a differential diagnosis between it and arthritis deformans. The deformities of arthritis deformans are usually seen first of all in the hands and fingers, and it has a persistent, chronic course. Furthermore, in gout we sometimes can feel the characteristic deposits in the tendons or skin (for instance, in the eyelids or external ear).

If there is chronic nephritis of gouty origin, its source can be recognized only from its association with other indubitable symptoms of gout, unless possibly the knowledge of certain ætiological factors, such as a history of gout in the family or of chronic lead-poisoning, should put us upon the right track. Ebstein has reported cases of "primary renal gout" where there was no arthritis during the whole course of the disease. Such cases can seldom be correctly diagnosed during life.

Brief mention should here be made of an experiment performed by Garrod,

which may be employed to demonstrate the existence of uric acid in the blood, for diagnostic purposes. A drachm or two of blood-serum, or of the serum obtained from a fly-blister, is put into a shallow watch-glass, and six or eight drops of a thirty-per-cent. solution of acetic acid are added to it. A linen thread is then laid in the fluid, and the whole allowed to remain at a moderate temperature for about a day. If the proportion of uric acid in the fluid is sufficiently large, crystals of that acid will now be found on the thread and may be recognized by their shape and chemical reaction. This "thread test" of Garrod's is not extensively used, because it does not succeed unless there is a comparatively large amount of uric acid in the blood, and, furthermore, uric acid may exist in the blood in health, or in other diseases than gout.

**Prognosis.**—However favorable the prognosis may be with regard to the single gouty attack, yet a permanent release from the disease is rarely to be hoped for. Only such patients as, from the first appearance of gout, pursue most carefully all the requisite prophylactic and dietetic measures, can expect that future attacks will be rare and comparatively mild, and that severe lesions of the internal organs will not occur. So long as the kidneys and other viscera are intact, there is no immediate danger to life, and the patient may attain advanced years despite his gout. The gradual and chronic alterations in the joints may, however, impede locomotion as well as all other movements of the body. Except for this, the general condition of the patient in the intervals between the attacks is often one of tolerable comfort. Indeed, it is frequently the case that the patient will feel his very best directly after a severe paroxysm, while rudimentary or atypical attacks are often regarded as of ill omen. Really, however, there is no serious danger until a chronic nephritis is developed. The prognosis then becomes as unfavorable as in the other forms of contracted kidney (*q. v.*), and involves the same possibilities.

**Treatment.**—All authorities agree that the first essential in treating gout is a proper regimen. Unless the patient has energy enough to yield the most implicit obedience to the injunctions regarding diet and mode of life in general, from the first appearance of his disease, no great benefit can be obtained from treatment.

Various authorities have, of late, prescribed special diets for the gouty. These differ considerably from one another, but the discrepancies are not actually so great as they seem to be at first glance; and, after all, more importance attaches to the quantity of the ingesta than to their quality. As most gouty patients are corpulent, the diet to be prescribed for them is mainly that indicated by their corpulence. The first point is to limit the total amount of ingesta. No more should be eaten than is absolutely required to satisfy hunger. The diet may be a mixed one—that is, may contain albuminoids, carbohydrates, and fats; but the quantities of each of these ingredients should be small (*vide* following chapter). The albuminoids should not be too abundant, in order that the formation of uric acid may be limited; the fats and carbohydrates should be cut down, in order that the albuminoids may be thoroughly oxidized and thus any further deposit of adipose tissue avoided. Acid articles of diet should be forbidden, lest they promote the deposit of uric acid in the tissues. The experience of certain physicians tends to show that a diet mainly vegetable is better borne by gouty patients than animal food. In this case also, however, it will be seen that the essential point is the quantity. With a vegetable diet, the amount of ingested food, and still more the amount of nourishment absorbed from the *primæ viæ*, is almost sure to be less than upon an exclusive meat diet. The patient should, therefore, be told that his diet should consist mainly of lean meat, fish, broth, green vegetables, small amounts of milk, eggs, and bread. Sweet puddings, fat meat, potatoes, or sour and acid food of any kind should be avoided. Fruit may be allowed in small quantities. Water is the best beverage; but it is not advisable, and may even be

prejudicial, to drink too large an amount of any fluid (*vide infra*). Large quantities of alcohol are sure to injure the patient. If they can not be absolutely proscribed, yet at least their amount should be reduced to a minimum.

[Many gouty persons, especially those suffering from the irregular form of the disease and acid dyspepsia, are more comfortable and seem to do better on a diet which is largely nitrogenous, the starches and sugars being greatly limited in amount. The diet, in fact, should be similar to that laid down for diabetes mellitus, though not so strictly carried out. In chronic and irregular cases it is often desirable to prescribe a stimulant, for a time at least; brandy, whisky, or gin, well diluted with water, is perhaps the best form.]

By thus limiting the amount of food taken, we shall promote metamorphosis and avoid any excessive formation of uric acid. A more direct means of hastening the conversion of the albuminoids is muscular exercise. If a corpulent patient is still vigorous and is not threatened by any serious internal disease, he should be urged to take a large amount of exercise in mountain-climbing, gymnastics, gardening, or similar pursuits. The motto of such a patient should be "little sleep and great activity." This same indication of accelerating tissue-metamorphosis is fulfilled also by bathing. In early stages cool baths and sponging are useful, as are also baths containing common salt, or perhaps even sea-bathing cautiously employed. In more advanced cases, particularly if the joints present permanent lesions, the warmer baths are more desirable, such as are found in Teplitz, Wildbad, Wiesbaden, Baden-Baden, Carlsbad, Ems, and Aix.

The internal administration of alkalies is an efficient adjuvant to the dietetic and hygienic prescriptions above enumerated. For a long period the use of alkaline mineral-waters has been found to be most beneficial. Experience confirms the confidence which theoretical considerations would lead us to have in their value in checking the deposit of uric acid, so far as it is occasioned by excessive acidity of the circulatory fluids (*vide supra*). The sodic chloride contained in these waters stimulates the conversion of the albuminoids. The waters also increase the activity of the kidneys, benefit gastric catarrh, and overcome constipation, and in all these ways combine to produce a favorable effect upon the patient's health. Still another factor is the judicious diet and mode of life at such health resorts. The waters of Carlsbad and Vichy have gained the greatest repute in gout, although the waters of Ems and Neuenahr have an analogous composition, and doubtless would produce similar effects. Of the waters which contain sodic chloride, the most advisable are Wiesbaden, Baden-Baden, Kissingen, and Homburg. The salts of lithium especially promote the solution of uric acid, and of late the waters which contain lithium have been strongly recommended. The natural springs of this sort, such as the Crown Spring in Obersalzbrunn, and those of Assmannshausen and Salzschlirf, contain comparatively insignificant amounts of lithium; and it might be a better way to use the artificial lithium waters, such as are made by Struve or Ewich. Another way is to prescribe carbonate of lithium, in powders containing two or three grains each (grm. 0.10-0.20), one powder two or three times a day, in a glass of Seltzer or Biliner water.

Other remedies formerly in vogue were said to correct the "gouty diathesis," but their efficacy is extremely dubious, and they need not be especially mentioned.

As to the treatment of the acute attack, it has ceased to be customary to employ any potent remedies. The patient must, of course, keep his bed. The affected joint should be wrapped up in cotton wool, the whole leg elevated, and a proper diet strictly enjoined. Free movement of the bowels should be maintained by means of an enema. If there is considerable gastric disturbance, bicarbonate of sodium, magnesia, or some bitter may be prescribed. The most certain remedy for severe pain is a subcutaneous injection of morphine. Less efficient are nar-

cotics locally applied, and warm compresses. Whether any internal remedies are calculated to abbreviate the attack is doubtful. Formerly colchicum (twenty or thirty drops of vinum colchici seminis three or four times a day) was the favorite medicine, but it seems to be going out of use. Salicylic acid and salicylate of sodium may be administered in the same way as in acute articular rheumatism, and sometimes, although not always, they are followed by improvement. Antipyrine, and perhaps antifebrine, sometimes succeed in allaying the pain in the affection of the joints. Some physicians recommend subcutaneous injections of antipyrine in the neighborhood of the joint, but we have no personal experience on this point.

[One reason why colchicum has fallen into relative disuse is that the relief obtained from it is often so prompt and complete that patients are tempted into continued indulgence in a faulty manner of life. It is also supposed by some that the drug interferes with the effort of nature to eliminate the poison, which becomes generally diffused, and sets up changes in the vessels and internal organs.

Precisely how colchicum acts we do not know, but that it does act, and sometimes with marvelous success, there can be no question.]

The chronic affections of the joints in gout are treated as are other varieties of chronic arthritis (*vide* page 915). The most efficient remedies are cautious massage and baths, including hot sulphur baths and mud-and-sulphur baths. The internal administration of the alkalies, lithium, and similar drugs, to combat the general gouty diathesis, should be associated with these external remedies. Some physicians report that iodide of potassium favors the absorption of the gouty deposits.

The treatment of the nephritis and other complications need not be discussed at length. The gout itself should always be the main object of our therapeutic efforts, and beyond this we may be guided by general principles.

## CHAPTER XII.

### OBESITY.

(*Corpulence. Polysercia adiposa.*)

**Definition and Ætiology.**—The amount of adipose tissue in the body is subject to considerable variation, and it is not possible to state absolutely what should be considered as normal and what as abnormal. For practical purposes we may draw the line where the increased size grows burdensome to the individual. After a certain point, any further addition to the amount of fatty tissue is almost sure to work serious injury, and is therefore to be regarded as an actual disease, and not merely an inconvenience. It should be said, however, that in such cases the symptoms of obesity are very frequently confounded with those springing from other disorders—these latter possessing, indeed, the same ætiology as obesity, but distinct from it.

The most frequent and important cause of obesity is the habitual ingestion of too large an amount of food. By "too large" is meant an amount sufficient to occasion a continual increase of the adipose tissue of the body, when this is already fairly well developed. It is a matter of indifference whether the excess is composed mainly of albuminoids, or carbohydrates, or fats; for in either case, if the quantity be sufficient, an increase of adipose tissue may take place. We shall soon see, however, that the excess is usually in fat and carbohydrates. Inasmuch

as this overfeeding is almost certain to be habitual, the excess at any one time need not be at all large. We often hear a corpulent person express his surprise that he grows heavier every day, although he "does not eat any more than others who are lean." The explanation is easy if we consider that a daily increase of five grammes of fat (one and one fourth drachms) suffices to increase the weight in ten years, or, say between the thirty-fifth and forty-fifth years, forty pounds avoirdupois. In reality the daily increase is sometimes greater than this.

The basis for a detailed consideration of the causes which lead to the deposit of fat will be gained by a consideration of the physiological laws relating to nutrition discovered by Voit, Pettenkofer, and their pupils. It has been shown that both the albuminoids and the carbohydrates of the food may be a source of fat, formed within the economy, and also that the fat contained in the food may be to a large extent directly deposited in the fat-cells of the body. One product of the decomposition of albuminoid substances is invariably fat. This usually undergoes further oxidation, but it is sometimes retained unaltered in the system. It would even seem that the albuminoids give rise to much more of the fatty tissues of the body than are produced from the carbohydrates ingested, although there is no doubt that these latter also yield fat. Carbohydrates do promote obesity, but less because they are a direct source of fat than because they are easily decomposed, and so shield both the ingested fat and that which is formed out of the albuminoids from oxidation. In this indirect way they do greatly favor a tendency to corpulence.

We thus perceive that various diets may, each one of them, permit of an increase of adipose tissue. In actual life, of course, the most frequent conditions are such as result from the customs and habits of the population in general. The diet is almost invariably a "mixed" one—that is, it contains albumen and fat and carbohydrates—and in most instances the obesity is due to an excessive amount of all three elements, or at least of the fat and carbohydrates. A person may, however, become corpulent who eats very little fat, provided he consumes a large quantity of albuminoids and carbohydrates; or if he eats very little starchy food, provided he consumes a large amount of meat and fat. Perhaps these facts may be made clearer by giving a concrete example. Voit tells us that a vigorous man who requires daily 118 grm. of albumen and 259 grm. of fat to maintain a physiological equilibrium as regards fat and albumen will, other things being equal, begin to store up fat if there is any further increase in the amount of fat in his diet. The same result will also take place if, instead of the rations previously stated, he ingests more than 118 grm. of albumen and 600 grm. of starch, or more than 664 grm. of albumen alone, or, finally, more than 118 grm. of albumen, 100 grm. of fat, and 368 grm. of starch.\* It is obvious that this last diet, which closely resembles the average diet of an adult† in good circumstances, whose weight is neither increasing nor diminishing, is the one most likely to be exceeded; whereupon there must take place a deposition within the system of the superfluous fat.

Among the various kinds of food is one group which deserves mention, as being an important factor in many cases of obesity; we refer to alcoholic bever-

\* This statement is founded upon an important discovery of Rubner, that, as far as the storing up of fat is concerned, the measure of value for different foods is the amount of heat given off by them when they undergo oxidation into carbonic-dioxide gas and water. Measured in this way, 100 grm. fat = 211 grm., albumen = 232 grm., starch = 234 grm., cane sugar = 256 grm., grape sugar.

† Probably the amount of fat contained in the food is often less than the above, and the amounts of albumen and starch somewhat larger. Voit estimates the diet of a well-to-do person at 127 grm. albumen, 89 grm. fat, and 362 grm. starch; and that for a vigorous laborer at 118 grm. albumen, 56 grm. fat, and 500 grm. starch. Of course, these figures are merely approximate.

ages. There can be no doubt that intemperance in this regard plays a prominent part in many instances. Sufficient illustration is furnished by brewers, hotel-keepers, and the inhabitants of countries like Bavaria, where beer drinking is prevalent. In this particular it is evident that beer works more harm than does wine or strong liquor; for beer contains, in addition to the alcohol, an appreciable amount of starchy material, making the sum total from the beer drunk during the entire day a considerable one. Many persons who would be extremely indignant if called "tipplers," habitually take five or six glasses of beer a day, equivalent to 150 grm. of starch, or, in other words, one half the total amount of starch required by the system. Even this quantity is frequently exceeded. Of course, the three or four per cent. of alcohol which the beer contains also promotes the deposition of fat. Alcohol is readily oxidizable, and it thus shields to a considerable extent the fat already present in the body; and it also, in all probability, works such an injury to the tissues as to diminish their power of effecting decomposition. We must also remember that most beer drinkers take little exercise. The long sitting at the beer table, and the mental and physical sluggishness which immoderate indulgence in beer always causes, and finally the increasing corpulence itself, make it clear why most beer drinkers dislike protracted exercise.

We have thus seen that in by far the larger number of cases obesity is mainly due to the ingestion of too much food. No weight need be attached to the usual statement of corpulent persons, that they eat no more than others. Few of them have any idea how much nourishment they do consume. Others, having already become corpulent, eat less, to be sure, than they used to, but nevertheless an amount sufficient to maintain the acquired weight.

Other factors may no doubt exert an influence upon the increase of adipose tissue by diminishing the consumption of fat in the system. The most important factor of this class is physical inactivity. Muscular contractions lead to the decomposition of a large amount of fat. This explains why people of sedentary habits, and those who sleep long and exercise little, are more apt to become corpulent than are manual laborers. Again, there are certain diseases which seem to promote corpulence. In anaemia there is sometimes a striking tendency to obesity, in part due to the diminished supply of oxygen and in part to diminished muscular activity. This same inactivity is probably the main cause of corpulence in paralysis (hemiplegia). It may be, however, that disturbances of the nervous system may directly affect metamorphosis. Thus, idiots and other subjects of congenital defects of the brain are liable to obesity. Disturbances of the circulatory system seem to favor the production of corpulence by impairing oxidation. This is seen in many young persons with cardiac disease, although it is not easy to exclude in this case the influence of still other factors, such as a sedentary life.

Finally, some cases of obesity seem to result from a constitutional and inborn predisposition. Young children sometimes suffer from obesity; and the condition seems in many cases to be hereditary. Many races and nations exhibit an especial tendency to corpulence—for example, the Jews. Age and sex have some importance in this regard: extreme obesity is seldom seen previously to the thirtieth year; and women appear to be somewhat more subject to the disease than men. The importance of a "tendency" to obesity should not be overrated. Upon careful investigation, we shall almost invariably find in the habits of the individual, as regards food and exercise, a satisfactory explanation of his obesity. Strictly speaking, the condition can not be regarded as a disease unless the habits as to diet and exercise fail to account for it.

**Pathology.**—After corpulence has passed a certain point the condition is evident at the first glance. The subcutaneous cellular tissue is one of the chief places in which the fat is deposited. Consequently, the panniculus adiposus soon attains

considerable thickness. The countenance grows more round and plump; beneath the chin is formed a second prominence known as the "double chin"; the chest appears broadened; the waist enlarges; and, particularly in women, the breasts are changed to great shapeless masses, over which the skin is so tightly stretched as to present *lineæ albicantes*. The abdominal walls are greatly altered. The belly projects more and more until it becomes actually pendulous, and its lower surface touches the interior surface of the thighs. Intertrigo is apt to occur in the groins, below the breasts, and between the buttocks. The skin everywhere has a fatty feel, due to the increased secretion of the sebaceous glands. This hyperplasia of the fatty tissue in the *panniculus adiposus* is associated with a deposit of fat in many parts of the interior of the body, including the mesentery, mediastinum, pericardium, and the capsules of the kidneys. Some of these will be mentioned again further on.

Of course, the circumference and weight of the body become greatly increased. As an approximate measure, it may be stated that for men of middle height a weight exceeding 90 kilo. (200 pounds), and for women 75 kilo. (165 pounds), may be regarded as abnormal.\* This increase in bulk is the first cause of subjective symptoms. An obese person has to exert a greater effort in making any motion than do other people, and as a necessary consequence he gets easily tired, and seeks as far as possible to avoid exertion. The increased demand upon the muscles explains the familiar fact that corpulent persons perspire so readily.

The graver symptoms of obesity, and properly the first pathological phenomena of the condition, relate to the respiration and the circulation. The patient begins to complain of shortness of breath, and is subject to marked dyspnoea upon running or climbing stairs. There may be, at the same time, cardiac disturbance, indicated by a rapid pulse, palpitation, intermission of the pulse, or other slight irregularities in cardiac action. All these symptoms grow gradually worse; and to them are added symptoms of cardiac failure and consequent passive congestion. There is a tendency to bronchitis and other catarrhal troubles. The appetite and digestion are affected, and oedema appears.

A careful analysis of all these symptoms shows that many causes combine to produce them, all having a common tendency to impede respiration, and, still more, circulation. One source of disturbance is the increased deposit of fat upon the framework of the body. It is probable that the excess of adipose tissue covering the thorax exerts a direct influence in obstructing the respiratory motion of the thoracic walls, and renders the respiration more superficial. In this way the return of venous blood to the heart and the pulmonary circulation are both impeded, because the negative pressure in the chest is less than normal. Likewise the diminished amount of bodily exercise affects the circulation unfavorably. Brauner has shown how numerous are the arrangements connected with the fasciæ for promoting the venous currents, by means of the negative pressure resulting from the movements of the body. Whether the fat deposited around the heart directly obstructs the cardiac movements is somewhat doubtful, though this view is held by many. The fatty infiltration of the myocardium is of more importance: the fat is deposited in the intermuscular connective tissue. This lesion, however, is not of very frequent occurrence, nor does it produce so grave results as do certain other cardiac changes, which are either secondary to the obesity or complications of it.

There is no doubt that, in almost all cases where the corpulence actually induces grave disturbance, the cardiac symptoms are of prime importance. These are due, as has just been indicated, in part to the increased amount of adipose

\* Even 150 kilo. (330 pounds) has been repeatedly observed.

tissue, and in still greater part to complications, most of which are excited by the same causes as is the obesity itself. The abundant adipose tissue may obstruct the circulation in the smaller blood-vessels and capillaries inclosed within it. And, furthermore, the excessive development of fatty tissue probably leads to the growth of new blood-vessels, and, as a consequence, to an increase in the total volume of the blood. This is one way in which the demands made upon the heart are rendered greater than normal, and explains why the corpulent frequently exhibit cardiac hypertrophy. Other influences are also at work to produce this same result: they are, in the first place, the same factor which occasions the obesity itself, namely, the ingestion of increased amounts of food and drink (see the chapter on cardiac hypertrophy), and, secondly, certain other lesions which are frequently associated with obesity and are referable to the same causes as it is. Chief among this latter class is general arterio-sclerosis. If this involve the coronary arteries, it may in turn occasion still further damage—for example, degenerative myocarditis (compare page 309.) Chronic interstitial nephritis is another not infrequent complication. This is in part referable to the same causes as is the obesity. Gout and diabetes are less frequent.

We thus see that obesity is often merely one of many injurious results occasioned by an improper mode of life. It is, in a certain sense, the first danger-signal, warning the patient and his physician to avoid the graver disturbances which threaten. This is a point of great practical importance; for, when once we have a combination of obesity with cardiac hypertrophy, fatty infiltration of the heart, arterio-sclerosis, or interstitial nephritis, the various causes and effects act and react upon one another in a way most perilous to health, and even to life. There is no need of describing the grave disturbances which invariably develop at the close of the scene. They are the result of chronic cardiac insufficiency, and have been fully described under cardiac disease.

In every case of obesity the physician should examine the heart, lungs, vascular system, and kidneys, particularly if there be already subjective disturbance. The examination of the heart may present considerable difficulties, because the results of palpation and percussion are so obscured by the thick cushion of fat which covers the thorax. We can, however, have recourse to auscultation, and can feel the pulse. The pulse may be either rapid, or slow, or irregular. We need not mention any minute particulars as to the examination. It may be stated, however, that a hepatic enlargement is often found, but it is much less often the result of fatty infiltration than of simple hypertrophy or passive congestion.

We have thus seen that corpulence may sometimes be associated with grave and dangerous lesions; but, on the other hand, it should be stated that this unfortunate condition by no means invariably exists. Not infrequently the corpulence remains moderate, in which case it is not really dangerous, however inconvenient. This is true of a proportion of those cases which are due to the ingestion of a large amount of nourishment, associated with defective oxidation, and where there are no other unfavorable influences at work. The obesity of hard drinkers is almost always a more or less dangerous condition, while that seen in many elderly persons and in women is often comparatively free from peril. These latter individuals are, to be sure, discommoded by their great weight, can accomplish less than they used to, are easily put out of breath, and have a certain tendency to catarrhal inflammations and rheumatic difficulties; but they escape the severer lesions above enumerated. Even these apparently harmless conditions should not be disregarded by the physician, as he can never be absolutely certain that grave complications may not be developed eventually.

**Treatment of Obesity.**—To cause the disappearance of the accumulated fat, it is necessary to promote its oxidation in the system and to prevent the ingestion of

new supplies of fat. To accomplish this purpose we possess only two means—first, a limitation of the ingestion of such kinds of food as may lead to the formation of fat in the system, and, secondly, stimulation of those factors which occasion the destruction of the fat already present. All the various methods of treating obesity, without exception, aim either to diminish the supply or to increase the destruction of fat.

The methods vary greatly. It must be borne in mind that the diminution of the adipose tissue must not involve injury to the body itself. The treatment should not weaken the constitution, but should invigorate the patient, or at least be innocuous.

It is of prime importance, in every method of treatment, that the total quantity of ingested food should be diminished. It is a mistake to forbid the patient some particular kind of food—for instance, the carbohydrates or the fats—with the idea that they alone do harm, or to allow him unlimited quantities of other kinds of food, in the belief that they are harmless. Any person can eat albuminoids, fat and starch at every meal, and yet not grow fat; while, on the other hand, too much of any one of these may lead to an increase of adipose tissue. The amount of food which a person can take without increasing the amount of adipose tissue varies with the individual. It depends upon the amount of material already present in the body, and upon the various demands made upon the system, as well as other factors. This renders it difficult to draw up a universal dietary for the obese. We can best judge of the value of any course of treatment by its results, and these are best measured by the weight and the subjective condition of the patient.

Of the various elements of food, the albuminoids should be diminished least of any, because it would be sure to work injury to the system if they were supplied in too small an amount. Of course, the albuminoids must not be eaten to such an extent that the fat into which they decompose remains intact in the body. An increase in the amount of nitrogenous tissue is, however, desirable, because this promotes the vigor of the muscles and the heart, and so leads to the oxidation of larger quantities of the non-nitrogenous tissues.

The amount of fat and starch must be much more limited. The fats and starches are more potent in increasing adipose tissue and in shielding from oxidation the fat already stored up in the body than is nitrogenous food. It would not be at all advisable to forbid the use of either one of these two constituents of a mixed diet, allowing the other alone to be eaten. A varied diet is extremely desirable, even for one who is corpulent; and we should exclude neither fat nor starch wholly from the dietary, but we should merely limit the amounts to be taken. As already indicated, the amount of albuminoid food remaining unchanged, a person can eat double the quantity of starchy food that he can of fat, without increasing his adipose tissue. It is therefore irrational to allow the corpulent fat in larger proportions than starchy foods. The diet which Ebstein has recently proposed for the treatment of obesity does prove successful, but the explanation of its success lies in the comparatively small amounts of meat and fat ingested. Precisely the same results would be attained if a corresponding amount of starch were substituted for all or a portion of the fat; and in practice it is desirable, at least in most cases, to allow the patient both starches and fats. Of course, the likings and experience of the individual should be considered in each separate case. The Banting treatment, introduced in 1864, enjoyed for a time a great reputation. Its inventor applied it first of all to his own case, and with success. It rests upon a rational basis, inasmuch as the albuminoids are allowed in abundance, and the ingestion of fat and starch is limited. It lays too much stress, however, upon the exclusion of fat as compared with starch.

The principles here expounded are direct corollaries to the laws which Voit has taught us in regard to the different kinds of food. The physician who bears them in mind can lay down his own rules for the diet of his patient. As already stated, it is impossible to give figures which will apply to every case. If we take as a basis the average diet for an adult—that is, about 125 gm. albumen, 80 gm. fat, and 350 gm. starch—we might say that most cases of obesity would be sure to undergo improvement upon a diet containing 125 gm. albumen (or possibly even more than this), 40 gm. fat, and 150 gm. starch. The amounts of fat and starch could be even more diminished, but it is usually best not to be too precipitate. A gradual diminution of, say, two or three pounds a week, extending over a long period without interruption, is to be preferred to the rapid treatment common at many health resorts. Of course, the loss of fat is greater at the commencement of treatment than later on, when the amount of adipose tissue has already approached more nearly to normal, and the diet must undergo a gradual and corresponding change. It is of particular importance to increase the amount of non-nitrogenous foods in the later stages of treatment, lest the albuminoid tissues of the body become wasted.

The following dietary may be taken as an illustration of what would be suitable for a patient in the beginning of treatment: For breakfast, a cup of coffee with milk, and about 75 gm. of bread. At noon, a plate of soup, 150 to 175 gm. lean meat or fish, lettuce, green vegetables, and about 25 gm. bread. For dessert, about 75 gm. boiled rice, or some simple pudding, or 100 gm. fruit. To quench the thirst, water, or half a pint of light wine. In the afternoon, a cup of coffee, and with it not more than 20 to 30 gm. bread. For supper, two eggs, or 100 to 120 gm. meat, with 30 gm. bread, a little fruit, lettuce, half a pint of wine, or one or two cups of tea, not much sweetened. Butter should be entirely proscribed at first; later on it may be used in small amounts.

Some approach to this bill of fare must be enforced not merely for a few weeks, but for months. It is absolutely necessary that the patient should be weighed every two or three weeks. If the weight diminishes slowly and gradually, without any subjective disturbance, we have the best proof that the diet is a suitable one. If the weight does not diminish, then the amount of ingesta must undergo further reduction. If more food can be taken without the weight increasing again, a larger amount may be unhesitatingly permitted, and indeed may even be advisable if the patient be languid. The increase should at first, however, be mainly in the amount of albuminous food, the amount of starches and fats not being much increased. The "cure" can not be regarded as complete until the weight has been brought down to that of the average individual of the given age and sex. This goal having been reached, greater freedom in diet is permissible.

The object of the treatment just suggested is exclusively the limitation of the production of fat. We may also promote the destruction of the fat already stored up in the system. A chief means to this end is muscular exercise, which undoubtedly increases the oxidation of the adipose tissues. Carried out in a proper manner, it is therefore a most valuable adjuvant in treatment. Oertel has recently pointed out that muscular exertion does good in still another way—namely, by promoting cardiac activity and inducing deep respiratory efforts. Thus the heart is strengthened and circulation promoted. Mountain-climbing is one of the best modes in which to take the desired exercise. We need hardly say that the increased muscular activity makes it possible for the patient to take an increased amount of food without injury.

Baths also promote oxidation, but they are far less potent than is muscular exercise. Cold baths, brine baths, or baths containing carbonic-acid gas, may be employed. One way in which they do good is by stimulating the nervous system.

Oertel regards it of great importance to diminish the amount of water in the system, a point which has until very lately received little attention. The diminution in the amount of fluids may ameliorate any circulatory disturbance (*vide supra*) and relieve venous congestion, and it undoubtedly has some value in the treatment of obesity. Oertel has shown that a simple diminution in the amount of fluids ingested, when there is no other change in the diet or mode of life, will effect a diminution of the adipose tissues. This result is probably due mainly to the diminished strain upon the heart and the consequent increase of oxidation; but the chief cause of the rapid loss of weight, which we actually see in the corpulent as a result of the deprivation of fluid, is to be found not in the loss of fat, but in the marked loss of water contained in the body. "Desiccation" may further be promoted by stimulating the perspiration by bodily exercise or by steam baths. This withdrawal of liquid from the system, however, is advisable only in cases where there is already incipient cardiac failure.

It is evident that numerous excellent methods are at our disposal for the treatment of obesity; but their application to any particular case should be the result of a careful consideration of the special circumstances presented. A very essential point is that the injunctions of the physician should not merely be made, but be carried out; and it is precisely here that the treatment of many cases suffers shipwreck. We may be baffled by the patient's lack of energy and persistency, or by the importunate demands which his profession or social position make upon him. Indeed, it is sometimes absolutely impossible to prosecute the treatment at home, in which case bathing and health resorts are to be urgently recommended. There alone can the patient muster up the resolution necessary for carrying out the desired changes in his mode of life. The incontestable success of treatment at Carlsbad, Marienbad, Kissingen, Tarasp, and similar resorts is doubtless only to a very small extent the result of their specific medicinal influence, but it is mainly due to a strict observance of the above-described diet and regimen. The internal use of mineral waters is not entirely without a beneficial effect. Their laxative qualities diminish the absorption of food from the intestinal canal. It should be said, however, that the patient is at the same time exposed to the danger of a waste of his nitrogenous tissues. This is why patients frequently complain of the debilitating effect of these mineral springs; to avoid which, it would be well to increase the amount of albuminoids in the diet. We must also consider the need of guarding against too great a supply of fluid, with regard to what was said above as to the occasional service of "desiccation" of the body.

## CHAPTER XIII.

### SCROFULA.

**Definition and Symptoms of what is called Scrofula.**—We desire to present, at the close of this section, a brief description of scrofula, but merely from a practical standpoint. From a scientific point of view scrofula is not to be regarded as any special variety of disease. The term is applied to a group of symptoms seen most frequently in childhood, the essential features of which consist in the appearance of chronic enlargements of the lymph-glands, and in certain diseases of the skin and mucous membranes. The simultaneous appearance of these various phenomena does really produce a somewhat characteristic picture, which can frequently be recognized at the first glance.

Most scrofulous children appear pale, with a flabby skin and soft muscles.

The panniculus adiposus may nevertheless be tolerably well developed. Not infrequently the face is puffy, with prominent lips. This is called the "torpid habitus." In other cases the child has small features and a remarkably delicate white skin, which but partly conceals the superficial veins, and is readily suffused with blushes. To these the name "erethitic habitus" is applied. Enlarged lymph-glands are to be felt in the throat, at the angles of the lower jaw, and in the back of the neck, and occasionally in other parts of the body. These glands may remain indolent for a long while, or they may suppurate and break externally. Chronic cutaneous eruptions are often seen in various places. The most common of these is a scaly or impetiginous eczema, affecting the face, scalp, or extremities. More severe affections are lupus ("*lupus scrophulosorum*"), prurigo, and lichen scrophulosorum.

Of the mucous membranes, the conjunctiva and the lining membrane of the nostrils are most frequently affected. Conjunctivitis in various forms is a characteristic symptom of scrofula; as are also blepharitis ciliaris, keratitis, and chronic rhinitis, which last often terminates in a pronounced ozæna (*q. v.*). Chronic diseases of the ear are also frequent, such as otitis media, with perforation of the tympanum, and occasionally caries of the mastoid cells and its unfortunate results.

Of the deeper lying tissues, mainly the bones and joints suffer. The affections located here are almost exclusively "fungous"—namely, fungous osteitis and periosteitis, white swelling, and caries. Formerly there was frequent use of such terms as "scrofulous inflammation of the knee-joint," or "scrofulous caries of the ribs."

If we inquire into the nature of this strange group of symptoms thus briefly enumerated, we shall find that by far the greater number of cases of well-marked scrofula are examples of tuberculosis. Tubercular bacilli have been demonstrated in connection with most of the fungous or "scrofulous" diseases of the bones and joints. Ozæna is often a tubercular disease of the nose, lupus is a tuberculosis of the skin, and many forms of otorrhœa are really tuberculosis of the ear. The ætiology of "scrofula" is therefore in main part identical with that of tuberculosis (*q. v.*), and this explains why the old physicians habitually insisted upon the intimate relationship between the two diseases. It was formerly thought that scrofula often terminated in tuberculosis—that is, a scrofulous child is apt to suffer eventually from tuberculosis of the lungs, intestine, or brain. To-day we know that most scrofulous children do not become, but that they are already, tuberculous.

It must, however, be borne in mind that in practice many diseases are termed scrofulous which have nothing to do with tuberculosis. Many cases of perfectly innocent eczema of the face and scalp lead to swelling of the glands in the throat, and are therefore termed scrofulous eczema. These cases are probably most of them secondary, and the result of external irritation and the like. Again, many enlarged glands in the neck are the result of pharyngeal trouble, as after scarlet fever, and are equally devoid of a tubercular taint. Pseudo-leukæmic lymphomata may also occur in children; and it should be borne in mind that hereditary or acquired syphilis may produce in children lesions closely resembling those of scrofula.

It is therefore the duty of the physician in every case of "scrofula" to analyze the ætiology and symptoms carefully, in order to determine with what he has to deal. "Scrofula" should be regarded merely as a short way of naming a certain group of symptoms. It is convenient to retain the term as being less likely to startle the friends of the child than would the true name of the disease.

**Treatment.**—In the treatment of scrofula we have first to attack the various local diseases, and, second, to invigorate the general health. We can not here

enter into all the details of local treatment, but we must refer the reader to the special descriptions already given of the various local affections. We may, however, briefly mention a few facts with regard to the treatment of scrofulous swelling of the lymph-glands. Painting the overlying skin with tincture of iodine is a very common practice, but it seldom does much good. We have obtained more satisfactory results from iodoform collodium, or iodoform salve, or from the repeated inunction of *sapo viridis*. For particulars as to the opening of abscesses, or the extirpation of glands, we must refer to works on surgery.

Second, in the general treatment of scrofula every possible means is to be employed to invigorate the system. Abundant nourishment and fresh air are essential. The child may be taken either to the country, or the mountains, or the seashore. Cod-liver oil is regarded by some as a specific in scrofula; but its undoubted value really lies in the fact that it is an easily digested fat. Some children can take a considerably larger dose than others without its disturbing the stomach. Usually we prescribe two or three tablespoonfuls per diem. Salt baths enjoy a great reputation as a remedy in scrofula. If circumstances permit, the best way is to visit some place where there are brine baths, such as Kösen, Sulza, Salzungen, Arnstadt, Kreuznach, Münster am Stein, Rehme, Reichenhall, Ischl, and Colberg.

Treatment at these resorts is preferable to artificial baths at home, because it is under more favorable hygienic surroundings.

The chief internal remedies are iron, iodine, and arsenic. A favorite prescription is syrup of the iodide of iron. Arsenic promotes nutrition, and perhaps exerts some specific influence upon certain scrofulous (tubercular) local diseases, particularly the "fungous" affections and lupus.

## APPENDIX I.

### SUMMARY OF THE SYMPTOMS AND TREATMENT IN CASES OF POISONING.

1. **Sulphuric Acid.**—Mucous membrane of mouth, throat, œsophagus, and stomach deeply corroded. In the worst cases rapid death ushered in by convulsions and asphyxia, or more rarely consequent upon perforation of the stomach. Usually the case is more protracted. The mouth and throat are whitened, or in severe cases blackened. They are soon attacked by an intense ulcerative inflammation. Deglutition is extremely painful, and there are most distressing choking and retching. The vomitus contains black lumps. Profuse salivation. Pain along the œsophagus. Abdomen usually distended and very tender on pressure. There may be intestinal discharges of a bloody character, resembling dysentery. Urine is generally scanty, and often contains albumen and blood. Collapse. Small and rapid pulse.

In mild cases, slow recovery, the necrosed tissues gradually sloughing off. Cicatricial stricture of the œsophagus frequently ensues and may prove fatal. Neuralgia, hyperæsthesia, and various other nervous disturbances may also occur as sequelæ.

In fatal cases, the autopsy discloses necrosis, ulceration, and inflammation in the upper portion of the digestive tract. The lining of the stomach is usually coal-black. Well-marked parenchymatous degeneration of the liver and kidneys. Perhaps nephritis. In later stages, extensive cicatrices.

*Treatment*: If used at all, the stomach-pump must be introduced very cautiously, for fear of causing perforation. The best remedy to give at once is several teaspoonfuls of magnesia in water, or a few drops of liquor sodæ in mucilage. Later, the symptoms are to be combated with bits of ice, disinfecting mouth-washes and gargles, tonics, and cautious feeding with milk, eggs, etc. If stricture of the œsophagus develops afterward, an endeavor should be made to dilate it with bougies.

2. **Hydrochloric and Nitric Acids.**—Symptoms similar to those of sulphuric acid. The most prominent symptoms are the local ones, intense stomatitis, pharyngitis, etc. There is usually albuminuria, with casts and blood in the urine. Nitric acid sometimes stains the corroded spots, especially the angles of the mouth, yellowish; and the vomitus may have the same tinge (xanthoproteic acid). In poisoning from fuming nitric acid the inhaled vapors cause pulmonary symptoms. Prognosis and treatment as in case of sulphuric acid.

3. **Nitrous and Sulphurous Acid Fumes.**—Intense local inflammation of the air-passages. Violent dyspnoea, cough, abundant bloody or yellowish expectoration. There may also be grave nervous disturbance and collapse. *Treatment*: Symptomatic: sinapisms, narcotics, expectorants, and inhalations.

4. **Oxalic Acid.**—Local corrosive action similar to that of the other acids, only

less severe. In severe cases collapse from cardiac paralysis. Apt to occasion certain nervous symptoms—formication, anæsthesia of the finger-tips, tonic and clonic convulsions, trismus, and tetanus; later paresis. There is sometimes sugar in the urine, and nephritis may develop. Anuria is frequent, and is due to plugging of the tubules by calcic oxalate crystals. The treatment should be symptomatic, and should also include the administration of preparations of calcium—liquor calcis, calcii carbonas, or even egg-shells—to form insoluble calcic oxalate. Magnesia is also useful.

5. **Ammonia.**—The fumes affect the air-passages chiefly; the solution, the upper part of the digestive tract. The specific local effect is the production of an intense croupous inflammation of the mucous membrane. Accordingly, the symptoms are salivation, dysphagia, vomiting of strongly alkaline matter, and diarrhœa, or cough, dyspnœa, etc. In severe cases there is collapse, with rapid pulse, and such nervous symptoms as pain, paræsthesia, vertigo, convulsions, etc. *Treatment*: In fresh cases the stomach-pump. The cautious use of acids—for instance, acetic or citric. Also, symptomatically, emulsions of oil, bits of ice, and narcotics.

6. **Caustic Potash or Soda.**—Symptoms and treatment as in case of ammonia. In contrast to acid poisoning, it is to be noted that alkalies do not withdraw water and precipitate albumen, but dissolve it. The corroded spots are therefore not dry and brittle, but softened (“colliquation”).

7. **Potassic Nitrate.**—Vomiting and diarrhœa. Severe abdominal pain. Collapse, with cold skin and rapid, thready pulse. Occasionally the pulse is slow. Nervous disturbances, such as painful muscular contractions, and, in severe cases, convulsions and coma. *Treatment*: Symptomatic; opium and other narcotics, stimulants (camphor, ether), and bits of ice.

8. **Chlorine Gas.**—Violent convulsive cough. Bloody expectoration. Spasm of the glottis. Dyspnœa. Darting pains through the chest. Sneezing and profuse flow of tears. In severe cases pneumonia. *Treatment*: Fresh air. Inhalation of warm aqueous vapor, or of ammonia to form ammoniac chloride. Chloroform may also be tried, and narcotics.

9. **Iodine.**—1. *Acute iodism*, as seen, for instance, after the injection of large amounts of tincture of iodine into ovarian cysts: collapse, with pallor and cyanosis, and small and very rapid pulse. Vomiting. Often marked dyspnœa. Suppression of urine. Sometimes hæmoglobinuria. Later, the skin becomes very red. There is albuminuria; also sore throat, coryza, conjunctivitis, severe frontal headache, and cutaneous eruptions. 2. *Chronic iodism*, caused, for example, by long-continued internal administration of potassic iodide: coryza, conjunctivitis, sore throat. Gastric symptoms. Vertigo, headache, and similar nervous phenomena of a mild character. Acne or erythema, sometimes in the form of erythema nodosum. *Treatment*: In acute cases, white of egg and stimulants. Other than this, treatment must be symptomatic. Prophylaxis demands caution in the internal administration of iodine or its compounds. According to Ehrlich, the symptoms of iodism often disappear rapidly after the exhibition of about a drachm and a half (grm. 6) of sulpho-nitro-salicylic acid (sulphanilic acid).

10. **Bromine.**—1. *Acute poisoning* from the fumes of bromine excites the same symptoms as does chlorine gas. 2. *Bromism*, resulting from the long-continued use of potassic bromide, causes languor, debility, mental apathy, and impaired intellectual vigor. The reflexes are diminished, particularly the reflex irritability of the soft palate and pharynx. Anorexia. Diarrhœa. Impotence. Almost invariably a characteristic acne, the onset of which may be delayed by giving arsenic at the same time.

11. **Lead.**—(a) *Acute lead poisoning* produces severe gastro-enteritis. The best antidote is sulphate of sodium or magnesium; or phosphates, white of egg,

and milk. In fresh cases the stomach-pump, or emetics and purgatives. Other than this symptomatic treatment.

(b) *Chronic lead poisoning*: Seen in type-setters, type-founders, painters, potters, and others. General symptoms: Lead line on the gums, lead anaemia, and lead cachexia. Important groups of symptoms are: 1. *Lead colic*: Violent colicky pains, radiating from the umbilicus. Usually constipation, exceptionally diarrhoea. Abdomen concave and hard. Vomiting. Hard, slow pulse. Temperature usually normal. Urine sometimes contains a trace of albumen. Duration, one or two weeks. *Treatment*: If severe pain, opium and hot compresses. Atropine may also be tried. For constipation, enemata and gentle laxatives. Warm baths. 2. *Lead paralysis* (*vide* page 569). Paralysis of the laryngeal muscles due to lead poisoning has been reported. 3. *Saturnine encephalopathy*: Sudden development of grave cerebral symptoms; convulsions, coma, delirium, great mental uneasiness, and excruciating headache. Saturnine amaurosis. In severe cases, death. Cerebral lesions are very rarely found post mortem. *Treatment* is symptomatic. Lukewarm baths, with douching, narcotics, and stimulants. Later, potassic iodide. 4. *Lead arthralgia*: Most frequently attacks the knee. Also seen in the joints of the upper extremities. Sometimes associated with painful muscular contractions. Objective lesions are rarely seen. The treatment consists in warm baths and the administration of potassic iodide. It should be remembered that chronic lead poisoning may occasion gout and chronic interstitial nephritis. The reader is referred to the chapters describing these diseases.

12. **Copper** (*Blue Vitriol, Verdigris*).—(a) *Acute copper poisoning*: Copper taste. Vomiting of greenish matter, colic, tenesmus, and bloody stools. Also nervous symptoms, headache, vertigo, anaesthesia, paralysis, delirium. Collapse. Dyspnoea. *Treatment*: White of egg, milk, wood charcoal. Magnesia is also valuable. Yellow potassic ferrocyanide, milk sugar. (b) *Chronic copper poisoning* is rare. It occasions gastro-intestinal disturbance, colic, and a reddish or greenish discoloration of the hair.

13. **Zinc** (*Zinc Sulphate and Chloride*).—In acute poisoning, symptoms of severe gastro-enteritis, especially vomiting. Also albuminuria. *Treatment*: Albumen, tannin, and alkaline carbonates. *Chronic poisoning* (zinc fumes!): Fever, distress, vertigo, vomiting, metallic taste. General anaemia and emaciation.

14. **Mercury**.—(a) *Acute poisoning from corrosive sublimate*: The mucous membrane of the mouth, throat, oesophagus, stomach, and intestines is deeply corroded. Metallic taste. Vomiting. Diarrhoea with painful tenesmus. Ischuria or complete anuria. Collapse. Generally quickly fatal. *Treatment*: Milk, white of egg, reduced iron, narcotics. (b) *Chronic mercurial poisoning*: Seen in the makers of thermometers, scientific instruments, and mirrors. Rarely occasioned by the prolonged use of antisyphilitic remedies. The symptoms are anaemia, emaciation, with great muscular weakness, and gastro-intestinal disturbance. In the therapeutic use of mercury, besides the rarer mercurial enteritis, mercurial stomatitis is the most important toxic symptom; onset of foul-smelling necrosis of mucous membrane, with ulceration of mucous membrane of cheeks, jaws, gums, etc. *Treatment*: Immediate discontinuance of medication; potassic chlorate as mouth-wash and gargle.

*Mercurial Tremor*.—Tremor is common in chronic mercurial poisoning and is of special interest. It is usually preceded by a stage of pronounced mental irritability ("mercurial erethism"), and often some mental excitement, fright, etc., is the exciting cause of the tremor. The tremor itself is a pronounced intention tremor—that is, it is usually not present when the body is kept quiet, but it comes

on with all movements, like the tremor in multiple sclerosis. The finer the movements the patient tries to make the more marked is the tremor. Mental excitement usually increases the tremor considerably. In severe cases the tremor is so great that the patients can not leave their beds. In rare cases there is also paralysis.

*Treatment*: Dietetic and hygienic. Iodide of potassium, hyosine, and sometimes galvanism, are also useful.

**15. Phosphorus.**—(1) *Acute phosphorus poisoning*, as from matches: Violent epigastric pain, vomiting—the vomitus smells of phosphorus, and it may be phosphorescent. After these initial symptoms usually comes a period of comparative comfort, lasting two or three days. Then appear grave symptoms: jaundice, severe pain in the hepatic region and whole abdomen, hepatic enlargement, fever, feeble and rapid pulse, sometimes gastric or intestinal hæmorrhage, cutaneous ecchymoses, hæmaturia, epistaxis, or metrorrhagia. The intellect usually remains clear, except that just before death there may be drowsiness or convulsions. The urine contains albumen, blood, casts, bile-pigment, and sometimes leucine and tyrosine. No urea is excreted. Death occurs usually at the end of one or two weeks, but it may be more speedy. In mild cases the above symptoms are not strongly marked, and recovery may ensue. A very grave prognosis should be made in every case at the start. *Post-mortem appearances in acute phosphorus poisoning*: Jaundice. Dark blood. Numerous internal ecchymoses—for example, in the serous and mucous membranes and kidneys. Fatty degeneration of most of the internal organs, including the liver, heart, muscles, and kidneys. *Treatment*: In fresh cases, washing out of the stomach. Laxatives. As an emetic, sulphate of copper. The best antidote is old oil of turpentine (30–40 drops in mucilage). Oily substances should be avoided, as phosphorus is soluble in oil. Narcotics and other symptomatic remedies may also be indicated. (2) *Chronic phosphorus poisoning*: Necrosis of the lower jaw, less often of the upper jaw, extending from caries of the teeth. Necrosis of the bone, with exuberant growth of osteophytes.

**16. Arsenic** (Arsenious Acid, Schweinfurth Green, Scheele's Green, Arsenical Wall-paper).—(1) *Acute arsenic poisoning*: Symptoms of intense gastro-enteritis, suggesting cholera. Violent vomiting. Rice-water stools. Severe abdominal pain. Nervous symptoms: Vertigo, headache, faintness, twitchings. Cardiac weakness. Cyanosis. Collapse. Not infrequently a cutaneous eruption resembling urticaria or eczema. Sometimes albumen and blood are present in the urine. Severe cases are fatal in one or two days. With regard to arsenical paralysis, *vide* page 571. *Treatment*: At first the stomach-pump or emetics—for example, sulphate of zinc. The best antidotes are freshly prepared ferric hydrate in water, two to four tablespoonfuls every fifteen to thirty minutes; ferrum oxydatum saccharatum solubile (P. G.), in teaspoonful doses; magnesia; and, best of all, the compound of magnesia and ferric hydrate known as "*antidotum arsenici*" (P. G.), of which a tablespoonful may be given every fifteen to thirty minutes. (2) *Chronic arsenic poisoning*: Acquired in arsenic works and glass factories, or from arsenical fabrics, papers, and flowers. Conjunctivitis, chronic gastro-intestinal catarrh, eczema, and cutaneous ulcerations. Anæmia and cachexia, falling out of the hair, loss of sleep. Treatment is purely symptomatic, except as regards prophylaxis. In poisoning with arseniuretted hydrogen, hæmoglobinuria and jaundice occur, with severe nervous symptoms.

**17. Alcohol.**—(1.) *Acute alcoholic poisoning*: Unconsciousness; anesthesia; pupils either dilated or contracted, usually not reacting to light; pulse small, sometimes slow; skin cold and clammy; vomiting; stertorous respiration. There may be delirium and clonic convulsions instead of coma. Such cases last three or

four days. Death has been repeatedly observed. *Treatment*: Bathing and douching. Stimulants.

(2.) *Chronic alcoholism.* (a) *Physical and mental debility*: Chronic catarrh of the throat, larynx, stomach, and intestines. Alcoholic tremor. Numerous organic diseases, including cirrhosis of the liver, contracted kidney, cerebral disease, and neuritis.

(b) *Delirium tremens*: Usually a sudden onset, as in connection with some acute disease or after a surgical injury. Disordered intellect. Great restlessness, hallucinations (vermin, etc.), excitement, and loss of sleep. *Treatment*: Bathing and douching. Injections of strychnine. The use of chloral and other narcotics should be cautious. Physical restraint should be avoided if possible. The patient may often be allowed to go about the room as he likes, if only he be watched. Alcohol should be given if collapse be threatened.

18. *Chloroform*.—Unconsciousness. Loss of sensibility and reflexes. Slow pulse. Pupils dilated. Failure of respiration, and finally of the heart. Danger of heart failure, especially in persons with weak hearts. *Treatment*: Artificial respiration. Injections of strychnine. Stimulants. Counterirritation.

19. *Iodoform*.—(Repeatedly seen from the use of iodoform on wounds). First of all, nervous symptoms: headache, vertigo, sleeplessness. Peculiar psychoses, maniacal attacks, delusions of persecution, refusal of food. In severe cases convulsions, deep coma. Very small, rapid pulse. *Treatment*: symptomatic, by stimulants, baths, etc. Alkalies and atropine are recommended, but their action is doubtful.

20. *Carbonic-oxide Gas* (Illuminating Gas).—At first, vertigo, headache, throbbing in the temples, ringing in the ears, and spots before the eyes. The patient gradually becomes unconscious. Skin pale and cyanotic. Respiration intermittent. Subnormal temperature. The urine may contain albumen and sugar. The carbonic oxide may be demonstrated in the blood by means of the spectroscope. Its color is clear cherry-red (CO-hæmoglobine). Subsequently paralysis, disturbances of sensation and of speech. *Treatment*: Fresh air, artificial respiration, stimulants, transfusion.

21. *Sulphuretted Hydrogen*.—Headache, vomiting, diarrhoea. In severe cases, unconsciousness, dyspnoea, cyanosis, convulsions, and death. The blood is thin, fluid, and black (sulph-hæmoglobine). *Treatment*: Artificial respiration, fresh air, and the cautious inhalation of chlorine gas.

22. *Bisulphide of Carbon*.—(Workers in rubber factories). Vomiting. Severe nervous symptoms. Incontinence of urine, atrophic paralyses, anæsthesia, mental disturbances, especially loss of memory, spasmodic conditions, etc. The red blood-corpuscles are destroyed; the black blood contains many flakes of pigment. *Treatment*: symptomatic.

23. *Hydrocyanic Acid* (Potassic Cyanide; Bitter Almonds).—Characteristic odor of bitter almonds. In severe cases death may occur in a few minutes. If the course be more protracted, convulsive and extremely slow respiration, the expiratory act being much prolonged; the eyeballs protrude, and the pupils are somewhat enlarged and do not react to light. Cardiac weakness, cyanosis, unconsciousness. Twitching of the muscles. Trismus. *Treatment*: Merely symptomatic. Emetics, artificial respiration, cool douches, stimulants. Atropine may be tried; also, hydrated ferric oxide and chlorine water.

24. *Nitrobenzine* (Nitrobenzole, Oil of Mirbane).—Strong odor of bitter almonds. At first, dizziness. The skin soon assumes a bluish hue, rapidly increasing to the deepest cyanosis. Increasing anxiety, sense of suffocation, and gradual loss of consciousness. In severe cases, death, ushered in by convulsions. In milder cases, gradual recovery. *Treatment*: Stomach-pump. Artificial respira-

tion. Stimulants. In the Leipsic clinique, transfusion has worked admirably in two cases. The symptoms caused by aniline and the aniline dyes closely resemble poisoning from nitrobenzole.

25. **Carbolic Acid.**—Corrosion of mouth, throat, and stomach. In mild cases, vertigo and headache; in severe cases, coma, preceded in rare instances by symptoms of cerebral irritation. Contracted pupils. Vomiting. Pulse slow at first, then rapid. The urine has a dark, olive-green color. Sometimes hæmoglobinuria and nephritis. *Treatment:* Stomach-pump. Slaked lime and water. Large doses of sulphate of sodium are especially to be recommended.

26. **Atropine (Belladonna).**—Dryness of the mouth and throat. Excessive thirst. Dizziness and headache. Peculiar mental disturbances: hallucinations are particularly frequent. Pupils very widely dilated. Cutaneous erythema resembling that of scarlet fever. In severe cases, pulse enormously accelerated, with violent pulsation in the arteries. Convulsions may occur. Nervous symptoms persist for some time. *Treatment:* The following physiological antidotes should be tried: physostigmine (eserine), pilocarpine, and morphine.

27. **Digitalis.**—Vomiting. Diarrhœa. Pulse very slow (forty beats per minute, or less). Dyspnoea. Symptoms of collapse. Cold extremities, muscular tremor. Somnolence. In the worst cases, sopor and death. Even the milder cases are protracted. *Treatment:* Emetics, stomach-pump. Tannin. Camphor, strong *café noir*, ether, ammonia. Counter-irritation.

28. **Nicotine (Smoking; Tobacco Juice; Tobacco Enemata).**—1. *Acute:* Pulse small and slow, syncope, sense of oppression, salivation, vomiting. In severe cases, loss of consciousness, tetanic spasms, both pulse and respiration intermittent. 2. *Chronic* (from excessive use of tobacco): Palpitation, irregular action of the heart, paroxysms of asthma and angina pectoris. Tremor, muscular weakness. Loss of sleep. Sometimes there are symptoms of ataxia ("nicotine tabes" seen in cigar makers). Amblyopia, scintillating scotoma. Gastric disturbance, chronic catarrh of the pharynx and larynx. *Treatment:* In acute cases, stimulants. Chronic poisoning necessitates the giving up of tobacco. Further treatment is symptomatic.

29. **Strychnine.**—Violent tetanic reflex convulsions. Exaggeration of the cutaneous and tendon reflexes. Trismus. Opisthotonos. Pulse small and very rapid. The convulsions come in paroxysms, with intervals between them. The intellect is usually perfectly clear. Recovery occurs only in mild cases. *Treatment:* Emetics, stomach-pump. Tannin. Tincture of iodine. Castor-oil. The convulsions are to be combated by morphine, chloroform, chloral, or potassic bromide. Curare has also been tried.

30. **Coniine (Hemlock).**—In severe cases convulsions, then general paralysis, especially of the respiratory muscles, loss of consciousness, and death. Pupils dilated. In milder cases confusion, muscular weakness, vomiting, and diarrhœa. *Treatment:* Emetics, tannin, stimulants.

31. **Morphine (Opium).**—1. *Acute:* Begins with fatigue, headache, darkening of the visual field, nausea, vomiting. Then coma comes on with slow, stertorous, sometimes irregular respiration. Muscles completely lax. Pupils usually very small. Pulse often slow, but in other cases rapid and small. Toward the end of life Cheyne-Stokes's respiration. In milder cases only vomiting, stupor, headache, etc. *Treatment:* Sulphate of zinc, or some other emetic; stomach-pump. Tannin. *Café noir*. Atropine may be tried as a physiological antidote. Stimulants (camphor, ether) are best, also cold baths with shower-baths; artificial respiration. 2. *Chronic* (morphine habit): Emaciation, anaemia, headache, vertigo, wakefulness. Tremor. Mental disturbance. Unconquerable longing for morphine; and, if this be denied, the appearance of grave symptoms. To break up the morphine habit is almost impossible except in hospitals and special asylums. The with-

drawal of the drug is abrupt according to the practice of some, and gradual according to others. For particulars consult monographs.

**32. Ergot (Ergotine).**—1. *Acute*: At first nausea, vomiting, colic, and diarrhoea. Then vertigo, headache, and muscular weakness. Pulse slow. In severe cases, sopor, disturbance of respiration, and sometimes death. *Treatment*: Emetics and purgatives. Tannin. Ether, camphor, and *café noir* as stimulants. 2. *Chronic ergotism*: Gastric symptoms, vertigo, languor, cardiac weakness. The nervous disturbances are, however, of especial importance. Of these, paræsthesia has long been recognized. Recently attention has been attracted to the great resemblance of the nervous symptoms to those of tabes dorsalis; and there is, moreover, an anatomical change in the posterior columns of the cord. Convulsions and psychical phenomena are also observed. A second form of chronic ergotism is called gangrenous ergotism. It results in dry gangrene of the hands and feet. A line of demarcation forms and the gangrenous parts slough off. The process may be attended by fever and pyæmia. The probable explanation is that the minute blood-vessels become spasmodically contracted and thrombi form under the influence of the poison. The different symptoms are due in part to the different constituents of the ergot. The best known are sphacelinic acid, which is probably the cause of gangrenous ergotism and ergotine tabes; cornutine, which causes severe convulsive symptoms (convulsive ergotism) and uterine contractions; and finally ergotinic acid. The *treatment* of chronic ergotism is purely symptomatic.

**33. Poisonous Mushrooms.**—1. *Poisoning from morels*: Fresh morels ("morcheln" or "lorcheln") contain a poison which is readily soluble in hot water, and which evaporates completely if the morels be dried. Morels that have been dried or parboiled are therefore perfectly harmless, but the fresh ones are poisonous. The symptoms are nausea, vomiting, diarrhoea, headache, coma, and, above all, hæmoglobinæmia and hæmoglobinuria (*q. v.*), associated with which is a hæmatogenous icterus. In severe cases death occurs, ushered in by convulsions. *Treatment* is symptomatic, and includes the administration of emetics, purgatives, and stimulants. 2. *Poisoning from the red agaric (amanita muscaria)*: This contains the poisonous alkaloid muscarine. Gastric symptoms and diarrhoea. Mental excitement, delirium, tetanic and epileptiform convulsions. A rapid pulse, small pupils, disturbed vision from spasm of accommodation, sweating, salivation, and in most of the severe cases sopor and death. *Treatment*: Emetics, etc. Atropine, which acts as a physiological antidote to muscarine. Also tannine, and stimulants. 3. *Poisoning from tubercular mushrooms (amanita phalloides)*, confused with young button mushrooms (champignons). Digestive disturbances, later jaundice, somnolence, coma. The autopsy shows fatty degeneration of the liver, kidneys, and stomach, as in phosphorus poisoning.

**34. Poisoning from Sausages (Botulismus).**—This sometimes occurs as the result of eating partially decayed sausages. The symptoms are pain in the stomach, nausea, vomiting, colic, and diarrhoea. There are also marked feebleness, præcordial anxiety, and dyspnoea; vertigo, headache, somnolence; and very often disturbance of vision (amblyopia, spots before the eyes), and, what is surprising, ptosis. In severe cases, dysphagia, as a result of more or less complete paralysis of the tongue and the constrictors of the pharynx. The mouth is dry. The heart is feeble; this and the general prostration and malnutrition may prove fatal. The cases are usually protracted, rarely being very acute. The active principles (alkaloids of putrefaction) have lately become known in part. In sausage and also in meat poisoning the most important substance is ptomato-atropine, a substance which acts almost exactly like atropine. *Treatment*: Emetics, purgatives (calomel), stimulants, and, if indicated, artificial feeding.

**35. Poisoning from Meat.**—In repeated instances severe symptoms have been occasioned by eating tainted meat, or possibly that obtained from animals which had been diseased. These symptoms are certainly due to the products of putrefaction, substances which act partly like muscarine, partly like atropine, neurine, methylguanidine, etc. The special poison is not yet fully known. Probably there are several poisons, either chemical or organic and infectious. The usual symptoms are vomiting and diarrhoea. The case may closely simulate cholera. In most instances certain nervous phenomena are also observed—wakefulness, delirium, headache, and changes in the pupils. There may be roseola or wheals or erythema. Frequently there is a high fever, but sometimes the temperature is subnormal. The pulse is small and slightly accelerated, although it may occasionally be slower than normal. There is a sense of thoracic oppression. The cases are often protracted. Tendency to relapses. Death may occur. Post mortem, there is usually found an intense and often hæmorrhagic enteritis with secondary changes in the spleen, kidneys, lungs, and other organs. *Treatment*: Symptomatic: calomel, emulsions, stimulants, and baths. Food should be given cautiously.

**36. Poisoning from Fish.**—The eating of tainted fish has likewise caused grave disturbance. The symptoms vary. Usually there are pain in the stomach, præcordial anxiety, vertigo, dryness of the throat, aphonia, and labored respiration. There may also be disturbance of vision, amblyopia, and colored vision, or paralysis of the motores oculi and of accommodation. In severe cases there may be dysphagia and general paresis. Sometimes dyspnoea and cardiac weakness are observed. The cases are frequently very tedious. Here, too, there are many active poisonous products of putrefaction, among them one which acts like muscarine. *Treatment* similar to that recommended in the two preceding paragraphs.

**37. Poisoning from Mussels (*Mytilus Edulis*).** This is also common. A drawing feeling in the neck, a blunt feeling in the teeth, crawling and burning in the arms and legs, dullness in the head, mental excitability, feeling as if everything were light, as if the patient must fly; in the later stages dilated, immobile pupils, difficult speech, paresis and ataxia of the muscles; also nausea, skin eruptions (urticaria), fall of temperature. In severe cases death may ensue in a few hours. At the autopsy we find severe enteritis, enlargement of the spleen, and often a peculiar speckling of the liver. The poison of mussels that is known has been called mytilotoxine.

**38. Poisoning from Cheese.**—Vomiting, colicky pains, diarrhoea, vertigo, sense of thoracic oppression, headache, languor, and disturbance of vision. *Treatment* as in paragraphs 35 and 36.

## APPENDIX II.

### TABLE OF WEIGHTS AND MEASURES.

TABLE OF RELATION OF U. S. FLUID TO METRIC MEASURE.

Minims.	Cubic Centimetres.	Minims.	Cubic Centimetres.	Fluid Drachms.	Cubic Centimetres.	Fluid Ounces.	Cubic Centimetres.		
1	=	·06	30	=	1·85	4	=	118·24	
2	=	·12	40	=	2·46	6	=	177·39	
5	=	·31				8	=	236·53

6	=	·39									

### THE METRIC SYSTEM IN MEDICINE.

Old Style.		Metric.
℥ j or gr. j	=	06 grm.
f ʒ j or ʒ j	=	4 “
f ʒ j or ʒ j	=	32 “

The decimal *line*, instead of *points*, makes errors impossible. As ·06 (drug) is less than a grain, while 4· and 32· (vehicle) are more than the drachm and ounce, there is no danger of giving too large doses of strong drugs.

C.c. (cubic centimetres), used for grms. (grammes), causes an error of five per cent (excess).

A teaspoonful is usually 5 grms. ; a tablespoonful, 20 grms.

# INDEX.

- ABASIA, 803 (foot-note).  
 Abdomen in typhoid fever, 10.  
 Abdominal typhus, 1.  
 Abducens nerve, paralysis of, 556.  
 Abortion in acute yellow atrophy of the liver, 488;  
   in chorea, 784; in pernicious anæmia, 944; in typhoid fever, 18.  
 Abscesses, embolic, in lungs, 247; in appendicitis, 420; in glanders, 116; in parotitis, 349; in perinephritis, 868; in perityphlitis, 420; in smallpox, 56; in septico-pyæmia, 110; in typhoid fever, 17; of brain, 741; of liver, 476; of mediastinum, 273; of tonsils, 353; retropharyngeal, 360; sub-diaphragmatic, in peritonitis, 456.  
 Absorption, impaired, in chronic gastric catarrh, 375.  
 Accentuation of the aortic second sound in chronic nephritis, 859; in arterio-sclerosis, 833; of the pulmonary second sound in emphysema, 178; in mitral regurgitation, 285; in mitral stenosis, 287.  
 Accessorius nerve, spasm of, 574; position of head in spasm of, 574; paralysis of, 562.  
 Acetonæmia in diabetes, 969.  
 Acetone, odor of, in diabetes, 971; reaction, 969.  
 Achilles' tendon reflex, 545.  
 Acholia, 489.  
 Achromatopsia in hysteria, 801.  
 Acid dyspepsia, 382.  
 Acid, free, in gastric juice, tests for, 378.  
 Aconitine in neuralgia, 530; in trigeminal neuralgia, 523.  
 Acoustic nerve, atrophy of, in locomotor ataxia, 643.  
 Acromegaly, 589.  
 Actinomycosis, 274.  
 Acupuncture in aneurism, 338; in cardiac dropsy, 306.  
 Acute bulbar paralysis, 691.  
 Acute tuberculosis, 236.  
 Acute yellow atrophy of the liver, 485.  
 Addison's disease, 878.  
 Adenia, 951.  
 Adeno-carcinoma, 426.  
 Adenoid growths in pharynx, 358.  
 Adherent pericardium, 326.  
 Adrenals in Addison's disease, 879.  
 Ægophony, 200.  
 After-sensations, 609; in locomotor ataxia, 640.  
 Agaricine in pulmonary tuberculosis, 235.  
 Ageusia, 583.  
 Agraphia, 730.  
 Ague, 90.  
 Air, inspired, as carrier of infection, 208.  
 Alalia, 685.  
 Albumen in urine, tests for, 682.  
 Albuminous expectoration in pleurisy, 266.  
 Albuminuria, accidental, 824; in acute ascending spinal paralysis, 675; in acute Bright's disease, 841; in anæmia, 934, 942; in bulbar apoplexy, 692; in chronic Bright's disease, 852, 859; in diabetes, 970; in diphtheria, 70; in epilepsy, 773; in erysipelas, 64; in fevers, 837; in gout, 987; neurotic, 835; in osteomalacia, 927; physiological, 823; in pneumonia, 197; renal, genuine, 824; in scarlet fever, 41; in scurvy, 959; in smallpox, 56; spurious, 894; transitory, 825; in typhoid fever, 17; in yellow fever, 102.  
 Albuminuric retinitis, 854, 861.  
 Alcohol, effects of, on the digestive system, 372, 374; on the kidneys, 856; on the nervous system, 584; poisonous effects of, 1006.  
 Alcoholic beverages in anæmia, 936; in diabetes, 979; in gout, 991; in neurasthenia, 818; in obesity, 908; in pneumonia, 206; in tuberculosis, 232.  
 Alcoholic neuritis, 584.  
 Alcoholic poisoning, acute, 1006.  
 Alcoholism, 1006; acute, 1006; chronic, 1007; treatment of, 1006.  
 Alexia, 720.  
 Alimentary canal, tuberculosis of, 215, 423.  
 Alkalies in diabetes, 981; in gout, 991.  
 Allantiasis (botullismus), 1009.  
 Alopecia, 589.  
 Altitude in tuberculosis, 233.  
 Alum in intestinal catarrh of children, 417.  
 Amaurosis, anæmic, 932; in gastric ulcer, 387; hysterical, 802; uræmic, 892.  
 Amblyopia, 751; in hysteria, 802.  
 Ambulatory typhoid fever, 18.  
 Amimia, 720.  
 Ammonisæmia, 893, 890, 895.  
 Ammonia in asthma, 172; in diabetes, 981; poisoning from, 1004.  
 Amnesia, 717.  
 Amoeba coli (amoeba dysenteriae), 81; in liver abscess, 81; in lungs, 81.  
 Amoebic dysentery, 81.  
 Amphoric breathing, 222, 269.  
 Amyl nitrite in asthma, 172; in epilepsy, 778; in hemiplegia, 503; in trigeminal neuralgia, 523; in valvular disease, 307.  
 Amyloid disease, chronic nephritis combined with, 866; of kidney, 864; of liver, 468; in phthisis, 239; in syphilis, 895.  
 Amyotrophic lateral sclerosis, 641.  
 Anæmia, 934, 942.

- 984; from gastric atrophy, 939; in gastric cancer, 891; in gastric ulcer, 887; idiopathic, 928; tuberculosis as a complication of, 236, 424; progressive pernicious, 938; primary or essential, 928; secondary, 929; toxic, 931.
- Anæmia**, pernicious, 938; associated with atrophy of gastro-intestinal walls, 939; chemical examination of blood in, 943; diagnosis, 944; post-mortem lesions in, 940; symptoms of, 941; treatment of, 944.
- Anæmia**, simple constitutional, 928; diagnosis of, 936; symptoms of, 931; treatment of, 936.
- Anæmia**, spastic, 511; splenic, 944.
- Anæmic** murmurs, 933.
- Anæsthesia**, 510; dolorosa, 512; in hemiplegia, 733; in hysteria, 800; in locomotor ataxia, 636; in Morvan's disease, 679; in myelitis, 619; in neuralgia, 517; in neuromata, 586; in railway spine, 820; in unilateral lesions of the spinal cord, 683; of the skin, 510; of the trigeminus, 513.
- Analgesia**, 508; in hysteria, 800; in locomotor ataxia, 636, 640; in Morvan's disease, 679; in syringo-myelia, 678.
- Anarthria**, 685; in bulbar apoplexy, 692.
- Anchyllostomum duodenale**, 448.
- Aneurism**, 334; cylindrical, 334; dissecting, 340; fusiform, 334; sacciform, 334; of the abdominal aorta, 339; of carotid artery, 339; of the cerebral arteries, 725; of the heart, 308, 330; of subclavian artery, 339; of pulmonary artery, 218, 339.
- Aneurism of thoracic aorta**, 334; diagnosis of, 337; dyspnoea in, 336; hæmorrhage in, 337; pain in, 337; physical signs of, 335; symptoms of, 335; treatment of, 338; Tufnell's treatment of, 338.
- Angina pectoris**, 307, 309, 310, 318; pseudo or hysterical, 318.
- Angina** (see Sore Throat).
- Angio-neurotic œdema**, 588.
- Animal lymph**, 59.
- Animals**, lower, diphtheria in, 67.
- Ankle clonus**, 545; in cerebral hæmorrhage, 732; in hysterical paraplegia, 803; in myelitis, 620; in spastic paraplegia, 664; in tetanus, 792.
- Anosmia**, 532.
- Anterior crural nerve**, paralysis of, 568.
- Anthrax**, 117; bacillus, 117; in animals, 118.
- Antidotes in poisoning from atropine**, 1008; lead, 1004; mushrooms, 1009; phosphorus, 1006.
- Antidotum arsenici**, 1006.
- Antimony**, arsenite of, in cardiac valvular disease, 303.
- Antipyrine** in typhoid fever, 24.
- Antiseptic medication** in typhoid fever, 20.
- Antiseptics** in pyelitis, 884.
- Anuria** in hydronephrosis, 892; in nephritis, 841.
- Aorta**, aneurism of, 334; hypoplasia of, in chlorosis, 929; rupture of, 339.
- Aortic incompetency**, 287; sudden death in, 200; symptoms of, 287.
- Aortic orifice**, congenital lesions of, 294.
- Aortic stenosis**, 290.
- Apex of lungs**, catarrh affecting, 222.
- Apex pneumonia**, 195, 202.
- Aphasia**, 716; amnesic, 717; anatomical localization of, 716; ataxic, 717; diagnosis of, 719; hemiplegia with, 736; in typhoid fever, 16.
- Apheemia** (see APHASIA), 716.
- Aphonia**, hysterical, 803; in acute laryngitis, 130; in adductor paralysis, 140; in pericardial effusion, 825.
- Aphthæ**, 343.
- Aplasia of the lungs**, 181.
- Apoplectic cyst**, 727; habit, 726; scar, 727.
- Apoplexy**, 728; delayed, 728; from cerebral syphilis, 738; from hæmatoma of the dura mater, 697; from hæmorrhage into medulla and pons, 691; from tumors of the brain, 730; ingravescens, 728; in multiple sclerosis, 630; premonitory symptoms of, 728; pulmonary, 247; spinal, 604.
- Appendicitis**, 420.
- Appendix vermiformis**, perforation of, in typhoid fever, 11; situation of, 420.
- Apraxia**, 720.
- Pyrexia in relapsing fever**, 32.
- Arachnitis** (see MENINGITIS).
- Aran-Duchenne type of muscular atrophy**, 653.
- Arbutine** in cystitis, 896.
- Arch of aorta**, aneurism of, 334.
- Argyll-Robertson pupil**, 642; in ataxia, 642; in progressive general paralysis, 763.
- Arm**, peripheral paralysis of, 564.
- Arrhythmia**, 297.
- Arsenical neuritis**, 571.
- Arsenical poisoning**, 931, 1006; paralysis in, 571.
- Arsenic in anæmia and chlorosis**, 939; in asthma, 172; in cerebral tumor, 756; in chorea, 783; in diabetes, 981; in exophthalmic goitre, 598; in habitual headache, 531; in hysteria, 813; in leukaemia, 950; in locomotor ataxia, 648; in malaria, 97; in neuralgia, 519; in paralysis agitans, 787; in pernicious anæmia, 945; in pseudo-leukæmia, 963; in scrofula, 1001; in spasm of the muscles of the neck, 575; paralysis from, 571; poisoning from, 931, 1006.
- Arteries**, diseases of, 331; calcification of, 331.
- Arterio-sclerosis**, 331; in diabetes, 972; in obesity, 996; symptoms of, 332; treatment of, 334.
- Arteritis**, syphilitic, 757.
- Arthralgia** from lead, 1005.
- Arthritis**, acute rheumatic, 900; gonorrhœal, 901; in cerebro-spinal meningitis, 106; in dengue, 99; in diphtheria, 70; in dysentery, 79; in hæmophilia, 962; in purpura, 965; in scarlet fever, 43, 901; in tabes dorsalis, 644; multiple secondary, 901, 907; rheumatoid, 911; septic, 111, 907.
- Arthritis deformans**, 911; monarticular form of, 914; of the poor, 912; of the rich, 985; polyarticular form of, 914; sicca, 913.
- Arthrogryposis**, 576.
- Arthropathies** in tabes, 644.
- Arthrospores**, 82.
- Asafoetida** in hysteria, 813.
- Ascaris lumbricoides**, 445.
- Ascites**, 460; from cancerous peritonitis, 463; in cancer of the liver, 493; in cancer of the pancreas, 504; in children, 459; in chronic endocarditis, 299; in cirrhosis of the liver, 490; in scarlet fever, 42; in suppurative hepatitis, 477; in syphilis of the liver, 491; in thrombosis of the portal vein, 502; in tuberculous peritonitis, 459; physical signs of, 461; treatment of, 462.
- Ascitic fluid**, 461; hæmorrhagic, 461.
- Aspect**, facial, in paralysis agitans, 785.
- Asphyxia**, local, 588; death by, in phthisis, 217; in diphtheria, 68.

- Aspiration in empyema, 264 ; in pericardial effusion, 328 ; in pleuritic effusion, 264.  
 Aspiration pneumonia, 185.  
 Associated movements, 541 ; in cerebral hæmorrhage, 735 ; in facial paralysis, 561 ; in infantile cerebral paralysis, 745 ; of the facial muscles in progressive paralysis, 762.  
 Astasia-abasia, 803.  
 Asthenopia, neurasthenic, 816.  
 Asthma, bronchial, 168 ; cardiac, 296 ; crystals, 169 ; ætiology of, 170 ; hay, 124 ; humid, 152 ; Millar's, 142 ; nasal affections in, 171 ; nervous, 168 ; origin of, 170 ; renal, 860 ; sputum in, 860 ; symptoms of, 168 ; symptomatic, 170 ; thymic, 142 ; treatment of, 172 ; uræmic, 860.  
 Atavism, in hæmophilia, 963 ; in gout, 965, 967.  
 Ataxia, 542 ; after smallpox, 56 ; cerebellar, 723 ; drunkard's, 584 ; hereditary, 648 ; in diphtheria, 70 ; in locomotor ataxia, 696 ; in myelitis, 619 ; in peripheral neuritis, 583 ; in progressive paralysis, 764 ; in typhoid fever, 16 ; locomotor, 632.  
 Ataxic gait, 637.  
 Ataxic paraplegia, 649.  
 Atelectasis, pulmonary, 181.  
 Atheroma of the arteries, 831.  
 Athetosis, 541, 787 ; congenital, 788 ; idiopathic, 786 ; in cerebral paralysis of children, 745, 788 ; movements of, 541 ; nature of, 789 ; symptomatic, 788.  
 Athrepsia, 414.  
 Atresia ani, 432.  
 Atrophy, 414 ; idiopathic muscular, 658 ; juvenile muscular, 658 ; of brain, diffuse, in general paresis, 785 ; of cardiac muscle in pericarditis, 323 ; of muscles, various forms of, 658 ; progressive muscular, of spinal origin, 653 ; unilateral, of face, 594.  
 Atropine in asthma, 172 ; in epilepsy, 778 ; in exophthalmic goitre, 596 ; in neuralgia, 520 ; in progressive bulbar paralysis, 600 ; in pulmonary tuberculosis, 235 ; poisoning from, 1008.  
 Attitude in paralysis agitans, 785 ; in pseudo-hypertrophic muscular paralysis, 660.  
 Auditory center, affections of, 721 ; nerve in facial palsy, 550 ; vertigo, 769.  
 Aura, forms of, in epilepsy, 771.  
 Automatism in petit mal, 773.  
 Bacilli of anthrax, 117 ; Asiatic cholera, 82 ; cerebro-spinal meningitis, 103 ; diphtheria, 66 ; glanders, 116 ; laryngeal tuberculosis, 186 ; pneumonia, 180 ; pulmonary tuberculosis, 208 ; tetanus, 791 ; typhoid fever, 1.  
 Bacteria in hepatitis suppurativa, 476 ; gangrene of lungs, 241 ; pleurisy, 253, 254, 263 ; septic pyæmia, 109.  
 Balanitis in diabetes, 972.  
 Balsams in chronic bronchitis, 154 ; in pulmonary emphysema, 180.  
 Bandage for compression in chronic hydrocephalus, 769 ; for extension in pressure paralysis of the spinal cord, 614 ; for the legs in locomotor ataxia, 648 ; in anæsthesia of the trigeminus, 515 ; in neuralgia of the joints, 529.  
 Banting's treatment of obesity, 907.  
 Baræsthesiometer, 507.  
 Barrel-shaped chest in emphysema, 177.  
 Basedow's disease (see EXOPHTHALMIC GOITRE), 595.  
 Basilar artery, embolism and thrombosis of, 693.  
 Basilar meningitis, 702.  
 Baths in acute ascending spinal paralysis, 676 ; in acute poliomyelitis, 671 ; in anæsthesia of the trigeminus, 515 ; in bronchitis, 150, 155 ; in cerebral hæmorrhage, 737 ; in cerebral hyperæmia, 710 ; in cholera morbus, 413 ; in chorea, 783 ; in chronic spinal leptomeningitis, 601 ; in cutaneous anæsthesia, 515 ; in cystitis, 806 ; in diabetes, 980 ; in diphtheria, 73 ; in erysipelas, 64 ; in gout, 992 ; in habitual headache, 531 ; in hyperpyrexia of rheumatism, 911 ; in hysteria, 812 ; in multiple sclerosis, 631 ; in myelitis, 627 ; in nephritis, 847, 864 ; in nephrolithiasis, 868 ; in neuralgia, 521 ; in neurasthenia, 818 ; in neuritis, 584, 585 ; in obesity, 996 ; in osteomalacia, 927 ; in pachymeningitis cervicalis hypertrophica, 603 ; in paralysis agitans, 787 ; in paralysis of the upper limbs, 568 ; in pneumonia, 205 ; in progressive bulbar paralysis, 600 ; in progressive paralysis of the insane, 767 ; in purulent meningitis, 701 ; in pyelitis, 884 ; in rachitis, 924 ; in railway spine, 827 ; in rheumatism (acute articular), 910, 911 ; in rheumatism (muscular), 919 ; in scarlet fever, 45 ; in smallpox, 60 ; in spasms of the respiratory muscles, 577 ; in tetanus, 794 ; in tetany, 791 ; in typhoid fever, 23.  
 Baths, electric, in neurasthenia, 818.  
 Beaded ribs in rickets, 923.  
 Bedsores in myelitis, 622.  
 Beer-drinkers, heart disease in, 313.  
 Belladonna in asthma, 172 ; in diabetes, 981 ; in epilepsy, 778 ; in whooping-cough, 163 ; poisoning from, 1008.  
 Bell's palsy, 558.  
 Benzine in trichinosis, 124 ; in whooping-cough, 163.  
 Beri-beri, 583 ; in Japan, 582 ; in United States, 582.  
 Biermer's change of note in pneumothorax, 269.  
 "Big-jaw" in cattle, 274.  
 Bile coloring matter, tests for, 467.  
 Bile-ducts, ascarides in, 445 ; cancer of, 402.  
 Bile in intestinal catarrh, 464 ; in typhoid fever, 11.  
 Biliary abscess, 474, 476 ; acids in the blood, 466 ; acids in the urine, 467.  
 Biliary colic, 470.  
 Biliary fistulæ, 473.  
 Billous remittent fever, 95.  
 Birth palsies, 567.  
 Bismuth, subnitrate of, in gastric catarrh, 382 ; in intestinal catarrh of children, 417, 418.  
 Bitters in gastric catarrh, 381 ; in scurvy, 960 ; in valvular cardiac disease, 307.  
 Black expectoration, 245.  
 Black vomit, 102.  
 Bladder, cancer of, 897 ; care of, in myelitis, 627 ; catarrh of, 893 ; diphtheria of, 894 ; " hæmorrhoids " of, 429 ; paralysis of, in injuries to spinal cord, 607 ; paralysis of, in locomotor ataxia, 643 ; paralysis of, in myelitis, 621 ; paralysis of, in pressure-paralysis of the spinal cord, 613 ; paralysis of, in progressive paralysis, 761 ; paralysis of, in spinal apoplexy, 606.  
 "Bleeders," 963.  
 Bleeding. See HÆMORRHAGE.  
 Bleeding in cerebral hæmorrhage, 736 ; in heart disease, 306 ; in pneumonia, 205 ; in sunstroke, 748.  
 Bleeding (local) for cerebral abscess, 743 ; for cerebral hæmorrhage, 736 ; for cerebral hyperæmia, 710 ; for cystitis, 806 ; for hæmatoma of the dura mater, 698 ; for hæmorrhage into the spinal meninges, 603 ; for infantile spinal paralysis, 677 ; meningitis, 108, 701 ; for pericarditis, 263 ; for

- tonitis, 456; for pneumonia, 305; for sciatica, 537; for typhilitis, 421.
- Blepharitis ciliaris, 1000.
- Blepharospasm, 573.
- Blindness from anæmia (amaurosis, anæmic), 932; from tumors of the brain, 751.
- Blisters for neuralgia, 519; for sciatica, 537.
- Blood-casts, 826, 827.
- Blood, changes in the, 924.
- Blood, character of, in anæmia, 935; in cancer of the stomach, 393; in chlorosis, 935; in cholera, 87; in diabetes, 965, 975; in gout, 984; in hæmoglobinuria, 953, 955; in hæmophilia, 963; in leukæmia, 947; in pernicious anæmia, 948; in pseudo-leukæmia, 952.
- Blood, poverty of the, 928.
- Blood-test, Heller's, 828.
- Blood, transfusion of, in leukæmia, 951; in pernicious anæmia, 945; in poisoning from carbonic oxide gas, 1007; in poisoning from nitrobenzine, 1008.
- Blood-vessels, affections of, 831.
- Blue line on gums in lead poisoning, 1005.
- Boils after small-pox, 56; in diabetes, 973, 976.
- Bones, growth of, in infantile spinal paralysis, 669; in rachitis, 921.
- Bones, lesions of, in leukæmia, 946, 948; in rickets, 921; in scrofula, 1000; in typhoid fever, 17; marrow of, in leukæmia, 946; in osteomalacia, 926; in pernicious anæmia, 940, 941; in pseudo-leukæmia, 952; pain in, in leukæmia, 948; in pernicious anæmia, 942; softening of, in osteomalacia, 926; in rachitis, 921.
- Borborogmi in intestinal catarrh, 405.
- Bothriocephalus latus, 440, 442.
- Botulismus, 1009.
- Bovine tuberculosis, 308.
- Brachial paralysis, 564; combined, 567; in acute ascending spinal paralysis, 675; peripheral, prognosis and treatment of, 567.
- Brachial spasm, 575.
- Brain, abscess of, 741; diagnosis, 743; distinguished from tumor of, encapsulated, 743; focal symptoms, 742; idiopathic, 741; metastatic, 741; traumatic, 741; treatment of, 743.
- Brain, anæmia of, 708; ætiology of, 709; symptoms of, 709; treatment of, 709.
- Brain and cord, multiple sclerosis of, 627, 744. See also MULTIPLE SCLEROSIS.
- Brain, atrophy of, in progressive general paralysis, 765.
- Brain, cancer of, 749; congestion of, 709; cortical centers of, 711; cysts in, 441, 756.
- Brain, diseases of, remarks in regard to topical diagnosis of, 710.
- Brain, echinococcus of, 756; foci of sclerosis in syphilis, 757.
- Brain, glioma of, hæmorrhages into, 749; situation of, 749.
- Brain, hyperæmia of, 708; symptoms of, 710; treatment of, 710.
- Brain in cerebro-spinal meningitis, 104; inflammation of, 741.
- Brain, oedema of, in uræmia, 831.
- Brain, porencephalus of, 745.
- Brain, psammoma of, 749; sarcoma of, 749.
- Brain, sclerosis of, 627, 744; diffuse, 744; insular, 627.
- Brain, softening of, red, yellow, and white, 737, 739; ætiology of, 737; diagnosis of, 740; idiopathic, 744; in tumor of, 752.
- Brain, syphilis of, 757; apoplectic symptoms in, 758; diagnosis of, 759; disease of arteries in, 757; hereditary, 757; new growths in, 758; symptoms of, 758.
- Brain, syphiloma of, 749; situation of, 757, 758.
- Brain, tubercle of, 749.
- Brain, tumors of, 748; at base, 752; cerebral compression caused by, 749; diagnosis of, 754; in the cerebellum, 753; in the cerebral hemispheres, 752; in the cortex, 752, 754; involving nerves at base, 752; medical treatment of, 755; originating in the meninges, 749, 754; surgical treatment of, 756; symptoms, general, 749; symptoms, localizing, 751; varieties, 748.
- Brand's method in typhoid fever, 22.
- Breakbone fever, 99.
- Breathing (see RESPIRATION); mouth, 356.
- Breath, odor of, in diabetic coma, 973.
- Brickmaker's anæmia, 448.
- Bright's disease, 822; acute, 836; diagnosis of, 845; ætiology of, 836; parenchymatous form of, 839; prognosis in, 845; symptoms of, 841; treatment of, 846.
- Bright's disease, chronic, 849, 856; cardio-vascular changes in, 853, 859; causes of, 849, 856; interstitial form of, 856; parenchymatous form of, 849; symptoms of, 852, 858; treatment of, 855, 863.
- Bromide of ammonium in epilepsy, 778.
- Bromide of potash in abscess of the brain, 746; in athetosis, 789; in bronchial asthma, 172; in chorea, 783; in diabetes, 981; in epilepsy, 777; in epileptiform attacks following cerebral paralysis of children, 746; in habitual headache, 532; in hysteria, 813; in infantile convulsions, 780; in neuralgia, 530; in neurasthenia, 818; in paralysis agitans, 787; in spasm of the face, 573; in spasm of the glottis, 143; in spasm of the muscles of mastication, 572; in spasm of the muscles of the neck, 575; in tetanus, 794; in tetany, 791; in whooping-cough, 163.
- Bromide of sodium in epilepsy, 778.
- Bromine, poisoning from, 1004.
- Bromism, 1004.
- Bronchi, casts of the, 158; dilatation of, 164; stenosis of, 167.
- Bronchial blennorrhœa, 152.
- Bronchial catarrh (see BRONCHITIS), 146, 151.
- Bronchiectasis, 164; cylindrical, 164; saccular, 164; sputum in, 165.
- Bronchiolitis, 148; exudative, 171.
- Bronchitis, acute, 146; ætiology of, 146; symptoms of, 147; treatment of, 150; capillary, 148; after whooping-cough, 161; asthmatic, 171.
- Bronchitis, chronic, 151; ætiology of, 151; symptoms of, 151; treatment of, 153.
- Bronchitis, croupous, 158; fibrinous, 158; fetid, 155; hæmorrhagic, 147; in children, 149; in erysipelas, 64; in gout, 987; in malaria, 94; in measles, 47, 49; in rachitis, 923, 924; in small-pox, 56; in typhoid fever, 12; in valvular cardiac disease, 396; pseudo-membranous, 158; putrid, 155; secondary, 146; symptomatic croupous, 158; tubercular, 213.

**Carbolic acid** in articular rheumatism, 910; in diabetes, 981; in erysipelas, 65; in scarlet fever, 44, 45; in whooping-cough, 163; poisoning from, 1008.  
**"Carbolic mask,"** 157.  
**Carbouluria**, 1008.  
**Carbuncle** in diabetes, 973.  
**Carbunculus contagiosus**, 117.  
**Carcinoma.** See **CANCER**.  
**Carcinosis**, miliary, of the lungs, 250; of the peritoneum, 463.  
**Cardiac.** See also **HEART**.  
**Cardiac compensation**, rupture of, 283.  
**Cardiac failure**, 283.  
**Cardiac murmurs**, anæmic, 933; in chlorosis, 935; in chorea, 782; in idiopathic anæmia, 942; in leukaemia, 949.  
**Cardiac murmurs**, organic, in aortic insufficiency, 287, 288; in aortic stenosis, 290; in congenital heart affections, 293, 294; in mitral incompetency, 283; in mitral stenosis, 285; in tricuspid valve disease, 292.  
**Cardiac muscle**, atrophy of, from pericarditis, 326, 327; cloudy swelling of, 16, 298; fatty degeneration of, 313; lesions of, 298.  
**Cardiac neuroses**, 318; overstrain, 312.  
**Cardiac septa**, anomalies of, 394.  
**Cardialgia** in gastric ulcer, 385; in malaria, 95.  
**Cardio-sclerosis**, 307.  
**Cardio-vascular changes** in renal disease, 884, 888.  
**Carotids**, aneurism of, 339; compression of, in epileptic paroxysms, 778; ligature and compression of, in cerebral hæmorrhage, 786.  
**Caseation**, 213.  
**Castoreum** in hysteria, 813.  
**Castration** for hysteria, 813.  
**Casts of bronchial tubes** in fibrinous bronchitis, 158.  
**Casts of urinary tubules**, 826; epithelial, 827; fatty, 827; granular, 827; hyaline, 826; waxy, 827.  
**Casts, tube**, in acute Bright's disease, 842; in chronic Bright's disease, 852, 859.  
**Catalepsy**, 796; hypnotic, 796; hysterical, 796; in cerebral disease, 797; in connection with psychoses, 797.  
**Cataract** in diabetes, 972.  
**Catarrh**, acute gastric, 372; bronchial, 146; chronic bronchial, 151; chronic gastric, 374; chronic laryngeal, 132; dry bronchial, 152; gastro-duodenal, 464; nasal, 125; of the bladder, 893; simple chronic (nasal), 126.  
**Catarrhal inflammation**, influence in tuberculosis, 210.  
**Catarrhe pituiteux**, 152; see, 152.  
**Catarrhus æstivus**, 125.  
**Cathartics** in anæmia and chlorosis, 938; in cerebral hæmorrhage, 786; in cerebral hyperæmia, 710; in cirrhosis of the liver, 483; in dysentery, 80; in hæmatoma of the dura mater, 698; in hæmophilia, 965; in infantile convulsions, 779; in intestinal catarrh, 409; in locomotor ataxia, 648; in trichinosis, 123.  
**Catheterization** in myelitis, 627.  
**Cat's purr**, 284, 286.  
**Caustic potash**, poisoning from, 1004; **soda**, poisoning from, 1004.  
**Cautery**, actual, in acute ascending spinal paralysis, 676; in neuralgia, 519; in pachymeningitis cervicalis hypertrophica, 608; in pressure paralysis of the spinal cord, 614; in spasm of the muscles of the face, 573; in spasm of the muscles of the  
575.  
**Cavities and fissures in the spinal cord**, 677.  
**Cavities**, pulmonary, physical signs of, 1  
**Centrum ovale**, lesions of, as a cause of  
sia, 721; as a cause of hemiplegia, 721

- hemiplegia, 721; as a cause of monoplegia, 721; as a cause of word deafness, 721.
- Cephalæa (see HEADACHE, HABITUAL), 530.
- Cephalalgia (see HEADACHE, HABITUAL), 530.
- Cerebellar, ataxia, 723; vertigo, 723, 724.
- Cerebellum, tumors of, 753.
- Cerebral arteria, aneurism of, 725; arterio-sclerosis of, 725; endarteritis of, 725; syphilitic endarteritis of, 757; syphilis of, 757; syphilis of, as a cause of apoplectic attacks, 758; syphilis of, as a cause of cerebral softening, 738, 757; syphilis of, histology of, 757.
- Cerebral embolism, 737; in gout, 988; repeated attacks caused by, 740.
- Cerebral hemorrhage, 725; ætiology of, 725; aneurisms, miliary, in, 725; as a cause of cerebral hemiplegia, 731; convulsions in, 729; diagnosis of, 736; focal symptoms of, 731; hereditary tendency to, 726; in arterio-sclerosis, 726; in gout, 736; in tumors of the brain, 750; in valvular cardiac disease, 801; morbid anatomy of, 736; prognosis in, 736; symptoms of, 727; treatment of, 736; usual situation of, 726.
- Cerebral localization, 710.
- Cerebral meninges, diseases of, 696.
- "Cerebral rheumatism," 906.
- Cerebral sinuses, thrombosis of, 707.
- Cerebral symptoms in contracted kidney, 861, 862; in gout, 988; in nephritis, 831, 832; in pneumonia, 198; in pseudo-leukæmia lymphatica, 952; in purpura hæmorrhagica, 962; in relapsing fever, 32; in scarlet fever, 37; in septicæ-pyæmia, 111.
- Cerebral tuberculosis, 749, 755; symptoms of, 749.
- Cerebro-spinal meningitis, epidemic (see also MENINGITIS), 103; anomalous forms of, 107; complications of, 106; distinguished from tubercular meningitis, 107; encephalitic foci in, 104; malignant form, 104; sequelæ of, 107; treatment of, 108; varieties of, 105, 107.
- Cervical muscles, paralysis of, 562; in acute ascending spinal paralysis, 675; resulting from stasis, 677.
- Cervical muscles, spasm of, 574, 575; in hysteria, 804; prognosis of, 574; treatment of, 574.
- Cervical pachymeningitis, 602.
- Cervico-brachial neuralgia, 524.
- Cervico-occipital neuralgia, 523.

- Children, diabetes in, 967; pneumonia in, 200; rheumatism in, 900; broncho-pneumonia in, 185; tuberculosis of mesenteric glands in, 424; typhoid fever in, 4.
- Chloral in chorea, 783; in diabetes, 981; in eclampsia, 780; in neuralgia, 520; in tetanus, 794; in trigeminal neuralgia, 523.
- Chlorine gas, poisoning from, 1004.
- Chloro-anæmia in phthisis, 936.
- Chloroform in epilepsy, 778; in hepatic colic, 475; in hysteria, 804; in infantile convulsions, 779; in renal colic, 888; in spasms of the diaphragm, 577.
- Chloroform, poisoning from, 1007.
- Chloroform test for bile, 467.
- Chlorosis, 928, 934; diagnosis of, 936; distinguished from gastric diseases, 930; distinguished from renal diseases, 931; distinguished from syphilis, 931; distinguished from tuberculosis, 941, 936; Egyptian, 448; chlorosis, ætiology of, 928, 929; fever in, 934; heart symptoms in, 933; menstrual disturbance in, 935; morbid anatomy of, 933, 935; relapses of, 936; symptoms of, 934; treatment of, 936; with regard to sexual disturbances, 929, 935.
- Choked disk. See NEURITIS, OPTIC.
- Cholæmia, 468, 499.
- Cholelithiasis, 470.
- Cholera (Asiatic), 81; asphyxia in, 84; bacillus of, 82; complications of, 86; contagiousness of, 82; dejections in, 84; diagnosis of, 84; distinguished from acute arsenical poisoning, 87; eruption in, 86; exciting causes of, 83; period of incubation in, 84; post-mortem appearances in, 86; predisposition to, 83; prognosis of, 88; specific poison of, 82; treatment of, 88.
- Choleraic diarrhœa, simple, 84; premonitory, 84.
- Choleraic nephritis, 86.
- Choleraic typhoid, 86; uræmic, 86.
- Cholera morbus, 410; diagnosis of, 412; mortality in, 412; treatment of, 412; cholera nostras, 410; cholera sicca, 85; cholera typhoid, 86.
- Cholerine, 84.
- Cholesterine, calculi formed of, 471.
- Cholesterine and pigment, calculi formed of, 471.
- Chorditis tuberosa, 133.
- Chorditis vocalis inferior hypertrophica, 133.
- Chorea, 780; ætiology of, 780; as related to chorea major, 780; as related to embolic processes, 783; complications of, 780, 782; diagnosis of, 783; gravidarum, 781; in articular rheumatism, 780; nature and situation of the disease, 782; predisposition to, 780; premonitory symptoms of, 781; prognosis of, and treatment, 783; relapses in, 782; unilateral, 781.
- Chorea, endemic, 780; major, 780; rhythmic or hysterical, 810; Sydenham's, 780.
- Chorea, heart symptoms of, 782; infectious origin of, 780; seasonal relations of, 780.
- Chorea, Huntington's or hereditary, 780.
- Chorea, spasm, 573, 576, 810.
- Choroid, tubercles in, 240.
- Choroid, tuberculosis of the, in meningitis, 704.
- Chyluria, parasitic, 875.
- Cicatrices of the œsophagus, 366; of the œsophagus from sulphuric acid, 1003.
- Cicatricial induration caused by syphilis of the brain, 757.
- Cinchona, in purpura hæmorrhagica, 962; in scurvy, 961.
- Circulatory system, diseases of, 276.
- Circumcision, dangerous in hæmophilia, 964.
- Circumflex nerve, affections of, 564, 574.
- Cirrhosis, hypertrophic, of the liver, 483.
- Cirrhosis of kidney, 856; of liver, 478; of lung, 223; of pancreas, 504.
- "Clap-threads" in cystitis, 895.
- Clavicles, deformed, in rachitis, 923.
- Claw-shaped hand, 566.
- Climate, change of, in asthma, 172; in chronic

- Bright's disease, 855; in pulmonary tuberculosis, 232, 233.
- Clitoris, cauterization of, in hysteria, 813.
- Clonus, 545.
- Clownism in hysteria, 808.
- Club-foot resulting from infantile spinal paralysis, 869.
- Coagulation necrosis, 213.
- Coccydynia, 528; in locomotor ataxia, 528, 643; operative removal of coccyx for, 528.
- Cod-liver oil in diabetes, 979; in osteomalacia, 927; in pulmonary tuberculosis, 232; in rachitis, 925; in scrofula, 1001.
- Coffee-ground vomit, 392.
- Coin sound, 269.
- Colchicum in articular rheumatism, 910; in gout, 992.
- Cold pack, method of giving, 188.
- Colic, biliary, 470; hepatic, 470; in angio-neurotic oedema, 588; lead, 1005; renal, 884.
- Collapse stage, in cholera, 85; in cholera morbus, 411; in hepatic colic, 472; in peritonitis, 454; in pneumonia, 196; in pneumothorax, 268; in typhoid fever, 8, 26.
- Colloid cancer of peritoneum, 463; of stomach, 391.
- Colon, cancer of, 426.
- Colo-typhoid, 9.
- Columns, posterior, gray degeneration of, 632.
- Coma, diabetic, 973; causes of, 974; treatment of, 981.
- Coma, epileptic, 773; from heat stroke, 747; in abscess of the brain, 742; in acute yellow atrophy, 487; in alcoholic poisoning, 1006; in apoplexy, 729; in cerebral hæmorrhage, 729; in cerebral syphilis, 758; in multiple sclerosis, 630; in pernicious malaria, 94; in thrombosis of the cerebral sinuses, 707; in typhus fever, 30; in uræmia, 832, 834.
- Coma, post-epileptic, 773.
- Coma-vigil, in typhoid fever, 14.
- Comma bacillus, 82.
- Commotio spinalis, 819.
- Compensation in valve lesions, 232.
- Complexion in anæmia, 931, 934, 941; in diabetic coma, 973; in leukæmia, 949; in pseudo-leukæmia, 932.
- Compression as a cause of thrombosis, 502.
- Compression of the medulla oblongata, 695; diagnosis and prognosis of, 695.
- Compression of the œsophagus, 306.
- Conchicine in malaria, 97.
- Concretio pericardii, 326.
- Concussion of spinal cord, 819.
- Congenital heart affections, 293.
- Congo-red test for free acid, 378.
- Conjugate deviation in hemiplegia, 729.
- Conjunctivitis in difficult dentition, 351; in diphtheria, 69; in gout, 987; in measles, 48; in scarlet fever, 41; in scrofula, 1000; in whooping-cough, 160.
- Conscience musculaire, 509, 802.
- Constipation, habitual, 430; in diseases of the nervous system, 430; treatment of, 431.
- Constipation in anæmia and chlorosis, 932; in cases of cerebral tumor, 751; in cirrhosis of the liver, 480; in gastric catarrh, 379; in intestinal stenosis, 435; in jaundice, 460; in locomotor ataxia, 643; in myelitis, 621; in typhilitis, 419; in typhoid fever, 9.
- Constitutional diseases, 923.
- Consumption. See TUBERCULOSIS.
- Consumption, galloping, 217.
- Contracted kidney, 856; embolic, 872; genuine, 856; in arterio-sclerosis, 857; in gout, 856, 987; in obesity, 906; secondary, 849, 856.
- Contractions, rhythmical, 540.
- Contracture des nourrices, 789; hysterical, 803; in hemiplegia, 734.
- Convulsions, cataleptic, 541; epileptiform, 540, 764, 770, 773.
- Convulsions, epileptic, 771; hysterical, 806; in acute yellow atrophy, 487; in alcoholism, 1006; in cerebral embolism, 739; in cerebral hæmorrhage, 729; in cerebral hydatids, 756; in cerebral syphilis, 758; in cerebral tumors, 750; in chronic Bright's disease, 831; in compression of the medulla, 695; in diffuse sclerosis of the brain, 744.
- Convulsions, infantile, 779; diagnosis of, 779; etiology of, 779; relation to rickets, 779; symptoms of, 779; treatment of, 779.
- Convulsions in focal lesions of the cortex, 714, 724; in general paralysis, 764; in hæmatoma of the dura mater, 697; in hepatic colic, 472; in hydrophobia, 114; in hysteria, 806; in infantile cerebral paralysis, 744; in infantile spinal paralysis, 668; in meningitis, 700, 704; in multiple sclerosis, 630; in sunstroke, 747; in thermic fever, 747; in uræmia, 831; Jacksonian, 714.
- Convulsive tic, 573.
- Co-ordination, disturbance of, in tabes, 639.
- Copaiba, balsam of, in cirrhosis of the liver, 483; in cystitis, 896.
- Copaiba, resin of, in cirrhosis of the liver, 483.
- Copper, paralysis due to, 571; poisoning from, 1005; sulphate of, in chorea, 788; test for sugar, 968.
- Coprolalia, 573.
- Coprostasis, 432.
- Cor adiposum, 315.
- Cor villosum, 322.
- Coronary arteries, in angina pectoris, 306, 318; obliteration, 308.
- Corpora quadrigemina, lesions of, 722; as a cause of ocular disturbances, 722, 725; tumors in, 753.
- Corpulence, 992.
- Corrigan's pulse, 269.
- Corset-liver, 499.
- Coryza, 125; fever caused by, 126; foetida, 127; from the iodides, 125.
- Cortical epilepsy, 714.
- Costiveness, 430.
- Cough, during aspiration of pleural effusion, 206; hysterical, 577; in pertussis, 160; paroxysmal, in bronchiectasis, 164; spasmodic, 577.
- Cow's milk as food for infants, 411.
- Cow-pox, 58.
- Cracked-pot sound, 222.
- Cramps in cholera, 85.
- Cramps in the legs, 575; after severe physical exercise, 575; in hysteria, 575; liability to, 575.
- Cranimetric anomalies in the epileptic, 775; in the rachitic, 923.
- Craniotabes, in rachitis, 923; relation (alleged) to congenital syphilis, 921.
- Cranium, in osteomalacia, 927; in rachitis, 923.
- Creasote in gastric catarrh, 381; in intestinal catarrh of children, 417; in tuberculosis of the lungs, 231.
- Cremaster reflex, 543; in cerebral hæmorrhage, 732.
- Crepitant râles in croupous pneumonia, 195.
- Crepitatio redux, 195.
- Crescents in blood in malaria, 92.
- Crises, gastro-intestinal, 643; in locomotor ataxia, 643.

- Crisis**, in pneumonia, 199; in typhus fever, 29.
- Croup**, 65; ascending, 68; relation to diphtheria, 68.
- Croup, false**, 131.
- Croupous pneumonia**, 189.
- Crura cerebri**, lesions of, 723.
- Crural, anterior, paralysis of**, 568.
- Cry, cephalic**, 705.
- Crystals, Leyden's**, 169.
- Cundurango bark** in cancer of the stomach, 895.
- Cups, dry**, in acute ascending spinal paralysis, 676; in pressure paralysis of the spinal cord, 614.
- Curare** in paralysis agitans, 787; in spasms of the facial muscles, 573; in tetanus, 794; in tetany, 791.
- Curschmann's spirals**, 169.
- Cutaneous**. See also SKIN.
- Cutaneous abscesses** in erysipelas, 64.
- Cutaneous anæsthesia**, 510; bilateral, 511; cerebral, 510, 512; in diseases of the internal capsule, 721, 725; in hysteria, 512, 800; in laundresses, 511; in locomotor ataxia, 511; painful, 512; peripheral, 510, 511; spinal, 510, 511; symptoms of, 512; treatment of, 514.
- Cutaneous ecchymoses** in articular rheumatism, 904; in typhoid fever, 17.
- Cutaneous reflexes**, 543; diminution or absence of, 544; exaggeration of, 544; in cerebral hæmorrhage, 732; in epilepsy, 773; in infantile spinal paralysis, 669; in locomotor ataxia, 641; in myelitis, 620; in poliomyelitis of adults, 672; in pressure paralysis of the spinal cord, 612; in tetanus, 792; in the extremities, 543; sluggishness of, 543.
- Cutaneous sensibility, electro-**, 508.
- Cutaneous sensibility**, in locomotor ataxia, 639; in tubercular meningitis, 704; varieties, and modes of testing, 505.
- Cyanosis**, in acute tuberculosis, 237; in congenital heart disease, 293, 294; in emphysema, 176, 177; in epileptic paroxysms, 772; in stenosis of the pulmonary orifice, 293.
- Cynanche contagiosa**, 65; gangrenosa, 349.
- Cystic disease**, of kidney, 874; of liver, 494.
- Cystic duct, obstruction of**, 473.
- Cysticercus cellulose**, 441; in the brain, 756.
- Cysticercus racemosus**, 441.
- Cystine, calculi composed of**, 885.
- Cystitis**, 893; ætiology of, 893; chronic, 895; complications of, 896; in locomotor ataxia, 643; in myelitis, 621; in pressure paralysis of the spinal cord, 613; in spinal apoplexy, 605; symptoms, 894; treatment of, 896; tuberculous, 888; varieties, 894.
- Cysts**, in kidneys, 874; of brain, apoplectic, 727; of brain, thrombotic, 739; of larynx, 144; pancreatic, 504; porencephalic, 745.
- Dancing mania**, 780.
- Dandy fever (dengue)**, 99.
- Deaf-mutism after cerebro-spinal fever**, 107.
- Deafness**, in cerebral tumor, 753, 754; embolism and thrombosis of the basilar artery, 694; in epidemic cerebro-spinal meningitis, 107; in epilepsy, 772; in hysteria, 801; in lesions of the centrum ovale, 721; in locomotor ataxia, 643; in Ménière's disease, 769; in scarlet fever, 40; in uræmia, 832.
- Debility, nervous**, 815.
- Decubitus, acute malignant**, in hemiplegia, 735; (bed-sores) in transverse myelitis, 622 (treatment) 627.
- Decubitus laryngis** in typhoid, 13.
- Degeneration, fatty**, in acute phosphorus poisoning, 1006; in acute yellow atrophy, 486; in anæmia, 933, 940; in typhoid fever, 16; of the heart, 315; of the liver, 486, 498.
- Degeneration, parenchymatous**, in typhoid fever, 11, 16; of the kidney, 839.
- Degeneration, physical signs of**, in epileptics, 775.
- Degeneration, reaction of**, 551; anatomical changes in nerves and muscles in, 553; complete, 552; in amyotrophic lateral sclerosis, 652; in infantile spinal paralysis, 669; in lead paralysis, 570; in myelitis, 622; in paralysis of the deltoid, 564; in paralysis of the facial, 560; in poliomyelitis of adults, 672; in progressive bulbar paralysis, 687; in progressive muscular atrophy, 656; in secondary neuritis, 582; partial, 551.
- Degeneration, sclerotic, of the heart**, 307.
- Deglutition, impairment of**, in acute bulbar myelitis, 694; in acute bulbar paralysis, 692; in amyotrophic lateral sclerosis, 652; in chronic poliomyelitis, 673; in compression of the medulla, 695; in dilatation of the œsophagus, 363; in diphtheria, 70; in laryngeal catarrh, 131; in pericarditis, 325; in progressive bulbar paralysis, 686; in progressive muscular atrophy, 657; in pseudo-leukæmia lymphatica, 932; in thoracic aneurism, 337; in tonsillitis, 353; in trichinosis, 122.
- Deglutition, paralysis of**, in bulbar hæmorrhage, 692; in embolism and thrombosis of the basilar artery, 694; in hysteria, 808; in progressive general paralysis, 764.
- Deglutition pneumonia**, 185.
- Delayed resolution in pneumonia**, 202.
- Delayed sensation in tabes**, 640.
- Delirium, acute**, in lead poisoning, 1006; expansive, 763; in acute rheumatism, 906; in acute yellow atrophy, 487; in cerebral hæmorrhage, 738; in dengue, 100; in diabetes, 973; in hysteria, 807, 809; in meningitis, 105, 700, 705; in pneumonia, 198; in pyelphlebitis suppurativa, 501; in typhoid fever, 14; in typhus fever, 30.
- Delirium tremens**, 1007; in croupous pneumonia, 198.
- Delivery paralysis**, 567.
- Deltoid paralysis**, 564.
- Delusions of grandeur**, 763.
- Dementia from epilepsy**, 775.
- Dementia paralytica**, 760.
- Dengue**, 99.
- Dentitio difficilis**, 350.
- "Desiccation"** in small-pox, 54; in the treatment of obesity, 999.
- Desquamation**, in measles, 47; in scarlet fever, 41; in small-pox, 54; in typhoid fever, 17.
- Diabetes inositus**, 983.
- Diabetes insipidus**, 982; heredity in, 982, 983; related to diabetes mellitus, 976, 982; related to polyuria, 982.
- Diabetes mellitus**, 965; "accidental," 967; coma in, 973; complications of, 967, 971, 972; decipiens, 968; diagnosis of, 977; gangrene in, 973; hereditary influences in, 967; intermittent, 976; in children, 967; in obesity, 976; pancreas in, 966, 967; related to glycosuria, 976; theories of, 976; treatment of, 978; urine in, 967.
- Diagnosis, topical**, in brain diseases, 710.
- Diaphoresis** for bronchitis, 150; for nephritis, 847.
- Diaphragm, paralysis of the**, 568; in acute inflammatory bulbar paralysis, 694; modifying the movements of respiration, 568; treatment of 568.

- Diaphragm, spasm of, clonic, 577; in hysteria, 810; tonic, 576.
- Diarrhoea, in cholera Asiatica, 84; in cholera morbus, 411; in cirrhosis of the liver, 480; in dysentery, 78; in exophthalmic goitre, 597; in gastric catarrh, 379; in hysteria, 805; in intestinal catarrh, 404; in locomotor ataxia, 648; in noma, 347; in pneumonia, 197; in pulmonary gangrene, 243; in pulmonary tuberculosis, 227; in pyelophlebitis, 501; in rachitis, 924; in septico-pyæmia, 112; in typhoid fever, 9; in uræmia, 832; in whooping-cough, 162.
- Diathesis, gouty, 991.
- Diathesis, hæmorrhagic, in acute articular rheumatism, 904; in anæmia, 934; in jaundice, 466; in scurvy, 968.
- Diazo-reaction in typhoid fever, 18.
- Microtism of the pulse in typhoid fever, 16.
- Diet, in chronic gastric catarrh, 380; in constipation, 431; in diabetes, 978; in gout, 990; in infantile diarrhoea, 415; in obesity, 907; in scurvy, 960; in tuberculosis, 232; in typhoid fever, 22.
- Digestive system, diseases of, 341.
- "Digitalis eaters," 305.
- Digitaria in nephritis, 848; in pericarditis, 328; in pleurisy, 264; in pulmonary emphysema, 130; in typhoid fever, 26; in valvular cardiac disease, 304; poisoning from, 1008.
- Dilatation, bronchial, 164; stomacic, 306.
- Diphtheria, 65; and croup, 65, 68; bacillus of, 66; contagiousness of, 67; diagnosis of, 70; gangrenous, 69; in animals, 67; in measles, 49; laryngeal, 68; nephritis in, 70; neuritis in, 70; of nares, 68; prognosis of, 71; septic, 66; symptoms of, 67; systemic infection, 69; treatment of, 71.
- Diphtheritic colitis, 77, 78.
- Diplegia, facial, 690.
- Diplococcus pneumoniæ, 189.
- Diplopia, 553; in multiple sclerosis, 630.
- Disease, trichinatus, 121.
- Disinfection in infectious diseases, 26; in typhoid fever, 26.
- Dislocation, paralysis of the upper arm following, 564.
- Displacement, symptoms resulting from, of other organs, in pleurisy, 280; in pneumonia complicated by pleurisy, 196; in pneumothorax, 269.
- Dissecting aneurism, 340.
- Distoma hæmatobium, 874.
- Disuse, atrophy from, 622.
- Dittrich's plugs, 156.
- Diuretics in cirrhosis of the liver, 483; in nephritis, 848; in pleurisy, 264; in pulmonary emphysema, 180; in valvular cardiac disease, 306.
- Diverticula of the œsophagus, 363.
- Dochmius duodenalis, 448.
- Dorso-intercostal neuralgia, 324.
- Double vision, 553.
- Douche, cold, in cutaneous anæsthesia, 515; in diabetes, 980; in hysteria, 812; in neuralgia of the joints, 539; in neurasthenia, 818; in scarlet fever, 45; in spasm of the diaphragm, 577.
- Drainage and diphtheria, 67; and tonsillitis, 351; and typhoid fever, 3.
- Drinker's, gin, liver, 478.
- Drinking water as a cause of cholera, 83; of typhoid fever, 3.
- Dropsy. See also (Едемъ).
- Dropsy, cardiac, treatment of, 306; in amyloid disease of the kidney, 867; in aortic insufficiency, 290; in cancer of stomach, 393; in mitral insufficiency, 284; in mitral stenosis, 287; in phthisis, 229; in renal diseases, 828, 843, 853, 860; in scarlet fever, 41, 42; in typhoid fever, 16; in valvular cardiac disease, 299.
- Dropsy, intermittent, of the joints, 590.
- Dropsy of the gall-bladder, 473.
- Duchenne's paralysis, 686.
- Dullness, movable, in pleural effusion, 260; in pneumothorax, 269.
- Dumb ague, 94, 95.
- Duodenal ulcer, diagnosis of, from gastric, 423.
- Duodenum, cancer of the, 426; catarrh of the, 406, 464; fistula of the, 473, 474; ulcer, perforating, of the, 423.
- Dura mater, diseases of, 696; hæmatoma of, 696.
- Durando's remedy for biliary calculi, 475.
- Duroziez's double murmur, 290.

 Elastic tissue in sputum, 219.  
 Electrical reactions in facial palsy, 560, 561; in idiopathic muscular atrophy, 660, 662; in Landry's paralysis, 674; in multiple neuritis, 583; in poliomyelitis anterior, 669; in Thomsen's disease, 793.  
 Electricity in acute ascending spinal paralysis, 676; in acute bulbar paralysis, 695; in amyotrophic lateral sclerosis, 653; in anaesthesia of the trigeminus, 515; in anomalies of the sense of smell, 533; in anomalies of the sense of taste, 534; in articular neuroses, 529; in articular rheumatism, 911; in asthma, 172; in athetosis, 789; in cerebral abscess, 743; in cerebral hæmorrhage, 737; in cerebral syphilis, 760; in cervico-brachial neuralgia, 524; in chorea, 783; in chronic poliomyelitis, 674; in cutaneous anaesthesia, 515; in diabetes, 981; in dilatation of the stomach, 400; in epilepsy, 778; in exophthalmic goitre, 598; in facial paralysis, 562; in facial spasm, 573; in habitual constipation, 431; in habitual headache, 532; in hemicrania, 593; in hysteria, 812; in incontinence of urine, 898; in infantile cerebral paralysis, 745; in intercostal neuralgia, 525; in lead paralysis, 570; in locomotor ataxia, 647; in mastodynia, 535; in multiple sclerosis, 631; in muscular rheumatism, 919; in myelitis, 626; in nervous dyspepsia, 403; in neuralgia, 519; in neurasthenia, 818; in neuritis, 584; in occipital neuralgia, 523; in pachymeningitis cervicalis hypertrophica, 603; in paralysis of the diaphragm, 568; in paralysis of the motor branch of the trigeminus, 558; in paralysis of the ocular muscles, 557; in peripheral paralysis of the arm, 567; in pressure paralysis of the spinal cord, 614; in progressive muscular atrophy, 658; in progressive bulbar paralysis, 690; in progressive general paralysis, 767; in pseudo-muscular hypertrophy, 663; in railway spine, 821; in sciatica, 527; in spasm of the diaphragm, 577; in spasm of the muscles of the neck, 574; in spasm of the muscles of the shoulder, 575; in spasm of the trigeminus, 571; in spastic spinal paralysis, 666; in splenic leukaemia, 951; in tetany, 791; in unilateral progressive facial atrophy, 594; in writer's cramp, 579.  
 Electricity used to test sensibility, 508.  
 Electro-cutaneous sensibility, 508.  
 Electrolysis in aneurism, 338.  
 Embolic processes in the lungs, 247.  
 Embolism and thrombosis of the basilar artery, 693; a cause of softening of the medulla and pons, 693; ætiology of, 693; symptoms of, 693; treatment of, 694.  
 Embolism in chorea, 783; in typhoid fever, 16; of cerebral arteries, 737; of cerebral arteries, diagnosis of, 740.  
 Emetics in bronchitis, 151; in dysentery, 80; in infantile convulsions, 779; in pulmonary oedema, 184.  
 Emotion, convulsive expressions of, in hysteria, 807.  
 Emphysema, 173; acute, 162; atrophic, 173; compensatory, 175; complementary, 175; connected with whooping-cough, 162, 175; diagnosis of, 179; essential, 173; followed by pulmonary tuberculosis, 179; hypertrophic, hereditary character of, 174; interlobular, 175; interstitial, 175; prognosis of, 179; treatment of, 180; vesicular, 175; vicarious, 175.  
 Empyema, 262; necessitatis, 256; perforation of lung in, 262; terminations of, 263; treatment of, 264.  
 Encephalitis, curable form of, 744; in children, 744; non-purulent, 743; purulent, 741.  
 Encephalomalacia, 737.  
 Encephalopathy, lead, or saturnine, 1005; syphilitic, 758.  
 Enchondroma of the lungs, 250.  
 Endarteritis chronica deformans, 331.  
 Endocarditis, acute, 276; acute recurrent, 279; chronic, 280; diagnosis of, 279; diphtheritic, 277; ætiology of, 276; foetal, 277; in articular rheumatism, 276, 908; in chorea, 782; infectious, 276; in gonorrhoea, 276; in pneumonia, 197; in septicæmia, 111, 276; in tuberculosis, 228; malignant, 278; prognosis of, 280; recurring, 277, 279; rheumatoid, 278; ulcerative, 277; verrucosa, 277.  
 Endothelial carcinoma of the pleura, 272.  
 Enemata of cold water in jaundice, 469.  
 "English disease," 920.  
 Engouement, 190.  
 Enteric fever (see TYPHOID FEVER), 1.  
 Enteritis catarrhalis, 403; in children, 413; membranous or tubular, 408.  
 Enteroliths as a cause of appendicitis, 418, 419.  
 Enuresis nocturna, 898.  
 Eosinophilous blood-globules, 948.  
 Epidemic of typhoid fever in Plymouth, Pa., 4.  
 Epidermis, desquamation of, in scarlet fever, 41; in measles, 47; in smallpox, 54; in typhoid fever, 17.  
 Epilepsy, 770; ætiology of, 770; cortical, 714; diagnosis of, 776; diurnal, 774; heredity in, 770; in general paresis, 764; in lead poisoning, 1005; in regard to cerebral anaemia, 776; in regard to sudden somnolence, 773; in regard to teething convulsions, 774; Jacksonian, 714; masked, 773; nocturnal, 774; occurrence of various forms of, 771; precursive, 773, 774; reflex, 771; seat of the disease, 775; surgical treatment of, 777; traumatic, 771; treatment, 777.  
 Epileptic paroxysm, 771; aura preceding the, 771; convulsive stage of, 772; frequency of, 774; in progressive general paralysis, 764; rudimentary forms of, 773.  
 Epileptoid confusion of intellect, 773; sweating, 774.  
 Epistaxis, 129; in hæmophilia, 964; in scurvy, 129; in typhoid fever, 129; "renal," 802; vicarious, 129.  
 Erethitic habitus, 1000.  
 Ergot (ergotine) in acute ascending spinal paralysis, 676; in aneurism of the thoracic aorta, 438; in diabetes insipidus, 984; in exophthalmic goitre, 598; in habitual headache, 532; in hæmophilia, 965; in hemicrania, 593; in locomotor ataxia, 643; in myelitis, 627; in neuralgia, 520; in paralysis agitans, 787; in poliomyelitis of adults, 672; in progressive general paralysis, 767; in pulmonary tuberculosis, 235; in purpura hæmorrhagica, 962; in spastic spinal paralysis, 667; in spinal apoplexy, 605; poisoning from, 1009; psychoses due to, 1009.  
 Ergotism, 1009; convulsive, 1009; gangrenous, 1009.  
 Erosion, ulcers due to, in laryngeal catarrh, 130, 133.

- Eruptions** in anæmia, 932, 942; in diabetes, 967; in intestinal obstruction, 435; in peritonitis, 454.
- Eruption**, acute, in scarlet fever, 37; hæmorrhagic, in small-pox, 57.
- Erysipelas**, 61; abscess in, 64; after vaccination, 59; bullous, 63; complications of, 64; contagiousness of, 62; diagnosis of, 64; facial, 61; Fehleisen's streptococcus of, 62; gangrenous, 63; idiopathic, 61; inoculation of, 68; in small-pox, 56; migratory, 63; of the new-born, 61; prognosis of, 64; puerperal, 61; pustulous, 63; traumatic, 61; treatment of, 64; vesicular, 63.
- Erythema exsudativum**, 963.
- Erythromelalgia**, 588.
- État de mal**, 774.
- Eucalyptus**, oil of, in splenic leukæmia, 950.
- Eustrongylus gigas**, 875.
- Exaltation of ideas** in general paresis, 763.
- Exophthalmic goitre**, 595; acute form, 597; ætiology of, 595; diagnosis of, 597; diminution of electrical resistance in, 597; examination of heart in, 595; "Graefe symptom" in, 596; nervous symptoms in, 596, 597; pigmentation in, 597; treatment of, 598; tremor in, 596; urticaria in, 597.
- Exophthalmus** in exophthalmic goitre, 596; in paralysis of the motores oculi, 556.
- Expectorants** in bronchitis, 151, 154; in pneumonia, 188, 206; in pulmonary emphysema, 180; in pulmonary tuberculosis, 234.
- "**Expectoration albumineuse**" in pleurisy, 266.
- Expectoration** in asthma, 168, 169; in bronchiectasis, 165; in bronchitis, 147, 151, 156; in laryngeal catarrh, 131, 133; in pleurisy, 257; in pneumonia, 186, 193; in pulmonary cancer, 251; in pulmonary emphysema, 176; in pulmonary gangrene, 242; in pulmonary tuberculosis, 218.
- Eye**, motor nerves of, paralysis of, 555.
- Eye-strain** in migraine, 591.
- Eyes**. See also OCULAR and OPHTHALMIA.
- Eyes**, conjugate deviation of, in cerebral hæmorrhage, 729.
- Eyes**, disorders of, in acute bulbar paralysis, 604; in acute hydrocephalus, 703; in anæmia, 932, 942; in cerebral hæmorrhage, 729; in cerebral tumors, 751; in chorea, 781; in chronic hydrocephalus, 768; in diabetes, 972; in hæmatoma of the dura mater, 697; in hemispheres, 592; in hysteria, 801; in lesions of the central ganglia, 722; in lesions of the corpora quadrigemina and crura cerebri, 722; in lesions of the occipital cortex, 715; in leukæmia, 949; in locomotor ataxia, 635, 642; in measles, 48; in meningitis, 105, 700, 704; in miliary tuberculosis, 239; in multiple sclerosis, 630; in progressive bulbar paralysis, 687; in relapsing fever, 35; in septicopyæmia, 111; in thrombosis of the cerebral sinuses, 707; in trichinosis, 123.
- Face-ache**, Fothergill's, 521.
- Facial atrophy**, unilateral progressive, 594; paralysis, 558; ætiology of, 558; diagnosis of, 561; in acute bulbar paralysis, 604; in cerebral hæmorrhage, 731; in cerebral tumor, 752; in compression of the medulla oblongata, 695; in hæmorrhage into the medulla oblongata, 692; in progressive bulbar paralysis, 686; mimetic, 558; symptoms of, 558; through cold, 558; treatment of, 561; varieties, 559.
- Facial spasm**, clonic, 573; in epilepsy, 772; in meningitis, 105; treatment of, 573; spasm, mimetic, 572; spasm, tonic, in tetanus, 792.
- Fæcal concretions**, 418, 419; vomiting, 435.
- Fæces**, in disease of pancreas, 504; in jaundice, 466.
- Fainting**, 709; ætiology of, 709; in anæmia, 931; in cerebral hæmorrhage, 728; in cerebral tumor, 750; in epilepsy, 773; in insolation, 746; in leukæmia, 949; in pernicious anæmia, 941; liability to, 709; symptoms of, 709; treatment of, 709.
- Falling sickness**, 770.
- Famine fever**, 29.
- Farcy**, 116; acute, 116; chronic, 117.
- Farcy-buds**, 116.
- Fascia reflex**, 545; in cerebral hæmorrhage, 732.
- Fat**, ingestion of, in diabetes, 979.
- Fat-drops** in urinary casts, 827.
- Fatty acids**, crystals of, in the sputum of foetid bronchitis, 156.
- Fatty degeneration**, in anæmia, 933; of heart, 315; of kidneys, 839, 851; of liver, 486.
- Fatty granular globules** in urinary casts, 827; heart, 315; kidney, 839, 851; inflammatory, 839, 851; liver, 485, 489; liver in pulmonary tuberculosis, 228; liver in trichinosis, 123.
- Fatty stools**, 504.
- Febricula**, 31.
- Febris continua**, 7; erratica, 94; gastrica, 18; intermittens, 90, 92; nervosa stupida, 14; nervosa versatilis, 14; quotidiana, 98; recurrens, 31.
- Feeding**, artificial, in progressive bulbar paralysis, 690; in stenosis of the œsophagus, 388; in trismus, 572.
- Fehling's test** for sugar, 968.
- Fermentation test** for sugar, 969.
- Fever**, anæmic, 387, 394; cerebro-spinal, 103; "cold," 86; enteric, 1; gastric, 18; hectic, 225; hysterical, 904; in acute ascending spinal paralysis, 675; in acute miliary tuberculosis, 238; in angina, 361; in appendicitis, 420; in arthrogryposis, 576; in articular rheumatism, 901; in bronchitis, 148; in cardiac valvular disease, 301; in cerebral abscess, 742; in cholera, 85; in cirrhosis of the liver, 481; in cystitis, 695; in dengue, 99; in diabetes, 971; in diphtheria, 68; in dysentery, 79; in endocarditis, 278; in erysipelas, 63; in gastric catarrh, 373; in glanders, 117; in gout, 966; in hæmoglobinæmia, 954; in hepatitis, suppurative, 477; in infantile cerebral paralysis, 744; in infantile spinal paralysis, 668; in influenza, 70; in intermittent fever, 93; in intestinal catarrh, 406; in measles, 48; in meningitis, 103, 700, 704; in noma, 347; in osteomalacia, 927; in parotitis, 348; in pericarditis, 323; in perinephritis, 870; in pleurisy, 257; in pneumonia, 186, 192; in poliomyelitis of adults, 671; in primary multiple neuritis, 582; in pulmonary emphysema, 179; in pulmonary gangrene, 243; in pulmonary tuberculosis, 225; in purpura hæmorrhagica, 962; in purpura rheumatica, 962; in pyelitis, 883; in pyelophlebitis, suppurative, 501; in rachitis, 922; in relapsing fever, 33; in remittent fever, 33; in scarlet fever, 37; in septicopyæmia, 111; in small-pox, 55; in sunstroke, 747; in thermic fever, 747; in trichinosis, 123; in tuberculosis of the genito-urinary organs, 889; in typhilitis, 419, 420; in typhoid fever, 6; in typhus fever, 30; in yellow fever, 101.
- Fever**, intermittent, 90; lung, 189; ship, 38; splenic,

- 117; spotted, 98; swamp, 90; typhoid, 1; typhomalarial, 96; yellow, 100.  
 Fibrinous, bronchitis, 158; pneumonia, 189.  
 Fibroid disease of heart, 307.  
 Fibroma of the larynx, 144.  
 Fifth nerve, paralysis of, 557.  
 Filaria Bancrofti, 875; sanguinis, 875.  
 Fish, poisoning from the ingestion of, 1010.  
 Flapping joints in infantile spinal paralysis, 669.  
 Flatulence in hysteria, 805; in jaundice, 466.  
 Flexibility, waxy, 796.  
 Floating kidney, 876.  
 Fœtus, endocarditis in, 293.  
 Follicular catarrh of the intestines, 404.  
 Foot-baths in asthma, 172.  
 Forced attitudes, 541.  
 Forced movements, 541; in disease of the crura cerebelli ad pontem, 725; in paralysis agitans, 785.  
 Forearm, paralysis of, 554; paralysis of, in amyotrophic lateral sclerosis, 651.  
 Foreign bodies in the intestinal canal, 432.  
 Fothergill's face-ache, 521.  
 Fourth nerve, paralysis of, 556.  
 Fowler's solution. See ARSENIC.  
 Fowler's solution in chorea, 783; in endocarditis, 280; in valvular cardiac disease, 308.  
 Fractures in rachitis, 923; in osteomalacia, 927.  
 Fremitus, hydatid, 495.  
 Fresh-air treatment in tuberculosis, 223.  
 Friction in pericarditis, 324; in peritonitis, 453; in pleurisy, 258.  
 Friedreich's ataxia, 648.  
 Friedreich's sign in adherent pericardium, 326.  
 Frontal convolutions, lesions of the, 715; connected with the centers of speech, 715, 719; connected with the cortical motor centers, 715.  
 Frontal sinuses, catarrh of the, 126.  
 Fuchsine in nephritis, 846.  
 Furunculosis in diabetes, 972, 973, 977; in scarlet fever, 41; in typhoid fever, 17; in typhus fever, 30.  
 Gait in amyotrophic lateral sclerosis, 651; in locomotor ataxia, 637; in multiple sclerosis, 629, 630; in osteomalacia, 927; in pseudo-hypertrophic muscular paralysis, 659; in rachitis, 923; in spastic spinal paralysis, 665; pseudo-tabetic, 585.  
 Gall-bladder, dilatation of, 473; forming abdominal tumor, 473.  
 Gall-stones, 470; diagnosis of, 474; prognosis of, 474; treatment of, 474.  
 Galloping consumption, 217.  
 Galvano-cautery in hypertrophic pharyngitis, 360.  
 Galvano-puncture in aneurism of thoracic aorta, 338.  
 Ganglia, basal, tumors of, 752.  
 Ganglia, central, of the brain, lesions of, 721; lesions of, causing hemiplegia, 721, 722; lesions of, causing hemipia, 722; lesions of, causing post-hemiplegic chorea, 722.  
 Gangrene, embolic, 242, 248, 300.  
 Gangrene in diabetes, 971, 973; in ergotism, 1009; in exophthalmic goitre, 597; in pneumonia, 203; in small-pox, 56; in typhoid fever, 17; in typhus fever, 30; local or symmetrical, 548; of the lungs, 241; of the mouth, 347; senile, 333.  
 Garrod's thread-test for uric acid, 990.  
 Gastroecstasis, 396.  
 Gastric. See also STOMACH.  
 Gastric abscess, 383; cancer, 391.  
 Gastric catarrh, acute, 372; absorption impeded by, 375; chronic, 375; diagnosis of, 379; exciting causes of, 373, 374; gastric juice in, 374; liability to, 374; mucus secreted in, 375; peristalsis in, 375; treatment of, 373, 380.  
 Gastric crises in locomotor ataxia, 643; fever, 373; hæmorrhage, 388; hæmorrhage in cancer, 392; hæmorrhage in ulcer, 385, 386, 388.  
 Gastric juice, chemical examination of, 377; hyperacidity of, 382; subacidity of, 378.  
 Gastric pain in case of ulcer, 385; ulcer, 384; ulcer, clinical forms of, 385; ulcer, peptic, 384; ulcer, round, 384; vertigo, 401.  
 Gastritis, acute, 372; acute suppurative, 383; chronic, 375; phlegmonous, 383.  
 Gastro-intestinal symptoms in emphysema, 179.  
 Gastromalacia, 384 (foot-note).  
 Gastrorrhagia, 386, 388.  
 Gastrotomy, 395.  
 Gastroxyntsis, nervous, 401.  
 Gelsemium, tincture of, in neuralgia, 520; in trigeminal neuralgia, 523.  
 General paralysis, progressive, 760; ætiology of, 761; depressive form, 764; development of, 762; diagnosis of, 766; hereditary predisposition to, 761; influence of syphilis in, 761; maniacal exaltation in, 763; symptoms of, 761; treatment of, 766.  
 Genito-urinary organs, tuberculosis of, 888; diagnosis of, 890; treatment of, 890.  
 German measles, 51.  
 Giant cells, 212.  
 Gin-drinker's liver, 478.  
 Girdle-sensation in locomotor ataxia, 640.  
 Glanders, 116; acute, 116; chronic, 117; diagnosis of, 117; diagnosis from small-pox, 117; period of incubation in, 116; treatment of, 117.  
 Glioma of brain, 748, 755.  
 Globus hystericus, 810.  
 Glomerulo-nephritis, 841; in scarlet fever, 43.  
 Glossitis, acute parenchymatous, 245; treatment of, 346.  
 Glosso-labio-laryngeal paralysis, 685.  
 Glossy fingers in cervico-brachial neuralgia, 524; in trophic disorders of the nerves, 589.  
 Glottis, œdema of, 135; in Bright's disease, 136; in nephritis, 854; in small-pox, 56; in scarlet fever, 40; in typhoid fever, 14.  
 Glottis, openers of, paralysis of, 140.  
 Glottis, spasm of, 142; in hysteria, 810; in rachitis, 142, 924; in tetanus, 793; treatment of, 794.  
 Glotzaugenkrankheit, 595.  
 Gluteal paralysis, 569; reflex, 543.  
 Glycerine in diabetes, 979; in trichinosis, 123.  
 Glycogenic function of liver, 974.  
 Glycosuria, 966; ætiology of, 966; gouty, 988; in bulbar hæmorrhage, 692; in cerebral hæmorrhage; 729; in tetanus, 793.  
 Gmelin's test, 467.  
 Goitre, exophthalmic, 595; symptoms of, 595.  
 Goll, columns of, 510.  
 Gonorrhœal rheumatism, endocarditis in, 276.  
 Gout, 984; acute, 989; atypical, 987; chronic, 987; complications of, 988; diagnosis of, 989; ætiology of, 984; Elstein's theory of, 989; geographical distribution, 985; hereditary influence in, 985; influence of alcohol in, 985; influence of food in, 985; influence of lead in, 985; irregular, 987; morbid

- anatomy of, 986; nature of, 982; symptoms of, 986; treatment of, 990.
- Graefe's sign, 996.
- Grande hystérie, 808; contortions in, 808; epileptiform paroxysms in, 808; statueque postures and "attitudes of passion" in, 808.
- Grandeur, delusions of, in progressive general paralysis, 763.
- Grand mal, 771.
- Granular kidney, 856.
- Graphospasm, 577.
- Gravel, renal, 834.
- Graves's disease, 595.
- Green-sickness, 934. See also *Chlorosis*.
- Green-stick fracture in rickets, 923.
- Grinder's rot (pneumonoconiosis), 245.
- Grippe, la, 74.
- Guarana in habitual headache, 332; in hemicrania, 593; in intestinal catarrh of children, 417.
- Gummata in cerebral syphilis, 749, 757; in hepatic syphilis, 490; of spinal cord, 609; of liver, 490; of lungs, 252.
- Gums, affections of, in diabetes, 971; (blue line on), in lead poisoning, 1005; in scurvy, 960; in stomatitis, 841; in typhoid fever, 12.
- Gustatory paralysis, 533.
- Gymnastics in articular rheumatism (chronic), 916; in diabetes, 980; in gout, 900; in infantile spinal paralysis, 671; in neurasthenia, 817; in progressive muscular atrophy, 658; in writer's cramp, 579.
- Habitus, apoplectic, 726; emphysematous, 177; cretetic, 1000; phthisical, 221.
- Hæmatemesis, diagnosis from hæmoptysis, 368.
- Hæmatemesis, hysterical, 804; in acute yellow atrophy, 487; in gastric ulcer, 396.
- Hæmatemesis in leukaemia, 949; in scurvy, 959.
- Hæmatidrosis, 599.
- Hæmato-chyluria, parasitic, 875.
- Hæmatogenous jaundice, 490, 956.
- Hæmatoidine, granules of, in urinary casts, 827.
- Hæmatoma of the dura mater, 696; apoplectic symptoms in, 697; diagnosis of, 698; in chronic alcoholism, 697; in connection with the hæmorrhagic diathesis, 697; in progressive general paralysis, 697; origin of, 696; seat of, 696; treatment of, 698.
- Hæmatomyelia, 604.
- Hæmatorrhachis, 603.
- Hæmatothorax, 271.
- Hæmatozoa of malaria, 91.
- Hæmaturia, 828; as a sign of scurvy, 959; endemic, of Egypt, 874, 875; in acute nephritis, 842; in chyluria, 875; in renal calculus, 886; in renal cancer, 873; in tuberculosis of kidney, 889; in tumor of the kidney, 873; tropical, 875.
- Hæmline test, 392.
- Hæmoglobin, diminution of, in chlorosis, 935.
- Hæmoglobinæmia, 953; ætiology of, 953; in connection with malaria, 953; in connection with syphilis, 955; in poisoning from mushrooms, 953; paroxysmal, 954, 955; symptoms of, 954.
- Hæmoglobin, granules of, in the urine, 954.
- Hæmoglobinuria, 953; in poisoning from mushrooms, 953; in Raynaud's disease, 954; paroxysmal, 954; toxic, 953.
- Hæmolytic, in pernicious anaemia, 944; in toxic hæmoglobinuria, 954.
- Hæmopericardium, 830.
- Hæmophilia, 963; ætiology of, 963; complications of, 965; connected with anaemia, 965; prognosis of, 965; rudimentary forms of, 964; treatment of, (a) prophylactic, 965; (b) surgical, 965.
- Hæmoptysis, at onset of phthisis, 210; causes of, 218; hysterical, 804; in aneurism, 337; in bronchial catarrh, 147, 152; in pneumonia, 193; in pulmonary gangrene, 243; in pulmonary tuberculosis, 218; in scurvy, 959; periodic, 96; treatment of, 235.
- Hæmorrhage, cerebral, 725; in acute yellow atrophy, 487; in anaemia, 934, 939, 942; in cirrhosis of the liver, 480; in contracted kidney, 861; in endocarditis, 379; in epileptic paroxysms, 773; in hæmophilia, 963; in hysteria, 804; in leukaemia, 950; in malaria, 93; in malignant pustule, 119; in meningitis, epidemic cerebro-spinal, 104; in nephrolithiasis, 898; in pseudo-leukaemia, 952; in pyelitis, 833; in purpura hæmorrhagica, 963; in scarlet fever, 41; in scurvy, 958; in small-pox, 57; into spinal cord, 604; into the spinal meninges, 603; in syphilis of the rectum, 425; into ventricles of brain, 727; in typhoid fever, 10; in yellow fever, 102; pulmonary, 235.
- Hæmorrhagic diathesis, 963.
- Hæmorrhoids, 428; "attacks of," 428; bleeding from, 428; treatment of, 429.
- Hair, loss of, in typhoid fever, 17; in unilateral facial atrophy, 504.
- Hallucinations in hysteria, 807.
- Halo surrounding the pocks of small-pox, 63.
- Handwriting in general paresis, 763.
- Hay fever, 135.
- Headache, habitual, 530; in acute ascending spinal paralysis, 674; in anaemia, 932; in bronchitis, 148; in bulbar paralysis, acute, 694; in cerebral abscess, 742; in cerebral anaemia, 700; in cerebral hæmorrhage, 728; in cerebral syphilis, 759; in cerebral tumors, 759; in chlorosis, 935; in compression of the medulla oblongata, 695; in diabetes, 967, 973; in diseases of the cerebellum, 724; in epilepsy, 773; in exophthalmic goitre, 396; in hæmatoma of the dura mater, 697; in infantile spinal paralysis, 668; in leukaemia, 949; in meningitis, epidemic, 104; in meningitis, purulent, 700; in meningitis, tubercular, 703, 705; in nervous dyspepsia, 401; in neurasthenia, 815; in paroxysmal hæmoglobinuria, 954; in pernicious anaemia, 941; in pleurisy, 257; in pneumonia, 192; in poliomyelitis of adults, 671; in primary multiple neuritis, 583; in railway spine, 890; in small-pox, 53; in tetanus, 792; in thrombosis of the cerebral sinuses, 707; in typhoid fever, 5; in uræmia, 831; in writer's cramp, 578.
- Headache, nervous, 530; sick, 591.
- Head, deviation of, in cerebral hæmorrhage, 729; in progressive general paralysis, 761; rheumatism in, 918; sense of pressure in, in neurasthenia, 815.
- Head, tetanus of the, 792.
- Heart, aneurism of, 308; arrhythmia of, in valvular disease, 207; congenital affections of, 233.
- Heart, dilatation of, 313; in chlorosis, 935; in malaria, 94.
- Heart, disorders of, in diabetes, 972; in obesity, 995; in pneumonia, 197; in scurvy, 959.
- Heart, displacement in pleuritic effusion, 250; displacement in pneumothorax, 209; fatty degeneration of, 315.
- Heart, hypertrophy of, 312; diagnosis of, 314; idio-

- pathic, 812; in arterio sclerosis, 332; in obesity, 996; in renal disease, 884, 843, 853, 859; in scarlet fever, 43; treatment of, 816.
- Heart, indurated degeneration of, 308; in exophthalmic goitre, 595; infarctions in, 308.
- Heart, lesions of, compensated, 282; congenital, 293; lungs altered by disease of, 249.
- Heart, overexertion of, 312.
- Heart, palpitation of, diagnosis of the nervous form of, 319; in cardiac valvular disease, 296; in case of tapeworm, 443; in hysteria, 810; in neurasthenia, 816; in obesity, 995; in pernicious anaemia, 941; in scurvy, 958; nervous, 319; treatment of the nervous form of, 320.
- Heart, parenchymatous degeneration of, 307, 315; rupture of, in cardiac aneurism, 308; sclerosis of, 307.
- Heart, valvular disease of, 281; complications of, 295; multiple, 294; prognosis of, 301; treatment of, 308.
- Heart, weakened, 312.
- Heartburn in chronic gastric catarrh, 376.
- Heart failure, in diphtheria, 69; treatment of, in typhoid fever, 26.
- Heat, exhaustion, 746; stroke, 746.
- Hebrews, prevalence of diabetes among, 967.
- Hectic fever, 225.
- Hegar's funnel for rectal irrigation, 410.
- Heller's test for blood in the urine, 828.
- Helminthiasis, 440.
- Hemianæsthesia, in cerebral hæmorrhage, 773; in hysteria, 811, 813; in lesions of the internal capsule, 722, 725; in tumors of the cerebral hemispheres, 752; in unilateral cord lesions, 683.
- Hemianopia, in cerebral hæmorrhage, 733; in hemiplegia, 592; in lesions of the central ganglia, 722, 725; in lesions of the corpora quadrigemina, 722, 725; in lesions of the occipito-cortical region, 716, 725; in migraine, 592; in tumors of the base of the brain, 752; in tumors of the cerebral hemispheres, 752.
- Hemiatheiosis, post-hemiplegic, 788.
- Hemiatrophy, progressive facial, 594; loss of hair in, 594; seat of, 594; treatment, 594.
- Hemichorea, post-hemiplegic, 734; in infantile cerebral paralysis, 745; in lesions of the internal capsule, 721, 725; in lesions of the optic thalamus, 722, 725.
- Hemicrania, 591 (see also MIGRAINE); course of, 592; in diabetes, 973; ophthalmic, 592; paralytic, 592; spastic, 592; symptoms of, 592; treatment of, 593.
- Hemiplegia, 536.
- Hemiplegia, crossed, 692; in cerebral hæmorrhage, 731, 732, 735; in cerebral syphilis, 758; in diffuse cerebral sclerosis, 744; in hæmatoma of the dura mater, 697; in hysteria, 803; in infantile cerebral paralysis, 744; in lesions of the central ganglia, 721; in lesions of the crura cerebri, 723, 725; in lesions of the internal capsule and centrum ovale, 721; in lesions of the motor cortical region, 712; in locomotor ataxia, 645; in multiple sclerosis, 631; in progressive general paralysis, 704; in purulent meningitis, 700; in tumors of the cerebral hemispheres, 752; mental defects in, 735.
- Hepatic. See also LIVER.
- Hepatic abscess, 476; in dysentery, 79; in pyelophlebitis, suppurative, 501.
- Hepatic colic, 470; pulse, 289; vein, affections of, 500, 502.
- Hepatitis, chronic diffuse interstitial, 478; diffuse syphilitic, 491; suppurative, 476.
- Hepatization of the lungs, 190.
- Hepatogenous jaundice, 464.
- Heredity in diabetes insipidus, 982, 983; in hæmophilia, 963; in idiopathic muscular atrophy, 659, 661; in tuberculosis, 210.
- Herpes in acute gastric catarrh, 373; in cerebro-spinal meningitis, 106; in facial paralysis, 560; in intercostal neuralgia, 525; in locomotor ataxia, 644; in malaria, 94; in neuralgia, 517; in neuritis, 582; in pressure paralysis of the spinal cord, 612; in sciatica, 526; in trigeminal neuralgia, 522.
- Herpes labialis in angina, 352; in intestinal catarrh, 406; in malaria, 94; in meningitis, epidemic cerebro spinal, 106; in pneumonia, 192; in relapsing fever, 32; in scarlet fever, 41; in typhoid fever, 17; in typhus fever, 30.
- Herpes zoster, 525.
- Hiccough, 577; hysterical, 577; in anaemia, 933; in cholera, 85; in dysentery, 79; in hepatitis, suppurative, 477; in uræmia, 832; reflex, 577; treatment of, 577.
- Hoarseness in diphtheria, 68; in laryngeal catarrh, 132; in trichinosis, 122.
- Hodgkin's disease, 951; morbid anatomy of, 952; symptoms of, 952.
- Hot Springs of Arkansas, 916.
- Hyaline casts in urine, 826.
- Hydatid disease, 494.
- Hydatid thrill, 495.
- Hydræmia, 825.
- Hydrocephaloid symptoms, 411.
- Hydrocephalus, acute, 702, 708; ætiology of, 702; chronic, 767; chronic, after cerebro-spinal meningitis, 107; congenital, 767; congenital, diagnosis of, 708; course of, 767; effect of, upon shape of brain, 767; enlargement of head caused by, 708; following epidemic cerebro-spinal meningitis, 107; of adults, 708; skull in, different from the rachitic, 769; spurious, 411; symptoms of, 767, 768; the fluid of, 767; treatment, 769.
- Hydrochloric acid in anaemia and chlorosis, 938; in gastric catarrh, 373, 381; poisoning from, 1003; tests for, in gastric juice, 378.
- Hydrocyanic acid, poisoning from, 1007.
- Hydromyelus, 677, 678.
- Hydronephrosis, 890; congenital, 891; intermittent, 891.
- Hydropericardium, 329.
- Hydroperitoneum, 460.
- Hydrophobia, 113; diagnosis of, 114; hydrophobic stage, 114; maniacal stage of, 113; paralytic stage of, 113, 114; period of incubation in, 114; quiet form of, 113; raving form of, 113; treatment of, 114, 115.
- Hydrops vesicæ felleæ, 473.
- Hydrorrhachis, 679.
- Hydrothorax, 271; in scarlet fever, 42; in valvular cardiac disease, 299; treatment of, 271.
- Hyoscyamine in paralysis agitans, 787.
- Hyperacusis in facial paralysis, 559.
- Hyperæmia, 708.
- Hyperæsthesia, 505; in ataxia, 640; in hysteria, 802; in myelitis, 619; in neuralgia, 517; in neurasthenia, 815; in pulmonary tuberculosis, 226; in relapsing fever, 32; in spinal meningitis, 600; in typhoid

- fever, 16; in unilateral lesions of the spinal cord, 683; of smell, 532; of taste, 533.  
 Hyperidrosis, unilateral, 500.  
 Hyperosmia, 532.  
 Hyperpyrexia, hysterical, 804, 805; in rheumatic fever, 906; in scarlet fever, 88; in sunstroke, 747; in tetanus, 793.  
 Hypnotism in hysteria, 809.  
 Hypochondriasis and neurasthenia, 815; in gastric catarrh, 879; in habitual constipation, 430; in nervous dyspepsia, 401.  
 Hypodermic syringe in diagnosis of pleural effusion, 263, 265.  
 Hypoglossal nerve, paralysis of, 732; spasm of, 573.  
 Hypoglossus, paralysis of, in cerebral tumor, 732.  
 Hypophysis, tumor of, 752, 754.  
 Hypoplasia of aorta, 929.  
 Hypostatic congestion in typhoid fever, 12.  
 Hysteria, 755; aetiology of, 755; artificial production of spasms in, 802, 810; contractures and spasms in, 808; convulsive forms of, 806; course of, 810; diagnosis of, 811; disorders of sensation in, 800; fever in, 804; grand paroxysms of, 808; hæmoptysis in, 804; in connection with floating kidney, 877; joint affections in, 529, 804; liability to, 799; mental symptoms of, 805; metallotherapeutics in, 813; paralysis in, 803; produced by sexual influences, 800; special senses in, 800; stigmata in, 800; symptoms of, 800; traumatic, 798; treatment of, 811; visceral manifestations of, 806; with regard to exophthalmic goitre, 596.  
 Hysterical insanity in typhoid fever, 15.  
 Hystero-epilepsy, 106, 107.  
 Hysterogenic points, 802, 810.
- Ice in cerebral hæmorrhage, 736; in infantile spinal paralysis, 670; in injuries of the spinal cord, 607; in meningitis, 97, 701, 706; in spinal apoplexy, 606; in spinal meningeal hæmorrhage, 608.  
 Ichthyosis linguae et oris, 346.  
 Icteric casts in the urine, 467.  
 Icterus, acute febrile, 469; catarrhal, 461; gravis, 469; neonatorum, 490.  
 Idiocy in infantile hemiplegia, 745.  
 Idiopathic anaemia of Addison, 878.  
 Ileo-caecal region, gurgling in, in typhoid fever, 10.  
 Ileo-caecal tumor, 419.  
 Ileotyphus, 1.  
 Ileus from intestinal obstruction, 435; in typhoid fever, 11; paralytic, 432.  
 Illuminating gas, poisoning from, 1007.  
 Imbecility in infantile hemiplegia, 745; in multiple sclerosis, 630.  
 Imitation in chorea, 780.  
 Impotence in diabetes, 972; in locomotor ataxia, 643.  
 Inanition in nervous dyspepsia, 401, 402.  
 Incarceration, internal, of the intestines, 433; symptoms of, in case of floating kidney, 877.  
 Incontinence, nocturnal, of urine, 898.  
 Incoördination of arms, 542; of legs, 542.  
 Indican, test for, 436.  
 Induction of premature delivery, in chorea gravidarum, 784.  
 Induration, brown, of the lungs, 249; rheumatic, of the muscles, 917.  
 Infantile convulsions, 779.  
 Infantile paralysis, cerebral, 744; acute, 744; course of, 745; pathology of, 745; treatment of, 745.
- Infantile paralysis, spinal, 667. See SPINAL PARALYSIS OF CHILDREN.  
 Infarction, embolic, of the kidneys, 871; hæmorrhagic, of the lungs, 247.  
 Influenza, 74; diagnosis of, 77; aetiology of, 74; symptoms of, 75; treatment of, 77.  
 Inhalation-pneumonia, 186, 434.  
 Inhalations in bronchitis, 154; in diphtheria, 71; in laryngitis, 132; in pharyngitis, 359; in pulmonary gangrene, 244; in pulmonary tuberculosis, 231; in whooping-cough, 163.  
 Injection, intravenous, of salines in diabetes, 961; subcutaneous, of salines in cholera, 89.  
 Injury, mechanical, due to chorea, 783; due to epilepsy, 773.  
 Inoculation, against small-pox, 52, 58; protective, in hydrophobia, 115.  
 Insanity, post-febrile, 15; relation of heart disease to, 301.  
 Insects, the sting of, a cause of malignant pustule, 119.  
 Insolation, 746.  
 Inspection of meat, governmental, to prevent trichinosis, 123.  
 Insufficiency, valvular, 281.  
 Insufflation of powders in chronic pharyngitis, 359.  
 Insular sclerosis, 627.  
 Intention tremor in multiple sclerosis, 629; in myelitis, 619.  
 Intercoastal neuralgia, 524.  
 Intermeningeal apoplexy, 606.  
 Intermittent fever, 92; hepatic, 94; masked, 95; pernicious, 94; tertian, 93.  
 Internal capsule, lesions of, 721.  
 Intestinal calculi, 432; casts, 408.  
 Intestinal catarrh, 408; acute, 408; chronic, 408; follicular, 404; from the ingestion of poisons, 408; in rachitis, 924; of children, 413; treatment of, 409, 415.  
 Intestinal glands enlarged in leukaemia, 948; in pseudo-leukaemia, 953.  
 Intestinal hæmorrhage in dysentery, 79; in intussusception, 437; in pyæthrombosis, 502; in typhoid fever, 10; in ulcer of duodenum, 423; in ulcer of the stomach, 386.  
 Intestinal parasites, 440; polypti, 434.  
 Intestinal symptoms in cholera, 84; in dysentery, 78; in erysipelas, 63, 64; in gastric catarrh, 873, 879; in glanders, 116; in malignant pustule, 119; in measles, 49; in pulmonary gangrene, 243; in pulmonary tuberculosis, 227; in purpura hæmorrhagica, 962; in typhoid fever, 9, 10.  
 Intestine, cancer of, 426; diagnosis of, 426; treatment of, 427.  
 Intestine, compression of, from without, 434; constriction of, 433; dilatation of, 435; incarceration of, 433; intussusception of, 433; invagination of, 433; new growths in, 426, 432.  
 Intestine, obstruction of, 437; by enteroliths, 432; by foreign bodies, 433; by gall-stones, 432.  
 Intestine, perforation of, in typhoid fever, 11; strangulation of, 433; strictures and tumors of, 432; twists and knots of, 433; ulcers of, 432.  
 Intestine, large, catarrh of, 407; desquamative, 408.  
 Intussusception, 434.  
 Inunction, mercurial, in acute ascending spinal paralysis, 676; in acute bulbar paralysis, 695; in cerebral syphilis, 759; in hæmoglobinuria, 956; in loco-

- motor ataxia, 647; in myelitis, 626; in progressive general paralysis, 767; in spastic spinal paralysis, 667; in tumors of the brain, 775; in tumors of the spinal cord, 677.
- Invagination, 434.
- Iodide of iron in peritonitis, chronic, 400; in pressure paralysis of the spinal cord, 614; in scrofula, 1001.
- Iodide of potassium in acute ascending spinal paralysis, 676; in aneurism of the thoracic aorta, 338; in asthma, 172; in bronchitis, 153, 159; in cerebral syphilis, 759; in cerebral tumors, 755, 759; in chronic hydrocephalus, 769; in gout, 992; in habitual headache, 531; in lead paralysis, 570; in leptomeningitis, spinal, 601; in locomotor ataxia, 647, 648; in meningitis, cerebro-spinal, 108; in multiple sclerosis, 631; in myelitis, 626, 627; in neuralgia, 520; in pachymeningitis cervicalis hypertrophica, 603; in peritonitis, chronic, 400; in sciatica, 527; in spasm of the trigeminus, 572; in spastic spinal paralysis, 667; in syphilitic paralysis of the motores oculi, 567; in tumor of the spinal cord, 677.
- Iodine coryza, 125.
- Iodine, poisoning from, 1004.
- Iodine, tincture of, externally, in articular rheumatism, chronic, 915; in chronic nasal catarrh, 128; in pharyngitis, chronic, 359; in pleurisy, 264; in pressure paralysis of the spinal cord, 614; in spinal leptomeningitis, 601.
- Iodine, tincture of, internally, in diabetes, 981; in scrofula, 1001.
- Iodoform in diabetes, 981; in pleurisy, 264; in pseudo-leukæmia lymphatica, 953.
- Ipecacuanha in dysentery, 80.
- Iritis in gout, 987.
- Iron baths in anaemia and chlorosis, 928; in infantile spinal paralysis, 671; in locomotor ataxia, 647; in railway spine, 821.
- Iron, chloride of, in purpura hæmorrhagica, 962; reaction caused by, in diabetic urine, 970.
- Iron in anaemia and chlorosis, 927; in cardiac valvular disease, 303; in exophthalmic goitre, 508; in habitual headache, 531; in hemiparesis, 593; in nephritis, 855; in neurasthenia, 818; in osteomalacia, 927; in paralysis of the muscles of the larynx, 143; in pernicious anaemia, 950; in pulmonary tuberculosis, 235; in rachitis, 934; in scurvy, 961; in scrofula, 1001.
- Irradiation, 517.
- Irrigation in intestinal catarrh, 410; in the intestinal catarrh of children, 417.
- Ischuria in hysteria, 805.
- Itching in jaundice, 465; in uræmia, 853.
- Jacksonian epilepsy, 714.
- Japan, beri-beri in, 582.
- Jaundice, catarrhal, 464; choluria in, 467; diagnosis of, 468; epidemic form of, 464; febrile, 469; from gall-stones, 472; hæmatogenous, 460; hepatogenous, 464; in acute phosphorus poisoning, 1000; in acute yellow atrophy, 486, 487; in cancer of the liver, 493; in cancer of the pancreas, 504; in cirrhosis of the liver, 480, 484; in diabetes, 671; in gastric catarrh, 373; in gastro-duodenitis, 464; in hæmoglobinuria, 954; in hepatic colic, 472; in hepatitis, suppurative, 477; in pneumonia, 202; in pyelophlebitis, suppurative, 501; in syphilis of the liver, 491; in Weil's disease, 469; in yellow fever, 101; malignant, 489; of the new-born, 490; pernicious, 489; treatment of, 463; xanthelasma in, 465.
- Jaw. See MAXILLA.
- Joints, disorders of, in acute neuritis, 528; in cerebral hæmorrhage, 735; in dengue, 92; in endocarditis, 279; in erysipelas, 64; in gout, 980, 992; in hæmophilia, 965; in locomotor ataxia, 644; in meningitis cerebro-spinal, 106; in pernicious anaemia, 943; in purpura hæmorrhagica, 992; in scrofula, 1000; in scurvy, 959; in septic-pyæmia, 111; in small-pox, 56; in typhoid fever, 17; in valvular cardiac disease, 301.
- Joints, neuroses of, 528.
- Joints, sensibility of, 509.
- Jumpers, 576.
- "June cold," 125 (foot-note).
- Keratitis, in small-pox, 56.
- Kidney, abscess of, 808; amyloid or lardaceous disease of, 804; anomalies in position of, 876; calculi of, 884; cancer of, 872; circulatory disturbances in, 871; cirrhosis of, 856; congestion of, 871; cystic disease of, 874, 890; echinococcus of, 874; genuine contracted, 856; gouty, 857, 987; granular, 856; hydatids of, 874; in diabetes, 872; in diphtheria, 70; in hæmoglobinuria, 955; in leukæmia, 947; in obesity, 966; in pneumonia, 197; in pseudo-leukæmia, 932; in pulmonary emphysema, 179; in pulmonary tuberculosis, 228; in scarlet fever, 41; in septic-pyæmia, 112; large red, 850; large white, 851; movable, 876; new growths of, 872; parasites of, 874; pelvis of, dilatation of, 880; pelvis of, inflammation of, 881; sclerosis of, 856; secondary contracted, 849.
- Kidney, removal of, for cancer, 873.
- Kidney, rhabdo-myoma of, 872; sarcoma of, 872; surgical kidney, 868; tuberculosis of, 888; tumors of, 872.

- sis, 562; in gout, 992; in hysteria, 812; in infantile paralysis (cerebral), 745; in infantile paralysis (spinal), 671; in migraine, 593; in muscular rheumatism, 919; in neuralgia, 521; in neurasthenia, 817, 818; in paralysis agitans, 787; in progressive muscular atrophy, 658; in pseudo-hypertrophic muscular paralysis, 603; in sciatica, 527; in scorbutic ecchymoses, 961; in writer's cramp, 579.
- Mastication**, disturbances of, in progressive bulbar paralysis, 686, 687.
- Mastication**, muscles of, paralysis of, 557; in general paralysis of the insane, 764; in tumors at the base of the brain, 752; spasm of, clonic, 571; tonic, 571.
- Mastodynia**, 525; treatment of, 525.
- Measles**, 46; black, 48; catarrh in, 48; complications of, 48; contagiousness of, 46; diagnosis of, 50; diphtheria in, 49; inoculation of, 47; period of incubation in, 47; prognosis of, 50; prophylaxis of, 50; relation of, to pulmonary tuberculosis, 49; relation of, to whooping-cough, 49; treatment of, 50; typhoid, 49.
- Measles**, German, 51. See *RÖTHELN*.
- Measles** in pork, 441. See *TÄENIA*.
- Meat**, compulsory inspection of, in trichinosis, 123; poisoning from, 1010.
- Meckel's diverticulum** in obstruction of the intestine, 433.
- Median paralysis**, 566; disturbances of the functions of the forearm and hand in, 566; traumatic, 566.
- Mediastinal tumors**, 273; diagnosis of, 273; prognosis of, 274; treatment of, 274.
- Mediastino-pericarditis**, 325.
- Medulla oblongata**, acute apoplectic form paralysis of, 691; compression of, 695; diseases of, 685; progressive paralysis of, 685.
- Medulla oblongata and pons**, hæmorrhages into, 691; apoplexy from, 691; cysts and scars from, 691; seat and extent of, 691; treatment of, 693.
- Melæna neonatorum**, 390.
- Mellituria**, 966. See *GLYCOCURIA*.
- Memory**, weakness of, in exophthalmic goitre, 596.
- Ménière's disease**, 769; implication of the semicircular canals in, 769; in tabes, 643; treatment of, 769.
- Meningeal apoplexy**, 603.
- Meningeal hæmorrhage**, 603.
- Meningeal tumors**, 676; different forms of, 676; prognosis and treatment of, 677; symptoms of, 677.
- Meningitis**, basilar, 702.
- Meningitis of the convexity**, 698.
- Meningitis, epidemic cerebro spinal**, 103, 698, 701 (see also *CEREBRO-SPINAL MENINGITIS*); diagnosis of, 107; in pneumonia, 107; prognosis of, 107; secondary, 107, 698; sequele of, 107; siderans, 104; treatment of, 108.
- Meningitis, purulent**, 698; ætiological factors in, 698; complications of, 699; diagnosis of, 701; localization of the morbid process in, 699; metastatic, 699; primary, 698; symptoms of, 700; treatment of, 701.
- Meningitis, tubercular**, 702; causes of, 702; duration of, 705; hæmorrhages into the pia mater in, 703; hydrocephalic effusion into the ventricles in, 703; implication of the spinal cord in, 703; inflammatory changes in, 703; seat of miliary tubercles in, 703; symptoms of, 703.
- Meningitis, tubercular**, in children, 705; diagnosis of, 706; loud outcry of child in, 705; treatment of, 706.
- Meningocele**, 679.
- Menstruation** in chlorosis, 935; influence of, on epilepsy, 774; vicarious, 129.
- Mental disturbances** in acute general miliary tuberculosis, 239; in anæmia, 931; in articular rheumatism, 906; in athetosis, 789; in bulbar hæmorrhage, 691; in cerebral abscess, 742; in cerebral anæmia, 709; in cerebral embolism, 740; in cerebral hæmorrhage, 728, 730, 735; in cerebral hyperæmia, 710; in cerebral syphilis, 759; in cerebral tumor, 750; in cerebro-spinal meningitis, 105; in cholera, Asiatic, 85; in cholera morbus, 411; in chorea, 780, 782; in convulsions, 541; in cutaneous anæsthesia, 513.
- Mental disturbances** in diabetic coma, 973; in epilepsy, 770, 772, 773, 775, 777; in fainting attacks, 709; in general paralysis of the insane, 761; in habitual constipation, 430; in hæmatoma of the dura mater, 697; in hydrocephalus, 768; in hysteria, 806, 808; in infantile paralysis (cerebral), 745; (spinal), 668; in jaundice, 466; in meningitis, 700, 703; in multiple sclerosis, 630, 631; in neuralgia, 518; in neurasthenia, 815; in peritonitis, 454; in poliomyelitis of adults, 671; in pseudo-hypertrophic muscular paralysis, 600; in pulmonary tuberculosis, 226; in pyæphlebitis, 501; in sinus thrombosis, 707; in typhoid fever, 14, 15; in typhus fever, 30; in uræmia, 831; in valvular heart disease, 301; in writer's cramp, 578.
- Mercurialism**, chronic, 1005.
- Mercurial poisoning**, 1005.
- Metabolism**, defective, in neurasthenia, 816.
- Metallic tinkling**, 269, 270.
- Metalloscopy** in hysteria, 813.
- Meteorism** in hysteria, 805; in intestinal obstruction, 437; in intestinal tuberculosis, 424; in peritonitis, 453; in pulmonary tuberculosis, 227; in typhilitis, 419; in typhoid fever, 9.
- Micrococci** in cystitis, 864; in endocarditis, 277; in erysipelas, 61, 62; in pneumonia, 189; in septici-pyæmia, 109, 110.
- Migraine**, 591 (see *HEMICRANIA*); duration of the attacks of, 592; in general paralysis of the insane, 763; treatment of, 593.
- Miliary tuberculosis**, acute general, 236; cerebral symptoms in, 238; causes of, 236; diagnosis of, 240; intermittent form of, 238; prognosis of, 240; relation of, to tubercular meningitis, 238; symptoms of, 237; treatment of, 240; typhoid form of, 237.
- Milk-cure** in anæmia, 936; in nephritis, 846; in pulmonary tuberculosis, 232; in pyelitis, 884.
- Miller's cramp**, 579.
- Millar's asthma**, 142. See *GLOTTIS, SPASM OF*.
- Mimetic expression** in lesions of optic thalamus, 722.
- Mineral acids** in scurvy, 961.
- Mineral springs** in anæmia and chlorosis, 938; in bronchitis, 154; in cholelithiasis, 475; in diabetes, 981; in exophthalmic goitre, 598; in gastric catarrh, 381; in gout, 991; in habitual headache, 531; in intestinal catarrh, 410; in laryngeal catarrh, 134; in nephrolithiasis, 888; in neuritis, 584; in obesity, 999; in pulmonary emphysema, 180; in pyelitis, 884.
- Miserere** in intestinal obstruction, 435.
- Mitral insufficiency**, 283.
- Mitral stenosis**, 285.
- Mogigraphia**, 577. See *WRITER'S CRAMP*.
- Monophasia**, 718.

- Naso-pharyngeal catarrh, 357.
- Nationality in relation to hysteria, 709; to neurasthenia, 815.
- Nephritis, acute, 826, 830; acute hæmorrhagic, 840; acute infectious, 836; in articular rheumatism, 837, 900; in cholera, 86, 837; chronic, 840; chronic hæmorrhagic, 840; chronic interstitial, 856; chronic parenchymatous, 840; in diabetes, 972; diagnosis of, 845, 855, 879; in diphtheria, 70, 836; in endocarditis, 279, 837; in epidemic meningitis, 106, 837; gravidarum, 838; in intestinal affections, 837; in measles, 49, 837; in pneumonia, 197, 837; primary idiopathic acute, 838, 844; prognosis of, 845, 855; in pulmonary tuberculosis, 228, 837; in purpura hæmorrhagica, 902; purulent, 808; in relapsing fever, 35, 837; in rëtheln, 837; in scarlet fever, 41, 837; in scurvy, 959; in septico-pyæmia, 112; septic, 837; in small pox, 837; in sore throat, 837; in syphilis, 837; in tetanus, 792, 837; toxic, 837; treatment of, 840, 855, 871; in typhoid fever, 17, 837.
- Nephritis, chronic and subchronic, 849; diagnosis of, 855; prognosis of, 855; treatment of, 855.
- Nephrolithiasis, 884; diagnosis of, 887; heredity of, 885; origin of, 885; treatment of, 887.
- Nephrophthisis, 888. See TUBERCULOSIS, GENITO-URINARY.
- Nerves, atrophy of, in amyotrophic lateral sclerosis, 651; degenerative, 553, 589; in lead paralysis, 570; in locomotor ataxia, 633, 634; in paralysis, 559.
- Nerves, degeneration of, 533; in amyotrophic lateral sclerosis, 651; in the lumbar cord in tabes, 639; in spinal paralysis of children, 668.
- Nerves, excitability of, changes of electrical, 546; in facial paralysis, 569; in hysteria, 809; in neuritis, 583; in spinal paralysis of children, 669; in tabes, 639; in tetany, 790.
- Nerves, regeneration of, 533.
- Nerve-stretching in cervico-brachial neuralgia, 524; in facial spasm, 573; ataxia, 648; in neuralgia, 521; in paralysis agitans, 787; in sciatia, 527; in spasm of the cervical muscles, 575; in tabes, 648; in trigeminal neuralgia, 523.
- Nervines in palpitation of the heart, 320.
- Nervous fever, 14.
- Neuralgia, 515; in the anæmic, 816; in aneurism of the thoracic aorta, 327; brachial, 524; causes of, 518; cervico-brachial, 524; in diabetes mellitus, 517, 973; dorso-intercostal, 524; epileptiform, 523; in general paralysis of the insane, 763; of the genitals and rectal region, 528; in gout, 517; in hæmophilia, 365; hereditary predisposition to, 516; ilio-pathtic, 517; intercostal, 524; ischiatic, 520; lumbar, 526; in malaria, 95, 516; in neuromata, 566; occipital, 523; phrenic, 524; reflex, 517; rheumatic, 516; sciatic, 520; spermatic, 528; symptomatic, 517; syphilitic, 516, 523; treatment of, 518; trigeminal, 521; in typhoid fever, 16.
- Neurasthenia, 815; causes of, 815; course of, 816; and diabetes, 976; diagnosis and prognosis of, 816; disposition to, 817; symptoms of, 815; traumatic, 821; treatment of, 817.
- Neurectomy in neuralgia, 530.
- Neuritis, 579; of alcoholic subjects, 584; ascending, 581, 616; causes of, 580; chronic, 579, 584; diagnosis and prognosis of multiple, 584; epidemic, 582, hypertrophic, after cerebral hæmorrhage, 785; mental symptoms in, 585; multiple, 582; new formation of connective tissue in, 580; nodosa, 580; primary simple, 582; purulent, 580; in relation to primary degenerative atrophy of the nerves, 580; secondary, 581; spontaneous, 581; symptoms and cause of, 581; traumatic, 580; treatment of, 584, 585.
- Neuritis, optic, in acute general miliary tuberculosis, 240; in cerebral tumor, 751; in chronic hydrocephalus, 768; in hæmatoma of the dura mater, 607; in meningitis, 700, 704; in myelitis, 923.
- Neuroma, 585; amputation, 586; diagnosis of, 586; extirpation of, 586; false, 585; hereditary predisposition to, 586; after injuries of the nerves, 586; multiple occurrence of, 586; symptoms of, 586; treatment of, 586; true, 585.
- Neuroses, articular, 528; of the heart, 318; of the vagus, 319.
- Neurotomy in neuralgia, 530.
- Nicotine poisoning, 1008.
- Night-sweats in phthisis, 216.
- Nitric acid in diabetes insipidus, 964; in nephritis, 840; poisoning from, 1003.
- Nitrites in contracted kidney, 894.
- Nitro-benzene poisoning, 1007.
- Nitro-glycerine, in contracted kidney, 664; in hæmiplegia, 593.
- Nitrous-acid fumes, poisoning from, 1003.
- Nocturnal incontinence of urine, 898. See ENURESIS.
- Nodding spasm, 574.
- Nodules, myocarditic, in valvular disease of the heart, 208.
- Noma, 347; in measles, 40; treatment of, 347.
- Nose, affections of, in diphtheria, 68; in glanders, 116; in measles, 48; in scarlet fever, 39, 40; in typhoid fever, 14.
- Nose-bleed, 129; in contracted kidney, 664, 862; habitual, 129; in nephritis, 843; in relapsing fever, 35; in typhoid fever, 14; as vicarious menstruation, 129.
- Nutmeg liver, 407.
- Nux vomica in dilatation of the stomach, 400.
- Nystagmus in hereditary ataxia, 649; in lesions of the corpora quadrigemina, 722; in multiple sclerosis, 629; in purulent meningitis, 700; in sinus thrombosis, 707.
- Obesity, 992; causes of, 992; complications of, 995; treatment of, 996.
- Obstruction, intestinal, 432, 474; tables for diagnosis of, 457.
- Obturator paralysis, 569; symptoms of, 569.
- Occipital lobes, focal diseases of their cortex, 712, 743; relation of, to hemiplegia, 716, 725; relation of,

- to soul-blindness, 716; seat of the visual sense in the cortex of, 715.
- Occipital neuralgia, 523; bilateral, 523; painful points in, 523.
- Ocular nerves in meningitis, 700.
- Oculo-motor paralysis, 555; in diphtheria, 70; diplopia in, 555; in lesions of the corpora quadrigemina, 723; in lesions of the crura cerebri, 723, 725; partial, 556; periodical, 557; in purulent meningitis, 700; in tabes, 642; in tumor of the brain, 752.
- Oedema, 828.
- Oedema, acute angioneurotic, 588; in acute ascending spinal paralysis, 674; in anæmia, 934; in cancer of the stomach, 368; in contracted kidney, 860; in diabetes, 973.
- Oedema in leukæmia, 949; in myelitis, 622; in nephritis, 842, 852; in neuritis, 583; in scarlet fever, 49; in tetany, 790; in trichinosis, 123; in typhoid fever, 16; in valvular disease of the heart, 290.
- Oesophagitis, 361; catarrhal, 361; corrosive, 362; croupous-diphtheritic, 362; purulent, 362; treatment of, 362.
- Oesophagomalacia, 371.
- Oesophagus, cancer of, 369; complications of, 369; metastases of, 370; symptoms of, 369; treatment of, 370.
- Oesophagus, diffuse dilatation of, 363; after stenosis of the cardiac orifice, 363; symptoms of, 363; treatment of, 363.
- Oesophagus, dilatation of, 363; diseases of, 361.
- Oesophagus, diverticula of, 363; causes of, 364; complications of, 365; pressure, 363; symptoms of, 364; symptoms of compression in, 364; traction, 365; treatment of, 365.
- Oesophagus, paralysis of, 371; rupture of, 371; spasm of, 371; stenosis of, 366; auscultation of, 367; causes of, 366; examination of, by the sound, 367; prognosis and treatment of, 368; symptoms of, 366.
- Oidium albicans, 344.
- Oligocythæmia, 928.
- Omalgia, 917, 918.
- Ophthalmia in diphtheria, 69; in exophthalmic goitre, 596; neuroparalytic, in anæsthesia of the trigeminus, 513; in scrofula, 1000.
- Ophthalmoplegia, progressive, 690.
- Opisthotonos, 541; in epilepsy, 772; in tetanus, 792.
- Opium in Asiatic cholera, 69; in cholera morbus, 412; in diabetes, 960; in gastric ulcer, 396; in intestinal catarrh, 409; in intestinal catarrh of children, 410; in intestinal obstruction, 439; in nephritis, 849; in neuralgia, 520; in peritonitis, 456, 457; in tetanus, 794; in trigeminal neuralgia, 523; in typhilitis, 421; in typhoid fever, 25.
- Opium habit, 1008; poisoning, 1008.
- Optic atrophy in chronic hydrocephalus, 768; in diabetes, 972; in general paralysis of the insane, 763; in multiple sclerosis, 690; in tabes, 642.
- Optic neuritis. See NEURITIS.
- Orchitis in typhoid fever, 18.
- Orthopedics in pressure paralysis of the spinal cord, 614; in rachitis, 925; in spasm of the cervical muscles, 575; in spinal paralysis of children, 671.
- Osmic acid in neuralgia, 520.
- Osteomalacia, 925; diagnosis of, 927; examination of the bones in, 926; symptoms of, 926; treatment of, 927.
- Osteomyelitis in septico-pyæmia, 112.
- Ovarian neuralgia, 523.
- Ovarie in hysteria, 803, 810.
- Oxalic-acid poisoning, 1003.
- Oxygen inhalations in anæmia, 945; in diabetes, 980; in leukæmia, 951.
- Oxyuris vermicularis, 446; diagnosis of, 447; treatment of, 447.
- Ozæna, 126; in scrofula, 1000.
- Pachymeningitis cervicalis hypertrophica, 602; compression of the spinal cord in, 602; development of, 602; diagnosis of, 602; treatment of, 603.
- Pachymeningitis hæmorrhagica, 603, 696; development of, 603; interna, 603, 696; spinalis, 603; symptoms of, 603; treatment of, 603.
- Pain, sensations of, in chorea, 781; in chronic hydrocephalus, 768; conduction of, 619; in cramps, 542; in hysteria, 802, 810; in paralysis agitans, 786; prolonged, 509; rheumatoid, in general paralysis, 762; in tabes, 659; test of, 508.
- Palate, inflammation of, 351, 357.
- Palate, paralysis of, in compression of the medulla, 695; after diphtheria, 70; (unilateral) in cerebral hæmorrhage, 732.
- Palisade-worm, 875.
- Palpitation of the heart, diagnosis of nervous, 319; in hysteria, 806; nervous, 319; in neurasthenia, 816; in obesity, 995; in pernicious anæmia, 941; in scurvy, 958; in tape-worm, 443; treatment of nervous, 320; in valvular disease of the heart, 296.
- Palsy, shaking, 784. See PARALYSIS AGITANS.
- Pancreas, atrophy of, 503; in diabetes, 960, 975.
- Pancreas, cancer of, 504; diagnosis of, 504; symptoms of, 504; treatment of, 504.
- Pancreas, hæmorrhage of, 503.
- Pancreatitis, acute, 503; chronic indurated, 504.
- Pancreatized meat, enemata of, in stenosis of the oesophagus, 369.
- Papilloma of the larynx, 144.
- Paquelin's thermo-cautery in noma, 347.
- Para-anæsthesia, 512.
- Paradoxical contraction, 546.
- Paræsthesia, 505; in cerebral hæmorrhage, 733; in epilepsy, 772; in injuries of the spinal cord, 607; in neurasthenia, 816; in pressure paralysis of the spinal cord, 611; in spinal neurasthenia, 606; in subacute poliomyelitis, 673; in tabes, 639; of taste, 533; in tumors of the spinal cord, 677.
- Paragraphia, 730.
- Paraldehyde in neuralgia, 530; in neurasthenia, 819.
- Paralysie ascendante aigue, 674. See SPINAL PARALYSIS.
- Paralysie générale spinale antérieure subalgue, 673. See SPINAL PARALYSIS.
- Paralysis, 534; acute ascending spinal, 674, 675; arsenical, 571; in articular rheumatism, 905; atrophic, 538, 609; bilateral, 536; bulbar, 685; in bulbar hæmorrhage, 691; central, 534; cerebral, 536; in cerebral hæmorrhage, 729, 731, 732, 733, 734; in cerebral syphilis, 758; in cerebral tumor, 752, 753; in chronic hydrocephalus, 768; combined, of the upper extremity, 567; condition of the paralyzed muscles in, 539; in compression of the medulla, 695; cortical, 536; of the diaphragm, 568; diphtheritic, 70, 537; in embolism and thrombosis of the basilar artery, 693; of the facial muscles in facial paralysis, 558; flaccid, 539; forms of peripheral, 555; general, 760; in general paralysis of the insane, 764; glosso-labio-laryngeal, 685; in hydrophobia,

- 114; hysterical, 537, 809, 810, 811, 812; after infectious diseases, 537; after injury to the spinal cord, 607; of the laryngeal muscles, 139; lead, 569; in tabes, 636, 639, 641, 643, 649; of the lower extremity, 568; median, 566; in meningeal hemorrhage, 608; in multiple sclerosis, 620; of the muscles of the back, 564; in myelitis, 618; myopathic, 534; in neuralgia, 517; in neuritis, 582, 583, 585; oculomotor, 555, 556; of the œsophagus, 371; in pachymeningitis cervicalis hypertrophica, 602; peripheral, 596; in poliomyelitis of adults, 671, 673; in pressure paralysis of the spinal cord, 612, 613; in progressive bulbar paralysis, 685, 686; pseudo-hypertrophic muscular, 658; from psychical causes, 537; from ptomaines, 537; in purulent meningitis, 700; radial, 564; reflex, 537; refrigeratory, 537; rheumatic, 537; of the shoulder-muscles, 562; spastic, 539; in spina bifida, 680; spinal, 536, 600, 607, 671; in spinal apoplexy, 604; in spinal meningitis, 600; spinal atrophic of adults, 671; spinal, of children, 667; in spinal paralysis of children, 608; of the stapedius in facial paralysis, 559; symptomatology of, 538; after syphilis, 537; in syringomyelia, 678; after tuberculosis, 537; toxic, 537, 569; traumatic, 537; in tumor of the spinal cord, 677; in typhoid fever, 16; ulnar, 566; unilateral, 536; in unilateral lesion of the spinal cord, 683; of the upper extremity, 564; vaso-motor, 587.
- Paralysis agitans**, 784; development of, 784; diagnosis of, 786; displacement of the center of gravity in, 785; distinction of, from multiple sclerosis, 787; excretion in, 786; hereditary predisposition to, 784; pathology of, 786; symptoms of, 784; treatment of, 787; voice in, 786.
- Paramyoclonus multiplex**, 576, 810.
- Paramyotone**, ataxic, 796; congenital, 796.
- Paraphasia**, 718; association in, 718.
- Paraplegia**, 536; ataxic, 649; in acute ascending spinal paralysis, 674; in chronic hydrocephalus, 768; dolorosa, 614; in myelitis, 619; in tabes, 639.
- Parietal convolutions**, focal diseases of, 715; relation of, to cutaneous and muscular sensibility, 715.
- Parkinson's disease**, 784. See **PARALYSIS AGITANS**.
- Parotitis**, 348; contagiousness of, 348; diagnosis of, 348; duration of stage of incubation of, 348; metastatic, 349; primary, 348; in scarlet fever, 40; secondary, 349; in small-pox, 36; treatment of, 348, 349; in typhoid fever, 12.
- Partial paralysis of sensation**, 508; in tabes, 641; in syringomyelia, 678.
- Passive congestion of kidney**, 871; in pulmonary emphysema, 179; in valvular disease of the heart, 300.
- Passive congestion of liver**, 406; in pneumonia, 197; in pulmonary emphysema, 179; in valvular disease of the heart, 300.
- Passive congestion of spleen**, in cirrhosis of the liver, 480; in pulmonary emphysema, 179; in valvular disease of the heart, 300.
- Passive motion**, sense of, 510; of the extremities in hemiplegia, 737; in hysteria, 812; in spinal paralysis of children, 671.
- Patellar reflex**, 544; absence of, 641; in general paralysis of the insane, 763; in myelitis, 621; in neuritis, 586; in pressure paralysis of the spinal cord, 612; in pseudo-hypertrophic muscular paralysis, 660; in tabes, 644; in tetanus, 792.
- Pavement epithelium** in cancer of the œsophagus, 369.
- Pearly distemper** in cattle in relation to tuberculosis in man, 208, 209.
- Pelioma typhosum**, 17.
- Peliosis**, 961; rheumatica, 962; senile, 961.
- Pelvis** in osteomalacia, 926, 927; rachitic, 921.
- Pelvis of the kidney**, dilatation of. See **HYDRONEPHROSIS**.
- Pelvis of the kidney**, inflammation of. See **PYELITIS**.
- Pepsine** in gastric catarrh, 391.
- Percussion**, change of pitch on, over cavities, 223.
- Perforation**, peritonitis from, 449; in purpura hemorrhagica, 963.
- Peribronchitis**, tubercular, 213.
- Pericardial surfaces**, adhesion of, 326.
- Pericarditis**, 321; adhesive, 326; in articular rheumatism, 904; chronic, 323; diagnosis of, 327; externa, 322, 325; fibrinous, 322; hemorrhagic, 322; in pneumonia, 197; prognosis of, 328; in pulmonary tuberculosis, 228; purulent, 322; sero-fibrinous, 327; treatment of, 328; tubercular, 322, 327; in valvular disease of the heart, 298.
- Pericardium**, air in the, 330; blood in the, 326; dropsy of the, 329; inflammation of the, 321; obliteration of the, 326.
- Perichondritis**, laryngeal, 134; diagnosis of, 135; external, 134; internal, 134; secondary, 135; treatment of, 135.
- Perinephritic abscess**, 870; causes of, 870; symptoms of, 870; treatment of, 871.
- Perinephritis**, purulent, 870.
- Periosteal reflex**, 545; in cerebral hemorrhage, 732.
- Periostitis ossificans** in articular rheumatism, 913.
- Peripheral nerves**, diseases of, 565; forms of paralysis of, 555; inflammation of, 579; new growths in, 585.
- Peripleuritis**, 267; diagnosis of, 267; prognosis of, 267.
- Periproctitis**, 408.
- Peritoneal cancer**, 463; diagnosis of, 463; treatment of, 463.
- Peritoneal dropsy**, 400.
- Peritonitis**, acute, 449; acute circumscribed, 451, 452; adhesive, 451; in articular rheumatism, 450, 464; cancerous, 463; in children, 459; in cholelithiasis, 473; chronic, 457; circumscribed, 451; deformans, 458; diagnosis of, 456, 458; diffuse general, 457; fibrino-purulent, 450; hemorrhagic, with formation of hematoma, 459; in nephritis, 450; in pleurisy, 450; prognosis of, 456; in pulmonary tuberculosis, 227; sacculated, 451; septic, 451; treatment of, 456, 460; tubercular, 457; in typhoid fever, 18, 11.
- Peritonsillar abscess**, 354.
- Perityphlitis**, 418. See also **TYPHILITIS**.
- Peroneal paralysis**, 529.
- Pertussis**, 160. See **WHOOPING-COUGH**.
- Petechial typhus**, 28. See **TYPHUS**.
- Peyer's patches** in typhoid fever, 9.
- Pharyngeal catarrh**, chronic, 367; hypertrophic, 368; prognosis of, 359; treatment of, 359.
- Pharyngitis**, chronic, 367; granular, 357; atreta, 358.
- Pharynx** in measles, 47; in scarlet fever, 38; tuberculosis of, 226; in typhoid fever, 12.
- Phenacetine**, in chorea, 783; in headache, 592; in migraine, 693; in neuralgia, 520; in neurasthenia, 418.
- Phlebitis**, purulent, in septicæmia, 119.
- Phloridzine** as cause of glycosuria, 267.
- Phosphate calculi** in nephrolithiasis, 885.

- Phosphorus, 648; in pernicious anæmia, 945; in neuralgia, 530; in osteomalacia, 927; in rachitis, 925; in tabes, 618.
- Phosphorus necrosis, 1006.
- Phosphorus poisoning, 1006; acute, 1006; chronic, 1006.
- Phrenic nerve, paralysis of, 568.
- Phthisis, fibroid, 223.
- Phthisis, laryngeal, 136. See TUBERCULOSIS.
- Phthisis pulmonalis, 207. See TUBERCULOSIS.
- Physostigmine, in chorea, 783.
- Piano-player's cramp, 579.
- Picric acid in trichinosis, 124.
- Pigeon-breast, rachitic, 923.
- Pigment calculi in cholelithiasis, 471.
- Pigment induration in pulmonary tuberculosis, 314.
- Pilocarpine in diphtheria, 72; in nephritis, 847.
- Pine-needle baths in muscular rheumatism, 919.
- Pin-worms, 446.
- Piperin in leukaemia, 950.
- Pitch, change of, on percussion over cavities, 222.
- Pityriasis versicolor in pulmonary tuberculosis, 229.
- Plethora, 709.
- Pleura, cicatricial contraction of, in pleurisy, 258, 260; fistule of, after empyema, 264; new growths of, 272.
- Pleura in leukaemia, 947; in pneumothorax, 268; in pulmonary tuberculosis, 226.
- Pleurisy, 253; adhesive, 255; in articular rheumatism, 904; complications of, 261; diagnosis of, 262; with effusion, 258; fibrinous, 254, 257, 261; in pneumonia, 193; primary, 253; prognosis of, 263; purulent, 262; secondary, 253; in septicæmia, 112; in small-pox, 56; tapping in, 264; treatment of, 264; tubercular, 254, 261; in typhoid fever, 13.
- Pleuritic effusions, 258; ossification, 265; thickening, 255, 260.
- Pleuritis, 253; sicca, 254, 257.
- Pleuro-pericarditis, 325.
- Pleuro-pneumonia, 189.
- Plexus paralysis of the brachial plexus, 567.
- Pneumatic treatment in bronchitis, 154; in emphysema, 181.
- Pneumatometer, 173.
- Pneumonia alba in pulmonary syphilis of the newborn, 256; anomalies in course of, 200; asthenic, 201; in articular rheumatism, 906; bilious, 197; catarrhal, 184; central, 201; cheesy, 187, 213; in children, 200; chronic interstitial, 163; complications of croupous, 193; crossed, 191; croupous, 189; delayed resolution of croupous, 202; diagnosis of croupous, 203; in diphtheria, 69; disposition to croupous, 189; endemic occurrence of croupous, 190; erysipelatous, 190; fibrinous, 190; genuine, 189; infectious nature of croupous, 189; intermitting, 199; lobar, 189; lobular, 184, 213; in measles, 49; migrans, 196; in nephritis, 843; in old people, 200; pathological lesion of catarrhal, 185; of croupous, 190; primary, 189; prognosis of croupous, 204; in rachitis, 923; in scurvy, 959; in small-pox, 56; symptoms of catarrhal, 186; of croupous, 193; in tetanus, 792; traumatic, 189; treatment of catarrhal, 188; of croupous, 204; typhoid, 201; wandering, 196.
- Pneumonoconiosis, 245.
- Pneumopericardium, 330.
- Pneumothorax, 267; circumscribed, 268; closed, 269; diagnosis of, 270; open, 269; in pulmonary tuberculosis, 226; sacculated, 268; treatment of, 270; in typhoid fever, 13; valvular, 270.
- Pneumo-typhoid, 13, 202.
- Podagra, 984. See GOUT.
- Points douloureux in neuralgia, 517.
- Poisoning, 1003.
- Polioencephalitis, 745.
- Poliomyelitis, acute, of adults, 671; diagnosis of, 672; relation of, to neuritis, 672; symptoms of, 671; treatment of, 672.
- Poliomyelitis, acute, in children 667. See SPINAL PARALYSIS OF CHILDREN.
- Poliomyelitis, subacute and chronic, 673; treatment of, 674.
- Polyæsthesia, 507; in tabes, 640.
- Polyarthritides, chronic, 911.
- Polydipsia in diabetes, 967, 971, 983; in hysteria, 805.
- Polymyositis, acute, 919.
- Polyp in the œsophagus, 366.
- Polysarcia adiposa, 992.
- Polyuria in anæmia, 934; in cerebro-spinal meningitis, 106; in contracted kidney, 859; in diabetes insipidus, 982-984; in diabetes mellitus, 967, 971, 976; in epilepsy, 773; in hysteria, 806.
- Pomegranate in tape-worm, 444.
- Pons, hæmorrhages into, 691. See also MEDULLA.
- Pork in relation to trichinosis, 122.
- Portal vein, purulent inflammation of, 500 (see PYLEPHLEBITIS); thrombosis of, 502. See PYLETHROMBOSIS.
- Post-epileptic insanity, 774.
- Posterior nasal catarrh, chronic, 126.
- Potassium, acetate of, in nephritis, 848; chlorate of, in cystitis, 896; nitrate of, poisoning from, 1004; picro-nitrate of, in chyluria, 876; salts, in scurvy, 960.
- Pott's boss on the vertebral column, 609.
- Power, sense of, 510.
- Pregnancy in epilepsy, 774; nephritis of, 845.
- Premature delivery in chorea gravidarum, 784.
- Pressure diverticula, 363.
- Pressure paralysis of the spinal cord, 608; bending of the cord in, 610; causes of, 608; complications of, 613; diagnosis of, 613; pathological lesion of the vertebræ and of the cord in, 609; place of compression in, 609; treatment of, 614; trephining for, 614.
- Pressure points in facial spasm, 572.
- Pressure, sense of, disturbances of, in tabes, 641; partial paralysis of, 507; test of, 507.
- Proctitis, 407.
- Professional diseases, 245.
- Professional neuroses of co-ordination, 577.
- Proglottides of tape-worm, 440.
- Propulsion in paralysis agitans, 785.
- Prosopalgia, 521. See TRIGEMINUS, NEURALGIA OF.
- Prostate in genito-urinary tuberculosis, 888.
- Pseudo-crises in croupous pneumonia, 199; in relapsing fever, 33.
- Pseudo-croup, 131.
- Pseudo-hypertrophy of the muscles, 659; beginning of, 659; increase of volume of different muscles in, 660; symptoms of, 659.
- Pseudo-leucocythæmia, 951.
- Pseudo-leukæmia, 951; diagnosis of, 953; examination of the blood in, 952; lymphatic, 952; relation of, to anæmia, 951; to infectious tumors, 951; symptoms of, 952; treatment of, 953.
- Pseudo-paralysis, spastic, 664.

- Pseudo-relapse in scarlet fever, 44.  
Pseudo-sclerosis, 631.  
Pseudo-tabes of alcoholic subjects, 584.  
Psoriasis of the tongue, 346.  
Psychical equivalent of epilepsy, 774.  
Ptosis in oculo-motor paralysis, 556.  
Pulmonary valve, insufficiency of, 293; stenosis of, 293.  
Pulsation, epigastric, in valvular disease of the heart, 284.  
Pulsus bigeminus, 298; celer, 299; inequalis, 297; irregularis, 297; paradoxus, 167, 334, 336; tardus, 333.  
Puncture in ascites, 462; in chronic hydrocephalus, 769; in cirrhosis of the liver, 483; in hydronephrosis, 892; in nephritis, 849; in pericarditis, 329; in pleurisy, 264; in pneumonia, 196; in pneumothorax, 271; in valvular disease of the heart, 306.  
Pupils in epilepsy, 773, 777; in general paralysis of the insane, 763; in hæmatoma of the dura, 697, 698; in meningitis, 700, 704; in pernicious anæmia, 942; in tetanus, 792; in thermic fever, 747.  
Pupils, immobility of, in eclampsia of children, 779; in epilepsy, 773, 777; in general paralysis of the insane, 763; in lesions of the corpora quadrigemina, 722; in tabes dorsalis, 636.  
Purpura, 961; hæmorrhagica, 962; hæmorrhagica, prognosis and treatment of, 962; rheumatica, 962; simplex, 962; urticaria, 962; variolosa, 57.  
Pus, collections of, as a cause of septicæ-pyæmia, 109.  
Pustule, malignant, 117. See MALIGNANT PUSTULE.  
Pustules in glanders, 116; in small-pox, 53.  
Putrefaction, abnormal intestinal, as cause of convulsions, 771.  
Pyæmic symptoms in sinus thrombosis, 708; in suppurative pyelphlebitis, 501.  
Pyelitis, 881; calculosa, 881, 884; in tabes, 643; in myelitis, 621; origin of, 881; symptoms of, 882; treatment of, 884.  
Pyelocystitis, 881.  
Pyelonephritis, 869, 882.  
Pyelphlebitis, chronic adhesive, 502.  
Pyelphlebitis, suppurative, 500; diagnosis of, 500; of the newborn, 500; symptoms of, 500.  
Pylethrombosis, 502; symptoms of, 502; treatment of, 503.  
Pyonephrosis, 882.  
Pyopneumothorax, 268.  
Quicksilver in intestinal obstruction, 439.  
Quincke's capillary pulse, 289.  
Quinine in asthma, 172; in diabetes, 981; in habitual headache, 532; in hæmoglobinuria, 956; in leukæmia, 950; in malaria, 96; in Ménière's disease, 769; in neuralgia, 519; in neurasthenia, 818; in neuroses of the heart, 319; in pulmonary tuberculosis, 235; in sciatica, 520, 527; after scurvy, 961; in trigeminal neuralgia, 520, 523; in trophic disturbances, 590; in typhoid fever, 20, 24, 25; in whooping-cough, 163.  
Rabies, 113. See HYDROPHOBIA.  
Race, influence of, on diabetes mellitus, 967; on hæmophilia, 963; on hysteria, 799; on yellow fever, 101.  
Rachitis, 920; acute, 924; chemical examination of the bones in, 921; chronic, 924; diagnosis and prognosis of, 924; foetal, 921; origin of, 920; relation of, to spasm of the glottis, 148; symptoms of, 922; tarda, 921; treatment of, 924.  
Radial paralysis, 564; chronic thickening of the extensor tendons in, 565; disturbances of function in, 565; in lead paralysis, 570; rheumatic, 565; traumatic, 564.  
Radiating fungus, 274.  
Rag-picker's disease, 119. See MALIGNANT PUSTULE.  
Railway-spine, 573. See TRAUMATIC NEUROSES.  
Raynaud's disease, 586; with hæmoglobinuria, 954.  
Rectal speculum in cancer of the rectum, 426.  
Rectum, cancer of, 426; inflammation of, 407; neuralgia of, 528; paralysis of, in injury of the spinal cord, 607; paralysis of, in myelitis, 621; syphilis of, 425; symptoms of, 425; treatment of, 425.  
Recurrent fever. See RELAPSING FEVER.  
Recurrent nerve, paralysis of, 139.  
Re-enforcement of patellar reflex, 544.  
Reflex centers, vaso-motor, 587.  
Reflexes, 543; in acute ascending spinal paralysis, 674; after cerebral hæmorrhage, 729, 732; in chorea, 782; in facial paralysis, 561; in injury of the spinal cord, 607; in tabes, 641; in myelitis, 620; in neuralgia, 570; in neuritis, 583, 584; in paralysis, 540; in pressure paralysis of the spinal cord, 612; in progressive bulbar paralysis, 687; in progressive muscular atrophy, 657; in sciatica, 536; in spinal apoplexy, 606; in spinal meningitis, 600; tests and condition of, 543; in tetanus, 792; in trigeminal neuralgia, 531; in tubercular meningitis, 704; in unilateral lesion of the spinal cord, 684.  
Reflex epilepsy, 771; neuralgia, 517; paralyses, 537; spasm, saltatory, 575.  
Refraction, errors of, as a cause of headache, 530; migraine, 591.  
Rehine bath, artificial, in myelitis, 627.  
Relapses of cholera, 86; of erysipelas, 64; of lead paralysis, 570; of scarlet fever, 44; of sciatica, 527; of typhilitis, 492; of typhoid fever, 19; of typhus fever, 30.  
Relapsing fever, 31; complications of, 35; contagiousness of, 32; epidemic occurrence of, in Germany, 31; inoculation of, 32; period of incubation of, 32; prognosis of, 35; spirilli in, 34; treatment of, 35.  
Renal crises in tabes, 643.  
Ren mobilis, 876.  
Resonance, thoracic, in pleurisy, 259.  
Respiration in acute ascending spinal paralysis, 675; in acute bulbar paralysis, 694; amphoric, 269; in amyotrophic lateral sclerosis, 652; in anæmia, 932, 942; in asthma, 168; bronchial, 223; in bronchitis, 148, 152; in bulbar hæmorrhage, 692; in cancer of the lungs, 251; in cerebral hæmorrhage, 729, 732; in chronic poliomyelitis, 673; in cirrhosis of the liver, 481; in diabetic coma, 973; in embolism and thrombosis of the basilar artery, 694; in epilepsy, 773; in exophthalmic goitre, 597; in hepatitis, 477; in hysteria, 803; interrupted, 222; in tabes, 643; metallic, 269; metamorphosing, 222; in miliary tuberculosis, 237, 239; in obesity, 995; in osteomalacia, 927; in phthisis, 222; in pneumonia, 186, 191; in progressive bulbar paralysis, 686; in progressive muscular atrophy, 656, 657, 658; in pseudo-leukæmia lymphatica, 952; in scurvy, 958; in tetanus, 793; in thermic fever, 747; in trichinosis, 122; in tubercular meningitis, 704, 705; in uræmia, 832.  
Respiratory spasms, 576; complicated, 577.

- Retina in chronic nephritis, 884; in contracted kidney, 861; in diabetes, 972; in leukæmia, 947.  
 Retinal hæmorrhages in septicæ-pyæmia, 111.  
 Retropharyngeal abscess, 360.  
 Retropulsion in paralysis agitans, 785.  
 Retro-tonsillar abscess, 354.  
 Revaccination, 59.  
 Rhabdomyoma, 872.  
 Rheumatism, acute articular, 900; alkaline treatment of, 910; cerebral, 905; in chorea, 780; chronic, 911; diagnosis of, 907; endocarditis in, 903; hyperpyretic, 905; prognosis of, 906; prophylaxis of, 911; scarlatinal, 43; symptoms, 901; treatment of, 907, 910.  
 Rhinitis, 125; chronic, 126; in scrofula, 1000.  
 Rickets, 920. See RACHITIS.  
 Râtheln, 51; period of incubation of, 51; prognosis of, 51; relation of, to measles, 51.  
 Romberg's symptom in locomotor ataxia, 686.  
 Root-zones, 510.  
 Rosary, rachitic, 923.  
 Roenthal-Leube meat solution, 389.  
 Roseola in typhoid fever, 16; in typhus fever, 30.  
 Round-worms, 445.  
 Sac, pericardial, air in, 330; blood in, 330.  
 Saccharine in diabetes, 980.  
 Sage-tea in phthisis, 235.  
 St. Anthony's fire, 61.  
 St. Vitus's dance, 780.  
 Salsam convulsions, 574.  
 Salicylate of sodium in articular rheumatism, 908; in diabetes, 961; in gout, 992; in habitual headache, 532; in hemicrania, 593; in neuralgia, 530; in typhoid fever, 24.  
 Salicylic acid in articular rheumatism, 907; in diseases of the trophic nerves, 590; in gastric catarrh, 381; in gout, 992; in muscular rheumatism, 919; in neuritis, 584; in purpura hæmorrhagica, 963; in tabes, 648; in tetanus, 784.  
 Salicylic delirium, 908; dyspnoea, 908; powder in phthisis, 235.  
 Salivation in diabetes insipidus, 968; in hydrophobia, 114; in stomatitis, 341; in ulcerative stomatitis, 343.  
 Salol in rheumatism, 910.  
 Salt in epilepsy, 778; in hæmoptysis, 235.  
 Salt-baths in gout, 991; in scrofula, 1001.  
 Saltpeter-paper in asthma, 172.  
 Sand-baths in articular rheumatism, 916.  
 Santonica in ascarides, 446.  
 Santonin in ascarides, 446.  
 Sarcina ventriculi, 370.  
 Sarcoma, alveolar, of the lungs, 250; of the kidneys, 872.  
 Scarification of the skin in dropsy, 306.  
 Scarlatina, 36.  
 Scarlatinal diphtheria, 40; eruption, 41; nephritis, 42, 43; poison, 36.  
 Scarlet fever, 36; contagiousness of, 36; diagnosis of, 44; disposition to, 36; epidemic occurrence of, 37; hæmorrhagic, 41; inoculation of, 36; miliary, 41; papular, 41; period of incubation of, 37; prognosis of, 44; rudimentary forms of, 43; tenacity of the contagium of, 36; treatment of, 44; typhoid form of, 44; variegated, 41.  
 Sciatica in diabetes, 973; diagnosis of, 527; relapses of, 527; symptoms and cause of, 526; treatment of, 527.  
 Sciatic paralysis, 569; treatment of, 569.  
 Scirrhus cancer of the œsophagus, 369; of the stomach, 391.  
 Sclérose en plaques, 627. See SCLEROSIS, MULTIPLE.  
 Sclerosis, amyotrophic lateral, 650; diagnosis of, 653; implication of the medulla in, 651; symptoms and course of, 651; treatment of, 653.  
 Sclerosis, disseminated, 627. See SCLEROSIS, MULTIPLE.  
 Sclerosis, multiple, of the brain and cord, 627; distinction of, from paralysis agitans, 631; hereditary predisposition to, 628; relation of, to chronic bulbar paralysis, 631; to chronic myelitis, 630; to general paralysis of the insane, 631; to spastic spinal paralysis, 631; seat of the sclerotic nodules in, 627; symptoms of, 629; treatment of, 631.  
 Sclerosis, postero-lateral, 649.  
 Sclerosis, primary lateral, 663.  
 Sclerosis, renal, 856.  
 Sclerotinic acid in phthisis, 235.  
 Scolex, 441.  
 Scoliosis, rachitic, 923.  
 Scorbutic anæmia, 959; ulcers, 959.  
 Scorbutus, 956. See SCURVY.  
 Scrofula, 999; relation of, to tuberculosis, 216, 1000; treatment of, 1000.  
 Scurvy, 956; causes of, 957; contagiousness of, 957; distinction of, from pelliosis and stomatitis, 960; epidemic occurrence of, 957; forms of, 960; symptoms of, 958; treatment of, 960.  
 Season and chorea, 780.  
 Seat-worms, 446.  
 Secondary degeneration. See SPINAL CORD (secondary degeneration).  
 Secretion, disturbances of, 590; in acute ascending spinal paralysis, 674; in anæmia, 933; in cerebral hæmorrhage, 723; in diabetes insipidus, 962; in exophthalmic goitre, 597; in hæmoglobinuria, 954; in hysteria, 805; in myelitis, 622; in neurasthenia, 816; in progressive bulbar paralysis, 687; in subacute poliomyelitis, 673; in tetanus, 793; in tetany, 790;  
 Secretions in diabetes, 975, 982, 983.  
 Semilunar valves, insufficiency of, 237.  
 Senile emphysema, 173.  
 Senile kidney, 333, 857.  
 Sensation, conduction of, in acute ascending spinal paralysis, 674; delayed, 500.  
 Sensation, paralysis of, in tabes, 640; partial, 505.  
 Sensibility, disturbances of, in acute ascending spinal paralysis, 675; in arsenical paralysis, 571; in bulbar hæmorrhage, 692; in caisson disease, 608; in cerebral hæmorrhage, 733; in compression of the medulla, 695; in crural paralysis, 568; in epilepsy, 772; in focal diseases of the crus, 723; of the internal capsule, 721; general consideration of, 505; in general paralysis of the insane, 763; in injury of the spinal cord, 607; in the larynx, 143; in median paralysis, 596; in multiple sclerosis, 630; in myelitis, 619; in neuralgia, 511; in neuritis, 584, 585; in obturator paralysis, 569; in paralysis, 539; in pressure paralysis of the spinal cord, 612; in radial paralysis, 565; in sciatica, 536; in sciatic paralysis, 569; in syringomyelia, 678; in tabes, 639; in tetanus, 792; in tumors of the base of the brain, 752; in ulnar paralysis, 566; in unilateral lesion of the spinal cord, 683; in writer's cramp, 578.  
 Sensory centers, 715.  
 Sensory nerves, diseases of, 505.

- Septico-pyæmia, 108; circulatory apparatus in, 111; cryptogenetic or spontaneous, 109; diagnosis of, 112; jaundice of the skin in, 112; prognosis of, 112; treatment of, 113.
- Sero-pneumothorax, 267.
- Serous membranes in articular rheumatism, 904.
- Serratus paralysis, 563; course of, 564; rheumatic, 563; traumatic, 563; treatment of, 564; wing-like position of the scapula in, 564.
- Serum albumen in albuminuria, 823.
- Sewing-machine girls, affection of, 579.
- Sex, influence of, in acute ascending spinal paralysis, 674; in acute yellow atrophy of the liver, 485; in amyotrophic lateral sclerosis, 650; in anæmia, 929, 934, 940; in cerebral hæmorrhage, 726; in cerebral syphilis, 757; in cerebral tumor, 748; in cholera, 83; in chorea, 781; in congenital myotonia, 795; in diabetes, 967; in exophthalmic goitre, 595; in Friedreich's ataxia, 648; in general paralysis of the insane, 761; in gout, 985; in hæmatoma of the dura mater, 697; in hæmophilia, 963; in hepatic colic, 470; in hemiparesis, 591; in hysteria, 799; in leukæmia, 946; in multiple sclerosis, 628; in neuralgia, 516; in obesity, 994; in osteomalacia, 925; in paralysis agitans, 784; in phthisis, 211; in poliomyelitis, acute, of adults, 671; in pseudo-hypertrophic muscular paralysis, 659; in pseudo-leukæmia, 952; in rachitis, 921; in tabes, 633; in tetany, 789; in unilateral facial atrophy, 594.
- Sexual excess, as cause of myelitis, 616.
- Sexual functions in diabetes, 972; in functional disturbances of the spinal cord, 606; in injuries of the spinal cord, 607; in myelitis, 621; in tabes, 648.
- Sexual organs in chlorosis, 929; in diabetes, 972; diphtheria of, 60; in exophthalmic goitre, 595; in gout, 987; in hysteria, 800; neuralgia of, 528; in neurasthenia, 816; (female) in peritonitis, 450.
- Shadows of red blood-corpuscles in hæmoglobinuria, 955.
- Shaking, 540.
- Shaking palsy, 784.
- Ship fever, 28. See TYPHUS FEVER.
- Shoulder, muscles of, paralysis of, 562; paralysis of, unilateral, in cerebral hæmorrhage, 732; spasm of, 575.
- Siderosis pulmonum, 245.
- Silver, nitrate of, in chorea, 783; in dysentery, 80; in intestinal catarrh of children, 417; in tabes, 648; in myelitis, 627; in spastic spinal paralysis, 667; in valvular disease of the heart, 303.
- Singultus, 577. See HICCUGH.
- Siphon, in washing out the stomach, 399.
- Skin, care of, in diabetes, 980; character of, in arthritis deformans, 915; itching of, in uræmia, 833.
- Skin, diseases of, in articular rheumatism, 904; in dengue, 99; in diabetes, 972; in gout, 987; in pneumonia, 198; in scarlet fever, 41; in scrofula, 999; in scurvy, 958; in small-pox, 55; in trichinosis, 123; in typhoid fever, 16.
- Skoda's resonance in pleuritic effusion, 259.
- Sleeplessness in neurasthenia, 816.
- Small-pox, 52; confluent, 53; contagiousness of, 52; diagnosis of, 57; hæmorrhagic, 57; mortality in, 57; period of incubation in, 53; prognosis of, 57; treatment of, 58.
- Smell, sense of, anæsthesia of, 532; anomalies of, 532; in epilepsy, 772; hyperæsthesia of, 532; in hysteria, 801; relation of, to anomalies of taste, 533; subjective sensations of, 532; test of, 532; treatment of anomalies of, 533.
- Sneezing spasm, 577.
- Sodic bicarbonate in diabetic coma, 961; bicarbonate in gastric catarrh, 382; carbonate in nephrolithiasis, 887; hydrate in sulphuric-acid poisoning, 1008; phosphate in nephrolithiasis, 887; sulphate in carbolic-acid poisoning, 1006.
- Soil theory in relation to typhoid fever, 3.
- Soil water in relation to cholera, 83; in relation to typhoid fever, 2, 3.
- Somnambulism in hysteria, 809.
- Soor, 344.
- Sore throat, 351 (see TONSILLITIS); catarrhal, 352; follicular, 353; hæmorrhagic, 354; necrotic, 354; parenchymatous, 353; phlegmonous, 354; in scarlet fever, 39; in small-pox, 56; in typhoid fever, 12.
- Soul-blindness, 716.
- Soul-deafness, 716.
- Southey's trocar in dropsy, 306.
- Spasm, 539 (see CONVULSIONS); of the cervical muscles, 573; clonic, 540; co-ordinated, 541; of the facial nerves, 572; forms of localized, 540; of the muscles of the lower extremity, 575; of the œsophagus, 371; of the respiratory muscles, 576; tonic, 540, 541; tonic-clonic, 540.
- Spasm of the glottis, 142. See GLOTTIS, SPASM OF.
- Spastic-paretic gait in multiple sclerosis, 630; in spastic spinal paralysis, 664; in syringomyelia, 678.
- Speech, disturbances of, 716; in acute bulbar myelitis, 694; in amyotrophic lateral sclerosis, 632; in athetosis, 787; in bulbar hæmorrhage, 692; in cerebral embolism, 740; in cerebral hæmorrhage, 728, 736; in cerebral syphilis, 759; in cerebral tumors, 750, 752; in chorea, 781; in compression of the medulla, 695; in embolism and thrombosis of the basilar artery, 694; in epilepsy, 772; in focal diseases of the centrum ovale, 720; in general paralysis of the insane, 762, 766; in hæmatoma of the dura, 697; in hereditary ataxia, 649; in meningitis, 704; in multiple sclerosis, 629; in progressive bulbar paralysis, 685, 687.
- Sphincter, reflex spasm of, in cystitis, 894.
- Spina bifida, 679; complication of, with purulent meningitis, 680; seat of, 679; surgical treatment of, 680; tumor formation in, 680.
- Spinal apoplexy, 604; symptoms of, 605; treatment of, 605.
- Spinal cord, anæmia of, 604.
- Spinal cord, cavity and fissure formation in, 677; in cerebro-spinal meningitis, 104, 105; circulatory disturbances of, 604; consumption of, 632; diffuse diseases of, 615; diseases of, 599; functional disturbances of, 605; functions of, 624; in gout, 988; hæmorrhages into, 604; new growths of, 676; systemic diseases of, 615; traumatic lesions of, 606.
- Spinal cord, compression of, 606; origin of, 608; seat of, 609; in spina bifida, 680.
- Spinal cord, concussion of. See TRAUMATIC NEUROSES.
- Spinal cord, degeneration of, in amyotrophic lateral sclerosis, 650.
- Spinal cord, disease of, after sudden lowering of atmospheric pressure, 608.
- Spinal cord, hyperæmia of, 604.
- Spinal cord, injuries of, 606; complication of, with secondary inflammation, 607; symptoms of, 607; treatment of, 607.

- Spinal cord, membranes of, acute inflammation of, 599; hæmorrhages of, 603; new growths of, 676.
- Spinal cord, secondary degeneration of, 690; after cerebral hæmorrhage, 732, 734; after cerebral lesions, 690; in compression of the cord, 610; in multiple sclerosis, 628; in transverse affections of the cord, 681; in tumors of the cord, 677.
- Spinal cord, softening of, 618.
- Spinal cord, tumors of, 676; differential diagnosis of, from transverse myelitis, 677; forms of, 676; origin of, 676; prognosis and treatment of, 677; relation of, to unilateral lesion of the spinal cord, 677.
- Spinal irritation, 606; in hysteria, 802; in neurasthenia, 815.
- Spinal meningitis, 599, 601; origin of, 599, 601; prognosis of, 600; symptoms of, 600, 601; treatment of, 601.
- Spinal muscles, paralysis of, 564; in pseudo-hypertrophic spinal paralysis, 564, 660.
- Spinal neurasthenia, 605; diagnosis of, 606; sensitiveness of the vertebrae in, 606; symptoms of, 606.
- Spinal paralysis, acute ascending, 674; acute infection in, 675; diagnosis and prognosis of, 676; symptoms of, 674; treatment of, 676.
- Spinal paralysis, atrophic, 671.
- Spinal paralysis of children, 667 (see INFANTILE PARALYSIS); from acute infection, 667; diagnosis and prognosis of, 670; relation of, to primary neuritis, 668; spinal cord in, 667; symptoms of, 668; treatment of, 670.
- Spinal paralysis, spastic, 663; diagnosis of, 666; pathological lesion in the cord in, 665; relation of, to chronic hydrocephalus, 665; treatment of, 666.
- Spine, stiffness of, in sinus thrombosis, 707; (tonic) in tetanus, 792; in tubercular meningitis, 703.
- Spirilli in relapsing fever, 34.
- Spirometer in pulmonary emphysema, 178.
- Spleen in acute ascending spinal paralysis, 675; in acute yellow atrophy of the liver, 486; in Addison's disease, 879; in articular rheumatism, 906; in cerebro-spinal meningitis, 106; in cirrhosis of the liver, 480; in erysipelas, 64; in hæmoglobinuria, 956; in hepatic syphilis, 491; in leukæmia, 946; in malaria, 94, 95, 96; in miliary tuberculosis, 239; in pernicious anæmia, 940; in phthisis, 228; in pneumonia, 197; in pseudo-leukæmia, 952; in pyelphlebitis, 501; in rachitis, 922; in relapsing fever, 32; in scarlet fever, 37, 43; in scurvy, 959; in septicopyæmia, 109, 112; in tubercular meningitis, 705; in typhoid fever, 11; in typhus fever, 30; in yellow fever, 101.
- Spleen, extirpation of, in leukæmia, 951.
- Splenic fever, 117.
- Splenization of the lung in atelectasis, 181.
- Splint-rest in sciatica, 528.
- Spondylitis deformans in chronic articular rheumatism, 914.
- Spoonwort in scurvy, 960.
- Spotted fever, 28, 103. See TYPHUS FEVER and CEBRO-SPINAL MENINGITIS.
- Stasis, oedema from, in renal diseases, 829.
- Status epilepticus, 774, 775.
- Stenocardia in hysteria, 761; in valvular disease of the heart, 297.
- Stenson's experiment in spinal anæmia, 604.
- Stimulants in cholera morbus, 412; in pneumonia, 806; in tetanus, 794.
- Stitch in the side in pleurisy, 256; in pneumonia, 192.
- Stomacace, 342. See STOMATITIS.
- Stomach. See also GASTRIC.
- Stomach, adhesions of, 387; in chlorosis, 935; in dysentery, 79; in erysipelas, 63; perforation of, 387, 394; in phthisis, 227; in pulmonary gangrene, 243; in purpura hæmorrhagica, 962; purulent inflammation of, 388; in yellow fever, 101.
- Stomach, abscess of, 383.
- Stomach-bougie in dilatation, 398.
- Stomach, cancer of, 391.
- Stomach, dilatation of, 396.
- Stomach, hæmorrhage from, 374; in gastric cancer, 392; in gastric ulcer, 386.
- Stomach, nervous affections of, 400; diagnosis of, 402; in hysteria, 805; nervous complications of, 400; peristaltic disturbance of the stomach in, 400; prognosis and treatment of, 402.
- Stomach-pump in chronic gastric catarrh, 377; in dilatation of the stomach, 399.
- Stomach, softening of, 388.
- Stomach, ulcer of, 384.
- Stomachics in gastric catarrh, 382; in jaundice, 466; in neurasthenia, 818.
- Stomatitis, 341; acute, 342; aphthous, 343; chronic, 342; in diabetes, 971; mercurial, 341; in scarlet fever, 39; scorbutic, 958; treatment of, 342, 343, 344; in typhoid fever, 12; ulcerative, 342.
- Stonecutters' lung, 245.
- Strabismus convergens in abducens paralysis, 556; in sinus thrombosis, 707.
- Stramonium cigarettes in asthma, 172.
- Strangulation, internal, 433.
- Stricture of the intestine, cicatricial, 432.
- Stripe-pneumonia, 189.
- Stroke, apoplectic, 728.
- Strongylus duodenalis, 448.
- Strongylus gigas, 875.
- Strophanthus in contracted kidney, 864.
- Struma in exophthalmic goitre, 596; extirpation of, 596; of the supra-renal capsules, 879.
- Strychnine in acute bulbar paralysis, 695; in cerebral hæmorrhage, 737; in diphtheria, 73; in facial paralysis, 562; in laryngeal paralysis, 142; in myelitis, 627; in neuritis, 585; in oculo-motor paralysis, 557; in progressive muscular atrophy, 658; in spinal paralysis of children, 671.
- Strychnine poisoning, 1008.
- Subsultus tendinum in typhoid fever, 14.
- Succussion of Hippocrates in pyo-pneumothorax, 209.
- Sudamina in articular rheumatism, 904.
- Sugar formation in diabetes, 970; influence of febrile diseases on, 971; influence of mental excitement on, 970; influence of physical exertion on, 970.
- Suggestion in catalepsy, 797; in hysteria, 808.
- Sulphonal in chorea, 783; in neurasthenia, 819.
- Sulphur in anæmia, 938; in hæmorrhoids, 429.
- Sulphur baths in lead paralysis, 570.
- Sulphuretted hydrogen poisoning, 1007.
- Sulphuric acid in purpura hæmorrhagica, 962.
- Sulphuric-acid poisoning, 1003.
- Sulphurous-acid poisoning, 1003.
- Sunstroke, 746; causes of, 746; symptoms of, 746; treatment of, 747.
- Support, mechanical, in spasm of the cervical muscles, 575; for the vertebral column in pressure paralysis of the spinal cord, 614.
- Suppositories in dysentery, 80.
- Suppuration as a cause of arthritis, 912.

- Suppurative fever in small-pox, 55.  
 Supra-renal capsules, diseases of, 878.  
 Suspension in tabes, 648.  
 Swamp fever, 90. See MALARIA.  
 Sweat-glands in jaundice, 487; in typhoid fever, 17; in uremia, 832.  
 Sweating in articular rheumatism, 904; in diabetes, 972; in hæmoglobinæmia, 954; in phthisis, 220, 229; in trichinosis, 123.  
 Sympathetic, irritation of, 591; in exophthalmic goitre, 597; trophic disturbances in, 591; paralysis of, 591; contraction of the pupils in, 591; in exophthalmic goitre, 597; in hemicrania, 591; vaso-motor disturbances in, 590.  
 Synovitis in articular rheumatism, 902; scarlatinal, 43.  
 Syphilis as cause of tabes, 632.  
 Syphilis of the rectum, 425.  
 Syphiloma, formation of, in syphilis of the liver, 490.  
 Syringomyelia, 677; extent of, 678; origin of, 678.  
 Tabes dorsalis, 632; ataxic stage of, 636; cause of anesthesia in, 641; development of, 632; diagnosis and prognosis of, 645; Friedreich's form of, 648; hereditary predisposition to, 632; histology of, 633; in chronic ergotism, 633; initial stage of, 635; involving cranial nerves, 642; partial paralysis of sensation in, 641; peripheral degeneration in, 634; peripheral paralysis in, 639; persistence of patellar reflex in, 641; pupillary changes in, 642; suspension in, 648; symptoms of, 636; syphilis as cause of, 632; terminal stage of, 636; treatment of, 646; trophic disturbances in, 644; with regard to progressive general paralysis, 645.  
 Tabes mesenterica, 459.  
 Tabes, motor, 654. See PROGRESSIVE MUSCULAR ATROPHY.  
 Tabes spastica, 663. See LATERAL SCLEROSIS.  
 Taches bleuâtres, 17.  
 Taches cérébrales, 705.  
 Tachycardia, 320.  
 Tactile circles, 506.  
 Tactile compasses, 506.  
 Tania echinococcus, 494; medio-canellata, 441; saginata, 441; solium, 449.  
 Tailor's cramp, 579.  
 Tampons in nasal catarrh, 128.  
 Tannin in chronic pharyngeal catarrh, 350; in nephritis, 846.  
 Tape-worms, 440; cures for, 443.  
 Taste, disturbances of, 533; central, 533; diagnosis of, 534; in epilepsy, 772; in facial paralysis, 559; in hysteria, 801; partial, 533; test of, 533; treatment of, 534.  
 Teeth, anomalies of, in diabetes, 971; in rachitis, 923.  
 Teething, 350; convulsions in, 351.  
 Telegrapher's cramp, 579.  
 Temperature, sense of, in paralysis agitans, 788; partial paralysis of, 508; perverse, 508; in syringomyelia, 678; in tabes, 641; test of, 508.  
 Temporal convolutions, focal diseases of, 710; relation of, to deafness, 718; relation of, to word-deafness, 716, 719; seat of the cortical center for hearing in, 716.  
 Tendinous spots on the pericardium, 323.  
 Tendon reflexes, 544; absence of, 545; in amyotrophic lateral sclerosis, 652; in cerebral hæmorrhage, 695; in cerebral paralysis of children, 745; in chronic hydrocephalus, 768; in epilepsy, 773; increase of, 545; in the lower extremities, 544; in multiple sclerosis, 629; in myelitis, 620; in poliomyelitis of adults, 672; in pressure paralysis of the spinal cord, 612; in progressive bulbar paralysis, 687; in secondary degeneration of the spinal cord, 682; in spastic spinal paralysis, 663, 665; in spinal paralysis of children, 699; in tabes, 641; in unilateral lesion of the spinal cord, 684; in the upper extremities, 545.  
 Tendons, sheaths of, in articular rheumatism, 902; thickening of, in radial paralysis, 565.  
 Tenesmus in dysentery, 78; in intestinal catarrh, 407.  
 Terminal phalanges, thickening of, in pulmonary stenosis, 263.  
 Testicles in genito-urinary tuberculosis, 680.  
 Tetanilla. See TETANY.  
 Tetanus, 791; bacilli of, 791; diagnosis of, 793; distinction of, from hydrophobia, 794; from meningitis, 794; from strychnine poisoning, 794; endemic and epidemic, 791; hydrophobic, 792; idiopathic, 791; influence of external conditions on, 791; intermittent (see TETANY, 789; neonatorum, 791; paroxysms of, 792; prodromal symptoms of, 791; rheumatic, 791; symptoms of, 792; toxins of traumatic, 791; treatment of, 794.  
 Tetany, 789; diagnosis of, 790; distinction of, from ergotism, 790; from professional neuroses, 790; epileptic, 789; origin of, 789; symptoms of, 789; treatment of, 791.  
 Thermæsthesiometer, 508.  
 Thermic fever, 746; pathology of, 746; symptoms of, 746; treatment of, 747.  
 Thermo-cantery in noma, 347; in pressure paralysis of the spinal cord, 614.  
 Thomson's disease, 795. See MYOTONIA.  
 Thoracic aorta, aneurism of, 334; causes of, 334; diagnosis of, 337; prognosis of, 337; symptoms of, 335; treatment of, 338.  
 Thoracotomy, 266.  
 Thorax, barrel-shaped, 177; compression of, in pulmonary emphysema, 180; deformity of, in osteomalacia, 926; in rachitis, 923; phthisical, 221; in pleurisy, 258; rigid dilatation of, 175.  
 Thrombi in typhoid fever, 16; in valvular disease of the heart, 300.  
 Thrombosis of the portal vein, 502.  
 Thrush, 344.  
 Thyroid gland, atrophy of, in myxedema, 580; extirpation of, for exophthalmic goitre, 598; relation of, to exophthalmic goitre, 597.  
 Tibialis paralysis, 569.  
 Tic convulsif, 572, 573 (see SPASM, FACIAL); douloureux, 521 (see TRIGEMINUS, NEURALGIA OF); rotoire, 574 (see SPASM OF THE CERVICAL MUSCLES).  
 Tissue metamorphosis, anomalies of, 928; in anemia, 933; in diabetes mellitus, 970.  
 Tissue, necrosis of, in gout, 968.  
 Toe-drop in peroneal paralysis, 569.  
 Tongue, atrophy of, in amyotrophic lateral sclerosis, 652; in progressive bulbar paralysis, 685; in progressive muscular atrophy, 657.  
 Tongue, injuries to, in epilepsy, 773.  
 Tongue, paralysis of, in acute bulbar paralysis, 694; in bulbar hæmorrhage, 692; (unilateral) in cerebral hæmorrhage, 731; in compression of the medulla, 695; in embolism and thrombosis of the basilar artery, 694.

- Tongue, spasm of, 573.  
 Tongue, ulcer on the frænum of, in whooping-cough, 161.  
 Tonics in scurvy, 900.  
 Tonsillitis, 351 (see *SORE THROAT*); diagnosis of, 355; follicular, 353; necrotic, 354; parenchymatous, 353; treatment of, 356.  
 Tonsils, abscess of, 353; chronic hypertrophy of, 356; treatment of, 356; extirpation of, 356; in leukaemia, 947; in pseudo-leukaemia, 952.  
 Torpid habitus, 1000.  
 Torticollis, rheumatic, 574; spastic, 574.  
 Touch, sense of, 506; condition of, 619; diminished in the tongue in facial paralysis, 559; in tabes, 640; test of, 506.  
 Tracheal catarrh, 146; stenosis, 166.  
 Tracheitis, 146.  
 Tracheotomy in diphtheria, 72; in cedema of the glottis, 136; in perichondritis, 185.  
 Traction diverticula in the œsophagus, 364.  
 Transfer in hysteria, 814.  
 Transudation in diabetes, 974; in leukaemia, 949.  
 Transverse myelitis, 615. See *MYELITIS*.  
 Traube's double sound in aortic insufficiency, 290.  
 Traumatic hysteria, 820.  
 Traumatic lumbago, 821, 918.  
 Traumatic neurasthenia, 821.  
 Traumatic neuroses, 819; cause of, 821; implication of brain in, 820; local, 820; origin of, after railway accidents, 819; relation of, to hysteria, 821; symptoms of, 819; treatment of, 820.  
 Tremor, 540; alcoholic, 540; in amyotrophic lateral sclerosis, 651; in epilepsy, 773; essential, 540; in exophthalmic goitre, 596; hysterical, 541; Intention, 540; mercurial, 1005; in multiple sclerosis, 629; in osteomalacia, 927; in paralysis agitans, 784; senile, 540; in typhoid fever, 14.  
 Trephining the skull in cerebral abscess, 743; in cerebral tumor, 756; in hydatids, 756; in meningeal hæmorrhage, 608; in pressure paralysis, 614; in traumatic epilepsy, 777; in tumors of the cord, 677; the vertebral column in injuries to the cord, 607.  
 Triceps paralysis, 563.  
 Trichina spiralis, 121.  
 Trichinosis, 121; treatment of, 123.  
 Tricocephalus dispar, 449.  
 Tricuspid insufficiency, 291.  
 Trigeminal, anaesthesia of, 513; neuromyolytic ophthalmia in, 513; occlusive bandage in, 515; skin of the face in, 514; in tabes, 641.  
 Trigeminal, neuralgia of, 521; in compression of the medulla, 695; in diabetes, 973; diagnosis of, 522; epileptiform, 522; infra-maxillary, 522; infra-orbital, 522; ligature of the carotid for, 523; operative treatment of, 523; prognosis of, 522; supra-orbital, 522; symptoms and course of, 521; treatment of, 522.  
 Trigeminal, paralysis of, 557; in bulbar hæmorrhage, 692; in progressive bulbar paralysis, 687.  
 Trigeminal, spasm of, 571; treatment of, 571.  
 Trismus, 571; artificial feeding in, 572; in cerebro-spinal meningitis, 105; in tetanus, 792; in tubercular meningitis, 705.  
 Trochlear paralysis, 556.  
 Trophic disturbances, 587; in arsenical paralysis, 571; of the bones and joints, 589; in cerebral hæmorrhage, 735; in cervico-brachial neuralgia, 534; in cutaneous anaesthesia, 512; in facial hemi-
- atrophy, 594; of the hair and nails, 589; in intercostal neuralgia, 525; in median paralysis, 556; in myelitis, 622; in neuralgia, 517; in neuritis, 583; in occipital neuralgia, 523; in paralysis, 538; in pressure paralysis of the spinal cord, 612; in progressive muscular atrophy, 653; in pseudo-hypertrophic muscular paralysis, 659; in sciatic paralysis, 589; of the skin, 588; in spinal paralysis of children, 669; in syringomyelia, 678; in tabes, 644; treatment of, 590; in trigeminal anaesthesia, 514; in trigeminal neuralgia, 522.  
 Trousseau's phenomenon in tetany, 790.  
 Trousseau's spots in tubercular meningitis, 705.  
 Tubercle bacilli, 208; detection of, 230.  
 Tubercula dolorosa of the peripheral nerves, 586.  
 Tuberculosis, 207. See also *MILIARY TUBERCULOSIS*.  
 Tuberculosis of the genito-urinary apparatus, 886; diagnosis of, 890; prognosis and treatment of, 890.  
 Tuberculosis of the intestines, 423; treatment of, 424.  
 Tuberculosis of the larynx, 136; diagnosis of, 137; treatment of, 138.  
 Tuberculosis of the lungs, 207; causes of, 208; complications of, 218; diagnosis of, 229; heredity of, 211; infectiousness of, 209; local, 212; physical examination in, 221; predisposition to, 210; prognosis of, 230; prophylaxis of, 231; symptoms of, 218; treatment of, 231.  
 Tuberculosis of the peritoneum, 457; of the pharynx, 226; of the serous membranes, 261, 327, 457; of the supra-renal capsules, 879.  
 Turpentine, inhalations of, in asthma, 172; in whooping-cough, 163.  
 Turpentine, oil of, in acute phosphorus poisoning, 1006; in cystitis, 896; in foetid bronchitis, 158; in genito-urinary tuberculosis, 890; in sciatica, 527; in tape-worm, 444.  
 Turpentine pipes in bronchitis, 154.  
 Tussis convulsiva, 160. See *WHOOPING-COUGH*.  
 Tylosis of the tongue, 346.  
 Typhilitis, 418; diagnosis of, 420; prognosis of, 421; treatment of, 421.  
 Typhoid, bilious, 35. See also *RELAPSING FEVER*.  
 Typhoid fever, 1; abortive, 18; bacilli of, 1; baths in, 22; in children, 19; contagiousness of, 2; in the corpulent, 19; diagnosis of, 20; disinfection in, 26; disposition to, 4; in drunkards, 19; immunity toward, 4; influence of age upon, 4; influence of season upon, 5; in old people, 19; outcry of children in, 19; peculiarities in the course of, 18; period of incubation of, 5; prodromal symptoms of, 5; prognosis of, 20; prophylaxis of, 26; recurrent fever-attack in, 8; relapses of, 19; relapses of, duration of, 19; relapses of, frequency of, 20; sopor in children in, 19; temperature curve in, 6; treatment of, 20; walking, 13.  
 Typho-malarial fever, 96.  
 Typhus abdominalis, 1 (see *TYPHOID FEVER*); levissimus, 18.  
 Typhus exanthematicus, 28 (see *TYPHUS FEVER*); levissimus, 31.  
 Typhus fever, 28; contagiousness of, 29; diagnosis of, 31; distinction of, from typhoid fever, 31; epidemic occurrence of, 29; immunity toward, 29; period of incubation of, 29; prodromal symptoms of, 29; prognosis of, 31; treatment of, 31.  
 Typhus recurrens, 31. See *RELAPSING FEVER*.  
 Tyrosine crystals in acute yellow atrophy of the liver, 468.

- Ulcers, atheromatous, 332; in laryngeal tuberculosis, 137; tubercular, 213; typhoid, 9.  
 Ulnar paralysis, 566; disturbance of function in, 566; traumatic, 566.  
 Umbilical hæmorrhage in relation to hæmophilia, 964.  
 Umbilical vein, inflammation of, in the new-born, 500.  
 Unilateral lesion of the spinal cord, 682.  
 Upper extremities, thickening and deformity of, in rachitis, 923.  
 Uræmia, 829; chronic, 831; in contracted kidney, 861; duration of, 833; in gout, 988; origin of, 830; in scarlet fever, 42; termination of, 834; in yellow fever, 102.  
 Urates in gout, 988.  
 Urea, deposit of, on the skin in uræmia, 832; in diabetes insipidus, 963; in diabetes mellitus, 969.  
 Ureter, obstruction of, in relation to hydronephrosis, 890.  
 Urethritis, 881.  
 Urethra in neurasthenia, 819.  
 Urethra, stricture of, in hydronephrosis, 891.  
 Urethral crises in tabes, 644.  
 Uric acid, in chorea, 780; in diabetes, 969; in gout, 988; in relation to contracted kidney, 858.  
 Urinary casts in renal disease, 823.  
 Urinary passages, parasites of, 874.  
 Urinary tests, Böttger's, 968; with chloroform, 467; in diabetes mellitus, 968; Fehling's, 968; with ferric chloride, for acetone, 970; Gmelin's, 467; heat, 834; Moore's, 968; with thread in gout, 990; Trommer's, 968.  
 Urine, in acute yellow atrophy of the liver, 487; amount of, in diabetes insipidus, 962; amount of, in diabetes mellitus, 967; in amyloid kidney, 866; in anæmia, 934; in cancer of the stomach, 894; in cerebral hæmorrhage, 729; in chlorosis, 935; in chorea, 782; in chyluria, 875; in cirrhosis of the liver, 481; in contracted kidney, 858; in cystitis, 894; in diabetes insipidus, 962; in diabetes mellitus, 966; in diphtheria, 70; in epilepsy, 773; in erysipelas, 64; in functional diseases of the spinal cord, 606; in gastric catarrh, 379; in genito-urinary tuberculosis, 889; in gout, 986; in hæmoglobinæmia, 954; in hydronephrosis, 893; in injuries of the spinal cord, 607; in jaundice, 467; in leukæmia, 949; in malaria, 94; in meningeal hæmorrhage, 603; in meningitis, 701, 705; in myelitis, 621; in nephritis, 841, 852; in osteomalacia, 972; in passive congestion of the kidney, 871; in pernicious anæmia, 942; in pneumonia, 197; in pressure paralysis of the spinal cord, 613; in pseudo-leukæmia, 952; in pyelitis, 882; in pyelophlebitis, 501; in rachitis, 924; in renal diseases, 823; in renal tumors, 873; in scarlet fever, 41; in small-pox, 56; in spinal meningitis, 600; in spinal paralysis of children, 669; in tabes, 643; in tetanus, 733; in typhoid fever, 17; in typhus fever, 30; in ulcer of the stomach, 387; in unilateral lesion of the spinal cord, 684; in whooping-cough, 161; in yellow fever, 102.  
 Urticaria in articular rheumatism, 904; in erysipelas, 64; in exophthalmic goitre, 597; in hæmoglobinæmia, 954; in jaundice, 465; in neuralgia, 517; in pneumonia, 198; in scarlet fever, 41.  
 Uterine neuralgia, 528.  
 Uva ursæ in nephritis, 848.  
 Vaccination, 58.  
 Vagus paralysis in relation to tachycardia, 321.  
 Valerian in diabetes insipidus, 964; in epilepsy, 778; in hysteria, 813.  
 Valvular disease of the heart, 280.  
 Varicella, 60; period of incubation of, 60; prognosis of, 61; treatment of, 61.  
 Variola, 52 (see SMALL-POX); hæmorrhagica pustulosa, 57; vaccina, 58; vera, 53.  
 Varioloid, 54. See SMALL-POX.  
 Varioloids miliaris, 55; verrucosa, 55.  
 Vaso-motor disturbances, 587; in bulbar hæmorrhage, 692; in cerebral hæmorrhage, 735; in cerebral hyperæmia, 710; in cervico-brachial neuralgia, 525; in epilepsy, 772; in exophthalmic goitre, 596; in hemicrania, 582; in hysteria, 804; in intercostal neuralgia, 525; in myelitis, 622; in neuralgia, 517; in neuritis, 583; in occipital neuralgia, 523; in paralysis, 539; in progressive bulbar paralysis, 687; in progressive muscular atrophy, 657; in sciatic paralysis, 569; in spinal neurasthenia, 606; symptoms of, 587; in trigeminal neuralgia, 521.  
 Vaso-motor paralysis, 587; redness of the skin with heightened temperature in, 587; in unilateral lesion of the spinal cord, 684.  
 Vaso-motor spasm, 588; relation of, to spontaneous symmetrical gangrene, 588; relation of, to scleroderma, 588; symptoms of, 588.  
 Veal, diseased, as a cause of typhoid fever, 3.  
 Vegetable acids in scurvy, 960.  
 Veins, diastolic collapse of, in obliteration of the pericardial cavity, 326.  
 Venesection. See BLOOD-LETTING.  
 Venous murmurs, anæmic, 933, 935; in leukæmia, 949.  
 Venous pulse, 272.  
 Venous stasis, 299.  
 Veratrine in pneumonia, 205.  
 Vermiform process in relation to intestinal obstruction, 433.  
 Vertebral column in arthritis deformans, 914; in cerebro-spinal meningitis, 105; in osteomalacia, 926; in rachitis, 923.  
 Vertigo ab aure læsa, 769; a stomacho læso, 379.  
 Vertigo in anæmia, 932; in bulbar hæmorrhage, 691; in cerebellar disease, 723; in cerebellar tumor, 753; in cerebral abscess, 742; in cerebral hæmorrhage, 728; in cerebral tumor, 750; in chlorosis, 935; in compression of the medulla, 695; in epilepsy, 772; in insolation, 746; in leukæmia, 949; in Ménière's disease, 769; in multiple sclerosis, 630; in neurasthenia, 816; in oculo-motor paralysis, 536; in pernicious anæmia, 941; in purulent meningitis, 700.  
 Vesical. See BLADDER.  
 Vesicatory. See BLISTER.  
 Villous cancer in the bladder, 897.  
 Violin-player's cramp, 579.  
 Vision, field of, in hysteria, 801.  
 Vocal cords, paralysis of, in diphtheria, 70; in hysteria, 803; in mediastinal tumor, 273; in pericarditis, 325.  
 Vocal fremitus in pleurisy, 260, 263; in pneumonia, 195; in pneumothorax, 269.  
 Volume, increased, of the lungs, 175.  
 Vomiting in acute yellow atrophy of the liver, 486; in Addison's disease, 880; in anæmia, 932; in cancer of the stomach, 392; in cerebellar disease, 724; in cerebral abscess, 742; in cerebral anæmia, 709; in cerebral hæmorrhage, 730; in cerebral tumor,

- 750; in cholera, 85; in cholera morbus, 411; in compression of the medulla, 695; in dilatation of the stomach, 897; in dysentery, 79; in erysipelas, 64; in exophthalmic goitre, 597; in gastric catarrh, 876; in hæmatoma of the dura, 697; in hæmoglobinæmia, 954; in hemicrania, 592; in hepatic colic, 472; in hepatitis, 447; in intestinal obstruction, 435; in Ménière's disease, 769; in meningitis, 104, 701, 705; in miliary tuberculosis, 289; morning, of drunkards, 876; in nephritis, 843, 864; in nephrolithiasis, 886; in nervous affections of the stomach, 400; in peritonitis, 454, 455; in pleurisy, 257; in pneumonia, 197; in phthisis, 227; in pulmonary gangrene, 243; in pyelophlebitis, 501; in scarlet fever, 37; in small-pox, 58; in tape-worm, 443; in thermic fever, 747; in typhilitis, 419; in typhoid fever, 10, 11; in typhus fever, 29; in ulcer of the stomach, 886; in uræmia, 822; in whooping-cough, 161; in yellow fever, 102.
- Voracity in tape-worm, 443.
- Vox choleraica, 85.
- Warmth, feeling of, increased in paralysis agitans, 796.
- Water cancer, 347.
- Water cushions in myelitis, 627.
- Water-pipe sound in open pneumothorax, 270.
- Waxy kidney, 864. See AMYLOID.
- Weakened heart, 312.
- Weeping spasms, 577; in hysteria, 807.
- Wet-nurse, milk of, 415.
- Whip-worm, 449.
- Whooping-cough, 160; catarrhal stage in, 160; contagiousness of, 160; convulsive stage in, 160; diagnosis of, 162; prognosis of, 162; sequelæ of, 162; treatment of, 162.
- Williams's tracheal tone in pleuritic effusion, 259.
- Wine in cholera morbus, 412; in typhoid fever, 22.
- Word-deafness, 718; in abscesses of the temporal lobes, 743.
- Worm abscess, 446.
- Worms, intestinal, 440.
- Writer's cramp, 577; diagnosis of, 578; Nussbaum's bracelet for, 579; origin of, 578; paralytic, 578; prognosis of, 578; spastic, 578; symptoms of, 578; treatment of, 578; tremulous, 578.
- Xanthelasma in jaundice, 465.
- Xanthine calculi in nephrolithiasis, 886.
- Yawning in paroxysmal hæmoglobinæmia, 954.
- Yawning spasm, 577.
- Yellow fever, 100; black vomit in, 102; causes of, 100; contagiousness of, 101; diagnosis of, 102; epidemic character of, 100; pathology of, 101; prognosis of, 102; symptoms and cause of, 101; treatment of, 102.
- Zinc, oxide of, in chorea, 783; in epilepsy, 778; in facial spasm, 573.
- Zinc paralysis, 571.
- Zinc, poisoning from, 1005.
- Zinc, sulphate of, in angina pectoris, 319; in gastric catarrh, 382.
- Zinc, valerianate of, in chorea, 783; in hiccough, 577; in spasm of the cervical muscles, 575; in trigeminal spasm, 572.

# THE DISEASES OF THE STOMACH.

BY DR. C. A. EWALD,

EXTRAORDINARY PROFESSOR OF MEDICINE AT THE UNIVERSITY OF BERLIN;  
DIRECTOR OF THE AUGUSTA HOSPITAL, ETC.

AUTHORIZED TRANSLATION  
FROM THE SECOND GERMAN EDITION, WITH SPECIAL ADDITIONS  
BY THE AUTHOR,

BY MORRIS MANGES, A. M., M. D.,

ATTENDING PHYSICIAN TO OUTDOOR DEPARTMENT, MOUNT SINAI HOSPITAL,  
NEW YORK CITY, ETC.

WITH THIRTY ILLUSTRATIONS.

8vo, 497 pages. Cloth, \$5.00; Sheep, \$6.00.

---

SOLD ONLY BY SUBSCRIPTION.

---

The following are extracts from a few of the notices that have appeared in the medical press:

"... We can recall no work on this special subject published in late years which is so thoroughly well written and useful as this of Ewald's. . . . Recent therapeutics of diseases of the stomach are discussed with candor and justice, yet critically. The author is an authority on what he writes. We believe him to be the best authority. . . . Some of his suggestions we have utilized and find them excellent."—*Texas Courier-Record of Medicine*.

"The profession are deeply indebted to Dr. Manges for this excellent translation of Dr. Ewald's lectures on diseases of the stomach, enriched by notes of the translator, revised by the author, which renders the work still more acceptable to the American reader. . . . The various diseases of the stomach are discussed with the detail and scientific accuracy for which the author is noted, and the work forms a very valuable addition to the library."—*New York Medical Times*.

"... There is no question but that Dr. Ewald has given us a work of great scientific value, and up to date in every particular. This is a book quite as valuable to the surgeon as to the physician, and no progressive medical man can afford to be without it."—*Omaha Clinic*.

"... The whole of this very important and difficult field is covered in a way that can not fail to commend itself to all physicians who desire to enlarge their sphere of professional knowledge and utility."—*Denver Medical Times*.

"The purchaser is impressed by the elegance of publication on opening this book, and such excellence is well fitted to such a work as this one is. . . . The work is thoroughly practical, and the physician who does not secure and carefully read it will deprive himself of a most important help in the treatment of diseases of the stomach."—*Virginia Medical Monthly*.

# TEXT-BOOK OF HUMAN PHYSIOLOGY,

*For the Use of Students and Practitioners of Medicine.*

By AUSTIN FLINT, M. D., LL. D.,

Professor of Physiology and Physiological Anatomy in the Bellevue Hospital Medical College, New York; Fellow of the New York State Medical Association, etc.

**FOURTH EDITION. ENTIRELY REWRITTEN.**

Large 8vo. 872 pages, with Two Lithographic Plates and  
316 Engravings on Wood.

---

*Cloth, \$6.00; sheep, \$7.00.*

---

"During the short time that has elapsed since the publication of the third edition of this work the advance in physiological knowledge has been so great that the author found it impossible to make the necessary corrections, and bring the text up to the present without entirely rewriting the work. Thus, while it is a descendent from former editions, the work is new in all its features. The form and typography have been changed. Many old figures have been expunged, and numerous new ones have been introduced. Most of the figures that have been retained are of cuts that have been re-engraved. Historical references contained in former editions have been greatly curtailed; unprofitable discussion of disputed questions and theories have been avoided; physiological chemistry has been omitted as far as practicable. The new book is therefore trimmed of all incidental subjects and topics, and the text confined to the statement of established facts."—*Physician and Surgeon.*

"This is the fourth edition of Flint's popular text-book on physiology, entirely rewritten, and so great have been the advances in our knowledge of this branch of medical science that little remains of the original text; even the defects, or rather deficiencies, of the edition of 1880 have rendered it imperative, in the light of recent progress, that a new edition be issued. The same general arrangement is preserved, and with reason. The beauty of Flint's Physiology consists in the exactness with which the author has carried out his intentions as expressed in the preface: 'I shall be more than satisfied if I have been able to give concise and connected statements of well-established facts, in such form that they can not be misunderstood. Peculiar views and theories, whether of the author or of others, have no proper place in a text-book which should represent facts generally recognized and accepted, and not the ideas of any one individual.' For a text-book containing the results of the most recent investigations in minute anatomy and physiology—one that studiously avoids profitless discussions of unsettled and disputed questions—one that is as exact and reliable as the present state of knowledge will permit, Flint's treatise can not be excelled."—*Kansas City Medical Index.*

# TEXT-BOOK OF OPHTHALMOLOGY.

By DR. ERNEST FUCHS,

PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF VIENNA.

*AUTHORIZED TRANSLATION  
FROM THE SECOND ENLARGED AND IMPROVED GERMAN EDITION,*

By A. DUANE, M. D.,

ASSISTANT SURGEON, OPHTHALMIC AND AURAL INSTITUTE, NEW YORK.

With One Hundred and Seventy-eight Illustrations, and an Appendix  
devoted to Instruments used in Ophthalmic Surgery  
and Examination of the Eye.

8vo, 788 pages. Cloth, \$5.00 ; Sheep, \$6.00.

---

*SOLD ONLY BY SUBSCRIPTION.*

---

THIS translation, made from advance sheets of the second German edition, will introduce to the English-speaking public of this country a book the high qualities of which have won for it the first place among works of its class in Europe. Dr. Fuchs's great opportunities for clinical observation, combined with his thorough practical knowledge of anatomical and pathological science, have enabled him to write a treatise which, for scientific accuracy and all-round completeness, will compare favorably with any work of its character; and his experience as a teacher and lecturer has enabled him to present the matter in a form eminently suited to the needs of the medical student and the general practitioner. Thus the work, while full, methodical, and in all respects brought down to the latest point of ophthalmological science, is couched in a clear and attractive style, which renders the book very easy reading; and great judgment has been shown in the amount of space allotted to the various subjects, those that are important receiving full attention, while matters of a merely scientific interest or dubious points are either briefly touched upon or are relegated to the fine print, where those who are curious in such matters can find them, but where they do not interfere with the continuity of the rest of the text.

# THE PRINCIPLES AND PRACTICE OF MEDICINE.

*Designed for the Use of Practitioners and Students of Medicine.*

By **WILLIAM OSLER, M. D.,**

Fellow of the Royal College of Physicians, London; Professor of Medicine in the Johns  
Hopkins University, and Physician-in-Chief of the Johns  
Hopkins Hospital, Baltimore.

SOLD ONLY BY SUBSCRIPTION.

---

*8vo. Cloth, \$5.50; sheep, \$6.50; half morocco, \$7.00.*

---

"By reason of extensive clinical, pathologic, and teaching experience, of exceptional opportunity and broad training, and of rare scientific attainments, there are few men better qualified than Dr. Osler to write a work on the Practice of Medicine. Here in Philadelphia, where Dr. Osler spent but too few busy years, he will not soon be forgotten; the impress of his work and character will long remain, and the impetus given to careful pathologic study and observation will be transmitted through his colleagues, his assistants, and his pupils. To say that Dr. Osler has performed his task well, is but to echo the verdict concerning the work he has done in the past. If there were one fault of which we would complain, it is expressed in the wish that he had said more than he has. Everywhere throughout the work one feels the delightful personality of the man. Every page contains evidences of original observation, and is marked by an enlightened conservatism. It would be difficult to select any one section and say that it is much better than the others. All are conspicuous for their comprehensiveness. The descriptions are in places concise, but there are no important omissions. Dr. Osler's work needs no special laudation. It speaks for itself. We most heartily commend his 'Practice of Medicine' to those who desire to be in possession of the most recent and best knowledge on the subject with which it has to deal."—*Medical News*.

"This volume exhibits originality at the very beginning, inasmuch as there is no preface. The author does not take us into his confidence as to his motive for adding another book on the 'Principles and Practice of Medicine' to those which have preceded his. He does not tell us whether it is because there were too many good ones or too many bad ones; whether the publisher tempted him, or his university demanded it; or whether it was simply that he had noticed that 'they all do it.' He skips into the public presence without a word, but with a sort of air which suggests: 'Here I am! Take me, or leave me, but you had better do the former!' He had probably heard that good wine needs no bush; and as he has written a good book, with an excellent dedication and some sound aphorisms from the Greek on the first sheet, it mattered less about his motives. At any rate, after the table of contents and a list of charts and illustrations, we find ourselves plunging immediately into typhoid fever, which heads Section I (on 'Specific Infectious Diseases') of this royal octavo volume of 1,080 pages. No preliminaries are devoted to such abstract subjects as nosology, symptomatology, etiology, inflammation, fever, etc. In this respect Osler's book resembles Strümpell's. The style in which Dr. Osler's book is written is clear, concise, and at the same time animated. The type is very good. The finish of the paper is excellent, but the texture is not strong, and we doubt whether it stands well the strain of the eager student who will certainly want to use it often and much, or the inadvertence of the busy practitioner who will sometimes consult it hastily. The book has evidently been 'trained down' as much as possible to secure handiness without sacrificing even more important essentials. We should be glad to be able to think and speak as highly of every medical book presented for review as we can of this. In truth, had our enemy written it, we should be unable to find much consolation in his commitment."—*Boston Medical and Surgical Journal*.

# MEDICAL AND HYGIENIC WORKS

PUBLISHED BY

D. APPLETON & CO., 1, 3, & 5 Bond Street, New York.

- 
- AULDE (JOHN). The Pocket Pharmacy, with Therapeutic Index. A *résumé* of the Clinical Applications of Remedies adapted to the Pocket-case, for the Treatment of Emergencies and Acute Diseases. 12mo. Cloth, \$2.00.
- BARKER (FORDYCE). On Sea-Sickness. A Popular Treatise for Travelers and the General Reader. Small 12mo. Cloth, 75 cents.
- BARKER (FORDYCE). On Puerperal Disease. Clinical Lectures delivered at Bellevue Hospital. A Course of Lectures valuable alike to the Student and the Practitioner. Third edition. 8vo. Cloth, \$5.00; sheep, \$6.00.
- BARTHOLOW (ROBERTS). A Treatise on Materia Medica and Therapeutics. **Seventh edition.** Revised, enlarged, and adapted to "The New Pharmacopœia." 8vo. Cloth, \$5.00; sheep, \$6.00.
- BARTHOLOW (ROBERTS). A Treatise on the Practice of Medicine, for the Use of Students and Practitioners. **Sixth edition,** revised and enlarged. 8vo. Cloth, \$5.00; sheep, \$6.00.
- BARTHOLOW (ROBERTS). On the Antagonism between Medicines and between Remedies and Diseases. Being the Cartwright Lectures for the Year 1880. 8vo. Cloth, \$1.25.
- BASTIAN (H. CHARLTON). Paralyzes: Cerebral, Bulbar, and Spinal. A Manual of Diagnosis for Students and Practitioners. With 136 Illustrations. Small 8vo, 671 pages. Cloth, \$4.50.
- BASTIAN (H. CHARLTON). Paralysis from Brain Disease in its Common Forms. With Illustrations. 12mo, 340 pages. Cloth, \$1.75.
- BILLINGS (F. S.). The Relation of Animal Diseases to the Public Health, and their Prevention. 8vo. Cloth, \$4.00.
- BILLROTH (THEODOR). General Surgical Pathology and Therapeutics. A Text-Book for Students and Physicians. Translated from the tenth German edition, by special permission of the author, by Charles E. Hackley, M. D. **Fifth American edition, revised and enlarged.** 8vo. Cloth, \$5.00; sheep, \$6.00.
- BOYCE (RUBERT). A Text-Book of Morbid Histology. For Students and Practitioners. With 130 Colored Illustrations. Cloth, \$7.50.
- BRAMWELL (BYROM). Diseases of the Heart and Thoracic Aorta. Illustrated with 226 Wood-Engravings and 68 Lithograph Plates—showing 91 Figures—in all 317 Illustrations. 8vo. Cloth, \$8.00; sheep, \$9.00.
- BRYANT (JOSEPH D.). A Manual of Operative Surgery. **New edition, revised and enlarged.** 793 Illustrations. 8vo. Cloth, \$5.00; sheep, \$6.00.

- BURT (STEPHEN S.). Exploration of the Chest in Health and Disease. 8vo. 210 pages. With Illustrations. Cloth, \$1.50.
- CAMPBELL (F. R.). The Language of Medicine. A Manual giving the Origin, Etymology, Pronunciation, and Meaning of the Technical Terms found in Medical Literature. 8vo. Cloth, \$3.00.
- CARMICHAEL (JAMES). Disease in Children. A Manual for Students and Practitioners. Illustrated with Thirty-one Charts. 12mo, 591 pages. (STUDENTS' SERIES.) Cloth, \$3.00.
- CASTRO (D'OLIVEIRA). Elements of Therapeutics and Practice according to the Dosimetric System. 8vo. Cloth, \$4.00.
- CHAUVEAU (A.). The Comparative Anatomy of the Domesticated Animals. Revised and enlarged, with the co-operation of S. Arloing, Director of the Lyons Veterinary School. Second English edition. Translated and edited by George Fleming, O. B., LL. D., F. R. C. V. S., late Principal Veterinary Surgeon of the British Army; Foreign Corresponding Member of the Société Royale de Médecine, and of the Société Royale de Médecine Publique, of Belgium, etc. 8vo, 1084 pages, with 585 Illustrations. Cloth, \$7.00.
- CORNING (J. L.). Brain Exhaustion, with some Preliminary Considerations on Cerebral Dynamics. Crown 8vo. Cloth, \$2.00.
- CORNING (J. L.). Local Anæsthesia in General Medicine and Surgery. Being the Practical Application of the Author's Recent Discoveries. With Illustrations. Small 8vo. Cloth, \$1.25.
- DAVIDSON (ANDREW). Geographical Pathology: An Inquiry into the Geographical Distribution of Infective and Climatic Diseases. 2 vols. 8vo. Cloth, \$7.00.
- DEXTER (FRANKLIN). The Anatomy of the Peritonæum. 12mo. With 39 colored Illustrations. Cloth, \$1.50.
- DOTY (ALVAH H.). A Manual of Instruction in the Principles of Prompt Aid to the Injured. Designed for Military and Civil Use. 96 Illustrations. 12mo. Cloth, \$1.25.
- ELLIOT (GEORGE T.). Obstetric Clinic: A Practical Contribution to the Study of Obstetrics and the Diseases of Women and Children. 8vo. Cloth, \$4.50.
- EVANS (GEORGE A.). Hand-Book of Historical and Geographical Phthisiology. With Special Reference to the Distribution of Consumption in the United States. 8vo. Cloth, \$2.00.
- EWALD (C. A.). Lectures on the Diseases of the Stomach. By Dr. C. A. Ewald, Professor of Pathology and Therapeutics in the University of Berlin, etc. Translated from the German by special permission of the author, by Morris Manges, A. M., M. D. Cloth, \$5.00; sheep, \$6.00.
- FLINT (AUSTIN). Medical Ethics and Etiquette. Commentaries on the National Code of Ethics. 12mo. Cloth, 60 cents.
- FLINT (AUSTIN). Medicine of the Future. An Address prepared for the Annual Meeting of the British Medical Association in 1886. With Portrait of Dr. Flint. 12mo. Cloth, \$1.00.
- FLINT (AUSTIN, JR.). Text-Book of Human Physiology; designed for the Use of Practitioners and Students of Medicine. Illustrated with three hundred and sixteen Woodcuts and Two Plates. Fourth edition, revised. Imperial 8vo. Cloth, \$6.00; sheep, \$7.00.
- FLINT (AUSTIN, JR.). The Physiological Effects of Severe and Protracted Muscular Exercise; with Special Reference to its Influence upon the Excretion of Nitrogen. 12mo. Cloth, \$1.00.

- FLINT (AUSTIN, JR.).** The Source of Muscular Power. Arguments and Conclusions drawn from Observation upon the Human Subject under Conditions of Rest and of Muscular Exercise. 12mo. Cloth, \$1.00.
- FLINT (AUSTIN, JR.).** Physiology of Man. Designed to represent the Existing State of Physiological Science as applied to the Functions of the Human Body. Complete in 5 vols., 8vo. Per vol., cloth, \$4.50; sheep, \$5.50.  
 \* \* Vols. I and II can be had in cloth and sheep binding; Vol. III in sheep only. Vol. IV is at present out of print.
- FLINT (AUSTIN, JR.).** Manual of Chemical Examinations of the Urine in Disease; with Brief Directions for the Examination of the most Common Varieties of Urinary Calculi. Revised edition. 12mo. Cloth, \$1.00.
- FOSTER (FRANK P.).** Illustrated Encyclopædic Medical Dictionary, being a Dictionary of the Technical Terms used by Writers on Medicine and the Collateral Sciences in the Latin, English, French, and German Languages. This work will be completed in four volumes. (*Sold only by subscription.*) The work will consist of Four Volumes, and will be sold in Parts; Three Parts to a Volume. Ten Parts are now ready for delivery.
- FOURNIER (ALFRED).** Syphilis and Marriage. Translated by P. Albert Morrow, M. D. 8vo. Cloth, \$2.00; sheep, \$3.00.
- FREY (HEINRICH).** The Histology and Histochemistry of Man. A Treatise on the Elements of Composition and Structure of the Human Body. Translated from the fourth German edition by Arthur E. J. Barker, M. D., and revised by the author. With 608 Engravings on Wood. 8vo. Cloth, \$5.00; sheep, \$6.00.
- FRIEDLANDER (CARL).** The Use of the Microscope in Clinical and Pathological Examinations. Second edition, enlarged and improved, with a Chromolithograph Plate. Translated, with the permission of the author, by Henry O. Coe, M. D. 8vo. Cloth, \$1.00.
- FUCHS (ERNEST).** Text-Book of Ophthalmology. By Dr. Ernest Fuchs, Professor of Ophthalmology in the University of Vienna. With 178 Woodcuts. Authorized translation from the second enlarged and improved German edition, by A. Duane, M. D. Cloth, \$5.00; sheep, \$6.00.
- GARMANY (JASPER J.).** Operative Surgery on the Cadaver. With Two Colored Diagrams showing the Collateral Circulation after Ligatures of Arteries of Arm, Abdomen, and Lower Extremity. Small 8vo. Cloth, \$2.00.
- GERSTER (ARPAD G.).** The Rules of Aseptic and Antiseptic Surgery. A Practical Treatise for the Use of Students and the General Practitioner. Illustrated with over two hundred fine Engravings. 8vo. Cloth, \$5.00; sheep, \$6.00.
- GIBSON-RUSSELL.** Physical Diagnosis: A Guide to Methods of Clinical Investigation. By G. A. Gibson, M. D., and William Russell, M. D. With 101 Illustrations. 12mo. (STUDENT'S SERIES.) Cloth, \$2.50.
- GOULEY (JOHN W. S.).** Diseases of the Urinary Apparatus. Part I. Phlegmasic Affections. Being a Series of Twelve Lectures delivered during the autumn of 1891. With an Addendum on Retention of Urine from Prostatic Obstruction in Elderly Men. Cloth, \$1.50.
- GROSS (SAMUEL W.).** A Practical Treatise on Tumors of the Mammary Gland. Illustrated. 8vo. Cloth, \$2.50.
- GRUBER (JOSEF).** A Text-Book of the Diseases of the Ear. Translated from the second German edition by special permission of the author, and edited by Edward Law, M. D., and Coleman Jewell, M. D. With 150 Illustrations and 70 Colored Figures on Two Lithographic Plates. 8vo. Cloth, \$5.00.

- GUTMANN (EDWARD). The Watering-Places and Mineral Springs of Germany, Austria, and Switzerland. Illustrated. 12mo. Cloth, \$2.50.
- HAMMOND (W. A.). A Treatise on Diseases of the Nervous System. With the Collaboration of Graeme M. Hammond, M.D. With One Hundred and Eighteen Illustrations. Ninth edition, with corrections and additions. 8vo. Cloth, \$5.00; sheep, \$6.00.
- HAMMOND (W. A.). A Treatise on Insanity, in its Medical Relations. 8vo. Cloth, \$5.00; sheep, \$6.00.
- HAMMOND (W. A.). Clinical Lectures on Diseases of the Nervous System. Delivered at Bellevue Hospital Medical College. Edited by T. M. B. Cross, M.D. 8vo. Cloth, \$3.50.
- HARVEY (A.). First Lines of Therapeutics. 12mo. Cloth, \$1.50.
- HIRT (LUDWIG). The Diseases of the Nervous System. A Text Book for Physicians and Students. Translated, with permission of the Author, by August Hoch, M.D., assisted by Frank R. Smith, A.M. (Cantab.), M.D., Assistant Physicians to the Johns Hopkins Hospital. With an Introduction by William Osler, M.D., F.R.C.P., Professor of Medicine in the Johns Hopkins University, and Physician-in-Chief to the Johns Hopkins Hospital, Baltimore. 8vo, 671 pages. With 178 Illustrations. Cloth, \$5.00; sheep, \$6.00.
- HOFFMANN-ULTZMANN. Analysis of the Urine, with Special Reference to Diseases of the Urinary Apparatus. By M. B. Hoffmann, Professor in the University of Gratz, and R. Ultzmann, Tutor in the University of Vienna. Third edition, revised and enlarged. 8vo. Cloth, \$2.00.
- HOWE (JOSEPH W.). Emergencies, and how to treat them. Fourth edition, revised. 8vo. Cloth, \$2.50.
- HOWE (JOSEPH W.). The Breath, and the Diseases which give it a Fetid Odor. With Directions for Treatment. Second edition, revised and corrected. 12mo. Cloth, \$1.00.
- HUEPPE (FERDINAND). The Methods of Bacteriological Investigation. Written at the request of Dr. Robert Koch. Translated by Hermann M. Biggs, M.D. Illustrated. 8vo. Cloth, \$2.50.
- JACCOUD (S.). The Curability and Treatment of Pulmonary Phthisis. Translated and edited by Montagu Lubbock, M.D. 8vo. Cloth, \$4.00.
- JOHNSTONE (ALEX.). Botany: A Concise Manual for Students of Medicine and Science. With 164 Illustrations and a Series of Floral Diagrams. 12mo. (STUDENT'S SERIES.) Cloth, \$1.75.
- JONES (H. MACNAUGHTON). Practical Manual of Diseases of Women and Uterine Therapeutics. For Students and Practitioners. 188 Illustrations. 12mo. Cloth, \$3.00.
- JOURNAL OF CUTANEOUS AND GENITO-URINARY DISEASES. Published Monthly. Edited by John A. Fordyce, M.D. Terms, \$2.50 per annum.
- KEYES (E. L.). A Practical Treatise on Genito-Urinary Diseases, including Syphilis. Being a new edition of a work with the same title by Van Buren and Keyes. Almost entirely rewritten. 8vo. With Illustrations. Cloth, \$5.00; sheep, \$6.00.
- KEYES (E. L.). The Tonic Treatment of Syphilis, including Local Treatment of Lesions. 8vo. Cloth, \$1.00.
- KINGSLEY (N. W.). A Treatise on Oral Deformities as a Branch of Mechanical Surgery. With over 350 Illustrations. 8vo. Cloth, \$5.00; sheep, \$6.00.

- LEGG (J. WICKHAM). On the Bile, Jaundice, and Bilious Diseases. With Illustrations in Chromolithography. 8vo. Cloth, \$6.00; sheep, \$7.00.
- LITTLE (W. J.). Medical and Surgical Aspects of In-Knee (Genu-Valgum): Its Relation to Rickets, its Prevention, and its Treatment, with and without Surgical Operation. Illustrated by upward of Fifty Figures and Diagrams. 8vo. Cloth, \$2.00.
- LORING (EDWARD G.). A Text-Book of Ophthalmoscopy.  
 Part I. The Normal Eye, Determination of Refraction, and Diseases of the Media. With 131 Illustrations, and 4 Chromolithographs. 8vo. Buckram, \$5.00.  
 Part II. Diseases of the Retina, Optic Nerve, and Choroid: their Varieties and Complications. The manuscript of this volume, which the author finished just prior to his death, has been thoroughly edited and revised by F. B. Loring, M. D., of Washington, D. C., and is now issued in the same style as the first volume. Profusely illustrated. Part II, buckram, \$5.00. Two Parts, buckram, \$10.00.
- LUSK (WILLIAM T.). The Science and Art of Midwifery. With 246 Illustrations. Fourth edition, revised and enlarged. 8vo. Cloth, \$5.00; sheep, \$6.00.
- MARCY (HENRY O.). The Anatomy and Surgical Treatment of Hernia. 4to, with about Sixty full-page Helio-type and Lithographic Reproductions from the Old Masters, and numerous Illustrations in the Text. (*Sold only by subscription.*)
- MARKOE (T. M.). A Treatise on Diseases of the Bones. With Illustrations. 8vo. Cloth, \$4.50.
- MATHEWS (JOSEPH M.). A Treatise on Diseases of the Rectum, Anus, and Sigmoid Flexure. 8vo. With Six Chromolithographs, and Illustrations in the text. (*Sold only by subscription.*)
- MILLS (WESLEY). A Text-Book of Animal Physiology, with Introductory Chapters on General Biology and a full Treatment of Reproduction for Students of Human and Comparative Medicine. 8vo. With 505 Illustrations. Cloth, \$5.00; sheep, \$6.00.
- MILLS (WESLEY). A Text-Book of Comparative Physiology. For Students and Practitioners of Veterinary Medicine. Small 8vo. Cloth, \$3.00.
- MORROW (PRINCE A.). A System of Genito-Urinary Diseases, Syphilology, and Dermatology. By various Authors. In Three Volumes, beautifully illustrated. (*Sold only by subscription.*) Vol. I. (*Vols. II and III in press.*)
- THE NEW YORK MEDICAL JOURNAL (weekly). Edited by Frank P. Foster, M. D. Terms, \$5.00 per annum.  
 Binding Cases, cloth, 50 cents each.  
 "Self-Binder" (this is used for temporary binding only), 90 cents.
- GENERAL INDEX, from April, 1865, to June, 1876 (23 vols.). 8vo. Cloth, 75 cts.
- NIEMEYER (FELIX VON). A Text-Book of Practical Medicine, with particular reference to Physiology and Pathological Anatomy. Containing all the author's Additions and Revisions in the eighth and last German edition. Translated by George H. Humphreys, M. D., and Charles E. Hackley, M. D. 2 vols., 8vo. Cloth, \$9.00; sheep, \$11.00.
- NIGHTINGALE'S (FLORENCE) Notes on Nursing. 12mo. Cloth, 75 cents.
- OSLER (WILLIAM). The Principles and Practice of Medicine. Designed for the Use of Practitioners and Students of Medicine. (*Sold only by subscription.*) Cloth, \$5.50; sheep, \$6.50; half morocco, \$7.00.

PELLEW (C. E.). A Manual of Practical Medical Chemistry. 12mo. With Illustrations. Cloth, \$2.50.

PEREIRA'S (Dr.) Elements of Materia Medica and Therapeutics. Abridged and adapted for the Use of Medical and Pharmaceutical Practitioners and Students, and comprising all the Medicines of the British Pharmacopœia, with such others as are frequently ordered in Prescriptions, or required by the Physician. Edited by Robert Bentley and Theophilus Redwood. Royal 8vo. Cloth, \$7.00; sheep, \$8.00.

PEYER (ALEXANDER). An Atlas of Clinical Microscopy. Translated and edited by Alfred C. Girard, M.D. First American, from the manuscript of the second German edition, with Additions. Ninety Plates, with 105 Illustrations, Chromolithographs. Square 8vo. Cloth, \$6.00.

PIFFARD (HENRY G.). A Practical Treatise on Diseases of the Skin. By Henry G. Piffard, A. M., M. D., assisted by Robert M. Fuller, M. D. With Fifty full-page Original Plates and Thirty-three Illustrations in the Text. 4to. (*Sold only by subscription.*)

POMEROY (OREN D.). The Diagnosis and Treatment of Diseases of the Ear. With One Hundred Illustrations. *Second edition*, revised and enlarged. 8vo. Cloth, \$3.00.

POORE (C. T.). Osteotomy and Osteoclasis, for the Correction of Deformities of the Lower Limbs. 50 Illustrations. 8vo. Cloth, \$2.50.

QUAIN (RICHARD). A Dictionary of Medicine, including General Pathology, General Therapeutics, Hygiene, and the Diseases peculiar to Women and Children. By Various Writers. Edited by Richard Quain, M.D. In one large 8vo volume, with complete Index, and 138 Illustrations. (*Sold only by subscription.*)

RANNEY (AMBROSE L.). Applied Anatomy of the Nervous System, being a Study of this Portion of the Human Body from a Standpoint of its General Interest and Practical Utility, designed for Use as a Text-Book and as a Work of Reference. *Second edition, revised and enlarged.* Profusely illustrated. 8vo. Cloth, \$5.00; sheep, \$6.00.

ROBINSON (A. R.). A Manual of Dermatology. Revised and corrected. 8vo. Cloth, \$5.00.

ROSCOE-SCHORLEMMER. Treatise on Chemistry.

Vol. 1. Non-Metallic Elements. 8vo. Cloth, \$5.00.

Vol. 2. Part I. Metals. 8vo. Cloth, \$3.00.

Vol. 2. Part II. Metals. 8vo. Cloth, \$3.00.

Vol. 3. Part I. The Chemistry of the Hydrocarbons and their Derivatives. 8vo. Cloth, \$5.00.

Vol. 3. Part II. The Chemistry of the Hydrocarbons and their Derivatives. 8vo. Cloth, \$5.00.

Vol. 3. Part III. The Chemistry of the Hydrocarbons and their Derivatives. 8vo. Cloth, \$3.00.

Vol. 3. Part IV. The Chemistry of the Hydrocarbons and their Derivatives. 8vo. Cloth, \$3.00.

Vol. 3. Part V. The Chemistry of the Hydrocarbons and their Derivatives. 8vo. Cloth, \$3.00.

ROSENTHAL (I.). General Physiology of Muscles and Nerves. With 75 Woodcuts. 12mo. Cloth, \$1.50.

- SAYRE (LEWIS A.). *Practical Manual of the Treatment of Club-Foot. Fourth edition, enlarged and corrected.* 12mo. Cloth, \$1.25.
- SAYRE (LEWIS A.). *Lectures on Orthopedic Surgery and Diseases of the Joints, delivered at Bellevue Hospital Medical College. New edition, illustrated with 224 Engravings on Wood.* 8vo. Cloth, \$5.00; sheep, \$6.00.
- SCHULTZE (B. S.). *The Pathology and Treatment of Displacements of the Uterus.* Translated from the German by Jameson J. Macan, M. A., etc.; and edited by Arthur V. Macan, M. B., etc. With one hundred and twenty Illustrations. 8vo. Cloth, \$3.50.
- SHIELD (A. MARMADUKE). *Surgical Anatomy for Students.* 12mo. (STUDENT'S SERIES.) Cloth, \$1.75.
- SHOEMAKER (JOHN V.). *A Text-Book of Diseases of the Skin.* Six Chromolithographs and numerous Engravings. Second edition, revised and enlarged. 8vo. Cloth, \$5.00; sheep, \$6.00.
- SIMPSON (JAMES Y.). *Selected Works: Anæsthesia, Diseases of Women.* 3 vols., 8vo. Per volume. Cloth, \$3.00; sheep, \$4.00.
- SIMS (J. MARION). *The Story of my Life.* Edited by his Son, H. Marion-Sims, M. D. With Portrait. 12mo. Cloth, \$1.50.
- SKENE (ALEXANDER J. C.). *A Text-Book on the Diseases of Women.* Illustrated with two hundred and fifty-four Illustrations, of which one hundred and sixty-five are original, and nine chromolithographs. Second edition. 8vo. (*Sold only by subscription.*)
- STEINER (JOHANNES). *Compendium of Children's Diseases: a Hand-Book for Practitioners and Students.* Translated from the second German edition, by Lawson Tait. 8vo. Cloth, \$3.50; sheep, \$4.50.
- STEVENS (GEORGE T.). *Functional Nervous Diseases: their Causes and their Treatment.* Memoir for the Concourse of 1881-1883, Académie Royal de Médecine de Belgique. With a Supplement, on the Anomalies of Refraction and Accommodation of the Eye, and of the Ocular Muscles. Small 8vo. With six Photographic Plates and twelve Illustrations. Cloth, \$2.50.
- STONE (R. FRENCH). *Elements of Modern Medicine, including Principles of Pathology and of Therapeutics, with many Useful Memoranda and Valuable Tables of Reference.* Accompanied by Pocket Fever Charts. Designed for the Use of Students and Practitioners of Medicine. In wallet-book form, with pockets on each cover for Memoranda, Temperature Charts, etc. Roan, tuck, \$2.50.
- STRECKER (ADOLPH). *Short Text-Book of Organic Chemistry.* By Dr. Johannes Wislicenus. Translated and edited, with Extensive Additions, by W. H. Hodgkinson and A. J. Greenaway. 8vo. Cloth, \$5.00.
- STRÜMPPELL (ADOLPH). *A Text-Book of Medicine, for Students and Practitioners.* Translated, by permission, from the sixth German edition by Herman F. Vickery, A. B., M. D., Instructor in Clinical Medicine, Harvard Medical School, etc., and Philip Coombs Knapp, Physician to Outpatients with Diseases of the Nervous System, Boston City Hospital, etc. With Editorial Notes by Frederick C. Shattuck, A. M., M. D., Jackson Professor of Clinical Medicine, Harvard Medical School, etc. Second American edition. With 111 Illustrations. 8vo. 981 pages. Cloth, \$6.00; sheep, \$7.00.

- THOMAS (T. GAILLARD). Abortion and its Treatment, from the Standpoint of Practical Experience. A Special Course of Lectures delivered before the College of Physicians and Surgeons, New York, Session of 1889-'90. From Notes by P. Brynberg Porter, M.D. Revised by the Author. 12mo. Cloth, \$1.00.
- THOMSON (J. ARTHUR). Outlines of Zoölogy. With thirty-two full page Illustrations. 12mo. (STUDENTS' SERIES.) Cloth, \$3.00.
- TRACY (ROGER S.). The Essentials of Anatomy, Physiology, and Hygiene. 12mo. Cloth, \$1.25.
- TYNDALL (JOHN). Essays on the Floating Matter of the Air, in Relation to Putrefaction and Infection. 12mo. Cloth, \$1.50.
- ULTZMANN (ROBERT). Pyuria, or Pus in the Urine, and its Treatment. Translated by permission, by Dr. Walter B. Platt. 12mo. Cloth, \$1.00.
- VAN BUREN (W. H.). Lectures upon Diseases of the Rectum, and the Surgery of the Lower Bowel, delivered at Bellevue Hospital Medical College. Second edition, revised and enlarged. 8vo. Cloth, \$3.00; sheep, \$4.00.
- VAN BUREN (W. H.). Lectures on the Principles and Practice of Surgery. Delivered at Bellevue Hospital Medical College. Edited by Lewis A. Stimson, M. D. 8vo. Cloth, \$4.00; sheep, \$5.00.
- VOGEL (A.). A Practical Treatise on the Diseases of Children. Translated and edited by H. Raphael, M. D. Third American from the eighth German edition, revised and enlarged. Illustrated by six Lithographic Plates. 8vo. Cloth, \$4.50; sheep, \$5.50.
- VON ZEISSL (HERMANN). Outlines of the Pathology and Treatment of Syphilis and Allied Venereal Diseases. Second edition, revised by Maximilian von Zeissl. Authorized edition. Translated, with Notes, by H. Raphael, M. D. 8vo. Cloth, \$4.00; sheep, \$5.00.
- WAGNER (RUDOLF). Hand-Book of Chemical Technology. Translated and edited from the eighth German edition, with extensive Additions, by William Crookes. With 336 Illustrations. 8vo. Cloth, \$5.00.
- WALTON (GEORGE E.). Mineral Springs of the United States and Canada. Containing the latest Analyses, with full Description of Localities, Routes, etc. Second edition, revised and enlarged. 12mo. Cloth, \$2.00.
- WEBBER (S. G.). A Treatise on Nervous Diseases: Their Symptoms and Treatment. A Text-Book for Students and Practitioners. 8vo. Cloth, \$3.00.
- WEEKS-SHAW (CLARA S.). A Text-Book of Nursing. For the Use of Training-Schools, Families, and Private Students. Second edition, revised and enlarged. 12mo. With Illustrations, Questions for Review and Examination, and Vocabulary of Medical Terms. 12mo. Cloth, \$1.75.
- WELLS (T. SPENCER). Diseases of the Ovaries. 8vo. Cloth, \$4.50.
- WORCESTER (A.). Monthly Nursing. Second edition, revised. Cloth, \$1.25.
- WYETH (JOHN A.). A Text-Book on Surgery: General, Operative, and Mechanical. Profusely illustrated. Second edition, revised and enlarged. 8vo. (Sold only by subscription.)
